Calculated forbidden band gap in periodic protein models indicating them to be insulators

THE idea of electron and hole transport between distant sites in biological macromolecules, especially in fibrous proteins[1] prompted quantum chemists to calculate the forbidden energy band gap in simple periodic protein models[2–7]. Conductivity measurements of several proteins under various conditions indicated a band gap or activation energy (E in the expression for the conductivity $\sigma = \sigma_0 \exp(-E/2kT)$ as function of the temperature T) of the order of 3 eV (refs 8, 9), a value in agreement with the only theoretical energy band gap available at that time (ref. 2). Therefore, the intrinsic mechanism of semiconduction along hydrogen bridges seemed to be well established in 1960. Later, however, both experimentally[10–13] and theoretically the question arose whether the conduction mechanism is really intrinsic. The more refined all-valence-electron quantum chemical calculations[3–7] indicated larger gaps (values in the range 6.1–16.7 eV were reported) than obtained in experiments. Most interestingly the calculation of Morokuma[5] at complete-neglect-of-differential-overlap level showed that in a polyglycine chain the bandgap was not too sensitive to the changes of the chain's conformation: in conformers with appreciable H-bonding the gap found was slightly larger than in the β-sheet conformation This latter finding pointed out the very small influence of H-bonds on the forbidden gap of periodic protein models. These semi-empirical calculation methods were designed for molecular purposes and there is still little known of their applicability to the calculation of the gap in crystals and polymers[14,19]. Thus we describe here use of the more reliable non-empirical ('*ab initio*') crystal orbital method[15] to calculate the band gap in a most simple polypeptide model β-polyglycine.

We used an STO-3G atomic orbital basis set[16]. After evaluation of all integrals[17], as usual in molecular *ab initio* calculations, we performed a self-consistent-field calculation using a first neighbour's interaction approximation. This highly sophisticated calculation resulted in a gap of 19.23 eV, the largest value obtained so far. Although larger numbers of included neighbours, basis set enlargement and correlation corrections may reduce this value by several eV, it seems impossible to reduce this value to the vicinity of the experimental gap. We may conclude therefore, that the intrinsic mechanism in a periodic protein model can be ruled out. Absolutely pure periodic proteins are thus good insulators. This conclusion will probably remain valid even in presence of orientational randomness of the constituent units. A set of aperiodic side chains, however, may serve as impurity centres, which support extrinsic type conduction.

The lowest energy optical transition of the electron system corresponds to the formation of excitons within the forbidden gap rather than to free electrons and holes. The order of magnitude of the energy of these excitons is expected to be 6–8 eV on the basis of the first electronic transition energies of small peptides[18]. Although this value is much larger than the experimental E it is necesarily smaller than the theoretical band-to-band gap found in our calculation.

Some technical details, which are of interest to specialists only, will be given elsewhere.

Estimation of heritability from IQ data on twins

IN a recent paper[1] a nationally representative sample of twins born in one week of March 1958 was investigated to estimate kinship correlations in mental test performance for monozygotic and dizygotic twins. The authors concluded that their study offered "supportive evidence for zero or low upper limit heritabilities of mental test performance". We have received several critiques of the paper which we publish below, together with a response from the authors.

ADAMS *et al.*[1] have used a method[2] of estimating heritability, that is not reliable. The formula $h^2 = (r_{MZ} - r_{DZ})/(1 - \rho_{00})$ was stated by Jensen[2], without any theoretical justification, to measure heritability. In this formula r_{MZ} and r_{DZ} are the phenotypic correlations between monozygotic and dizygotic twins, respectively, and can be observed directly, but ρ_{00}, the genetic correlation between sibs, cannot be observed. It can be obtained from their phenotypic correlation if heritability is known, which, of course, it is not.

To overcome this difficulty, Jensen[2] suggests that the formula $\rho_{00} = (1+\rho_{pp})/(2+\rho_{pp})$, where ρ_{pp} is the genetic correlation between mates should be used to find ρ_{00}. He gives Li[3], chapter 13, as reference for this formula. However, it does not appear there, and Professor Li informs me (personal communication) that he had never seen it before I brought it to his notice. This formula seems to have no theoretical justification. Moreover, it does not resolve the problem of finding genetic correlation. We now require the genetic correlation between mates which can be obtained from their phenotypic correlation if heritability is known. Thus, to use Jensen's formula for finding heritability of a trait, an estimate of that heritability is required.

Jensen[2] resolves the dilemma by assuming that the genetic correlation between mates is 0.25, without telling his readers how this figure is obtained from their phenotypic correlation of 0.6 (ref. 4). The value of ρ_{DZ}, actually ρ_{00}, which Adams *et al.*[1] use is based on this assumed genetic correlation. The value of 0.8 for the broad heritability of IQ which is often quoted by Jensen and others is also based on this value. It is difficult to find a scientific justification for the method or to have any faith in estimates of heritability based on it.

THE report by Adams *et al.*[1] is noncontributory to the estimate of heritability of mental test performance for three reasons:

(1) No adequate information is given on the zygosity of the twin pairs. With a small sample (<100 like sex pairs) there would have been little difficulty in testing the twins for genetic markers such as blood groups, or at least having the twins examined by an experienced human geneticist, with special tests on those difficult to assign. It is true that a competent questionnaire to the parents will enable the correct type of twinning to be established in some 90% of cases. But merely to ask the parents their opinion is unreliable. Parents tend to be influenced by what they are told in the neonatal period by the midwife or obstetrician who usually erroneously assume that dichorionic twins must be DZ. Any errors in the assignment of the type of twinning will lead to an underestimate of heritability by the twin comparison method.

(2) An estimate of heritability based on the difference between the intraclass correlations of MZ and DZ twins is confounded by any substantial degree of assortative mating of the parents for the character in question. Insofar as any parental resemblance is genetic this will raise the DZ correlation, but not the MZ correlation, and so lower the estimate of heritability below the true value. Assortative mating for intelligence test score in most surveys is high, about 0.5. Adams *et al.* claim that the effect of such assortative mating on the estimates of heritability is likely to be small. This is not correct. For example, on the simple model of purely additive inheritance, with 100% heritability of intelligence test score, and 0.5 genetic parental correlation, the expected genetic DZ correlation is not 0.5 but 0.75. To assume the value of 0.5 would give an h^2 of only 50% and not 100%. Jensen's quoted estimate of an expected DZ correlation of 0.55 seems implausibly low. It is the difficulty of estimating the expected genetic DZ correlation that make twin comparisons an unsatisfactory method of estimating heritability for any character for which there is substantial assortive mating.

(3) Estimates of h^2 from twin correlations based on only 140 pairs have a large sampling error.

ADAMS *et al.* estimate[1] of an upper limit of 0.373 is based on a sample consisting of 41 MZ and 95 DZ twin pairs. This estimate is subject to sampling error, and if one calculates a 95% confidence interval for the population value of the heritability one obtains an interval ranging from about zero to over 0.6. An exact interval is difficult to establish, but using an estimated s.e. of about 0.2, the value of 0.6 can be regarded as a conservative upper limit.

Thus, while the data the authors present are an interesting contribution to this subject and do not seem to support a heritability value as high as 0.8, the assertion of a 'low' upper limit is not really justified.

IT is perhaps surprising that the authors of a study[1] comparing 'mental abilities' in MZ and DZ twins should place such reliance on tests which are not validated, and were administered in a group situation, where contamination effects are difficult to control. If, as is probable, pairs of same-sexed twins sit next to one another in a classroom during the test, it is perhaps quite likely that they will achieve similar results.

An important but neglected study of twins by Claridge *et al.*[2] seems to have avoided at least some of the methodological difficulties which faced the National Children's Bureau study. Claridge's study compared 44 MZ and 51 DZ twin pairs, aged 16–55, resident in Glasgow. Zygosity was established through comparative blood grouping. Among the battery of tests completed by the subjects were the Progressive Matrices and the Mill Hill vocabulary test, well-established and validated measures of mental ability, individually administered.

The intraclass correlations for MZ pairs on the Progessive Matrices was 0.68, and for the DZ pairs it was 0 46. On the Mill Hill vocabulary test, the intraclass correlation in MZ pairs was 0.85, compared with 0.68 in the DZ pairs. For both tests, the intraclass correlation was significantly higher in MZ pairs. Although the authors do not discuss the implications which these results have for models of the inheritance of 'intelligence', it is clear that these results imply that at least some of the variance in mental abilities in this adult Scottish sample is due to inheritance.

[2] Claridge, G , Canter, S & Hume, W *Personality Differences and Biological Variations A Study of Twins* (Pergamon, Oxford, 1973)

THE report by Adams *et al*[1] of correlations between mental test scores of MZ and DZ twins raises questions about the variance of obtained correlations in twin studies which were not discussed by the authors. Instead, they used their data to suggest the dismissal of previous estimates of heritability; but if the figures are considered in relation to other findings more complex issues emerge. These are the questions of how the various samplings stand as bases for estimating the same population parameter, and of what other features of the testing and sampling (apart from the well known difficulties of mental testing and the identification of twin types) may contribute to the variance of sample correlations

The picture of twin study findings is represented in Table 1, where Adams' figures are compared with corresponding results from an earlier well-founded report[2], and with others from the review by Erlenmeyer-Kimling and Jarvik[3] which gave figures from 34 studies concerned with twins. The Adams figure for MZ twins lies at the lower limit of previous studies, while the figure for DZ twins lies in the upper part of the range Thus that particular sampling must yield one of the smallest, if not the smallest, difference between such correlations in the whole series of studies. Table 2 shows the statistical significance of the differences. While the Newman figures are not exceptional in this respect, the Adams figures clearly are.

Table 1 Correlation coefficients in the mental testing of twins

Source	Twin type (all reared together) MZ *r*	MZ *N*	DZ Same sex *r*	DZ Same sex *N*	DZ Opp. sex *r*	DZ Opp. sex *N*	DZ All *r*	DZ All *N*
Adams *et al.* (non-verbal group test, 1969)	0.762	41	0.604	55	0.487	40	0.594	95
Newman *et al* (group test, 1937)	0.992	50	—	—	—	—	0.621	51
Erlenmeyer-Kimling *et al* (median values of 34 studies, 1963)	0.87	1082 (in 14 studies)	0.53	11 studies	0.53	9 studies	0.53	2052 (in 20 studies)
Erlenmeyer-Kimling *et al.* (1963) upper limit	0 92		0.87		0.63		0.87	
Erlenmeyer-Kimling *et al.* (1963) low limit	0.76		0.45		0.37		0.37	

Table 2 Differences between correlations for MZ and DZ twins

Statistic	Source Adams MZ	Adams DZ	Newman MZ	Newman DZ	Erlenmeyer-Kimling MZ	Erlenmeyer-Kimling DZ
r	0.762	0.594	0.922	0.621	0.87	0.53
Fisher *z* difference	1 000–0.683		1.605–0.727		1.333–0.590	
σ_z difference	0.193		0.205		0.037	
Ratio	1.642		4.283		20.081	
Significance level	Not sig.		0.01		0.01	

In Table 3, figures are compared across the studies for both kinds of twins. For DZ twins none of the differences are statistically significant, even at the 0 05 level, and the samples could be treated as coming from the same population of such twins; but for the MZs the pattern is such that, whereas the Newman and Erlenmeyer-Kimling samples could be treated as bases for the estimation of the same population correlation, it is doubtful whether the Adams sample can be so regarded

This being so, it seems that Adams and his colleagues may have been hasty in offering their findings simply as evidence for a low heritability estimate, for their study is likely to be either a rather extreme sampling or evidence of a change in a population characteristic. Rather than discussing the implications for estimates of heritability it is important therefore to consider the possibility of change in the population correlation figure for MZ twins.

Table 3 Differences between corresponding correlations in different studies

Statistic	Difference Newman–Adams MZ	Newman–Adams DZ	Newman–Erlenmeyer-Kimling MZ	Newman–Erlenmeyer-Kimling DZ	Erlenmeyer-Kimling–Adams MZ	Erlenmeyer-Kimling–Adams DZ
Fisher *z* difference	0 605	0 044	0.272	0.137	0.333	0.093
σ_z difference	0.218	0 178	0 149	0.146	0.165	0.107
Ratio	2 775	0.247	1'825	0 938	2 018	0 869
Significance level	0.01	Not sig.	Not sig	Not sig	0 05	Not sig.

Since available twin studies span a considerable time, during which advice has been given to parents to treat identical twins as individual persons, this may have had the effect of increasing the within-pair variance. More sampling is necessary to test the present position further, as is a thorough analysis of data to test the hypothesis of a trend over time.

Adams *et al.* reply—None of the above criticisms substantially alters our conclusions, though some underline the caution appropriate in certain places.

Dr Vetta has to be thanked for showing that assumptions made by Jensen in deriving a formula for heritability estimation are without theoretical justification. It follows that the formula ought not to be perpetuated. As regards the implications of this for our own report we should like to make three points: (1) We calculated heritability both with and without Jensen's false assumptions; (2) the calculation itself (we made a point of saying) was the demonstration of an *erroneous* estimation by incorporation of 'treatment effects'; (3) our main conclusion was based on the comparison of raw correlations.

Carter underestimates the generally accepted level of accuracy of zygosity determination in twins by impressionistic methods. Such methods are routinely adopted, especially under difficult conditions such as the geographic dispersal of subjects. Vandenburg[1] has claimed in a review of the approach, that "it has been shown repeatedly that for large-scale twin studies a few questions about the frequency with which close friends or relatives mistake one twin for the other will provide a sufficiently accurate diagnosis within the limits of the accuracy of the variable under study whether it be a mental test score or a physical illness". Cederlof *et al.*[2], found 98% agreement with blood-typing for responses on one of their items on a mailed questionnaire.

Carter claims, however, that merely asking mothers is too unreliable because they may have been confused by neonatal misinformation. This is quite plausible, but we need evidence about the extent of confusion, especially many years after the births. Cohen *et al.*[3] mailed a questionnaire to 35 mothers of twins in their Louisville twin study. They asked them (among other things) whether the twins were identical or fraternal, and twins were subsequently blood-typed. In only two cases did definite misclassification occur through neonatal misinformation, and there were no other misclassifications. Hence their assertion that (apart from the above) "we did not find any mother who seriously believed that her MZ pair was DZ, nor any mother of DZ twins who believed that her twin pair was MZ". Their general conclusion was that "parental perceptions of identical and fraternal twins were extremely different". The correlations for height at 7 yr in our sample (height being a trait of indisputably high heritability) were: MZ=0.926; DZ$_{ss}$= 0.546. We thus do not believe our twin classification was too unreliable though, naturally, caution would not be unwarranted.

Carter illustrates how non-correction for assortative mating could underestimate h^2. The illustration depends, however, on the prior assumptions of high h^2 and high genetic correlation of mates. Both assumptions become less tenable as MZ and DZ correlations approach identity, as is the case in our sample. He does not explain, moreover, why Jensen[4] estimate of pDZ=0.55 "seems implausibly low". The simple fact is that values higher than that applied to previous twin correlations yielded impossible h^2 values >1.00. Both forms of special pleading (high Δrs implying low pDZ; low Δrs implying high pDZ) necessary to preserve $h^2=0.8$ indeed suggests a limitation of the method, but this does not diminish the finding of insignificant Δrs as an empirical contribution. Our sample size was comparable with (if not larger than) previous studies; bigger ones are unlikely to be forthcoming without transgressing very stringent sampling conditions, satisfying which was our study's main strength.

Harvey Goldstein quotes our conclusion, based on comparison of MZ and DZ$_{ss}$ correlations, and then claims that our "heritability estimate of 0.373" is consistent with an upper confidence limit of 0.6. It should be clear from our paper, however, that that estimate is based on MZ and DZ$_t$ correlations, for non-verbal correlations only, calculated purely to illustrate the inflating consequences of introducing 'treatment effects'. It would be quite indiscriminate to transpose that h^2 value and its 'guesstimated' confidence limit to MZ–DZ$_{ss}$ differences which (1) are not significantly different, (2) are quite different as regards verbal and non-verbal measures, and (3) probably themselves contain treatment effects. Our conclusion of "supportive evidence for zero or low heritabilities" seems to us a more circumspect one.

Bagley seems vague about test validity. The test we used has received some validation and a reference was given. It has been administered to two very large nationally representative samples of 11-yr olds so that excellent information is available about its distributional properties and correlations with other measures, teachers' impressions and so on. It should be pointed out that there is no universally validated and standardised intelligence test in this country, which explains the interest in the long-gestating British Intelligence Scale. As well as face-validity, ultimate validation is always by school attainments/teachers' perceptions; the items in our test conformed closely to the half dozen or so types used in conventional intelligence tests[5]. Bagley is quite wrong to uphold the Claridge *et al.* study as a model. For example, vocabulary test is not a usually accepted intelligence test and the Progressive Matrices has been far from satisfactorily validated and is also a group test. Moreover, it is a test for subjects of '11 years plus', whose use on very much older people for the purpose in mind is dubious. It is the problem of testing such a wide age-range of twins (16–55 yr) especially if the ranges for MZ and DZ twins are quite different, that has flawed previous studies and makes ours (of uniform age) unique. Furthermore, the small number of DZ pairs in the Claridge *et al.* study did not allow separation of opposite-sex and same-sex twins so that their (significant) correlation differences could quite easily be explained by the sort of 'treatment effects' which our own study suggests. Finally, the contamination effects of which Bagley speaks, relating to same-sex twins, are as applicable to MZ as to DZ twins, making separation of DZ$_{ss}$ and DZ$_{os}$ correlations all the more desirable.

Francis is wrong to think that we used our data primarily to suggest the dismissal of previous estimates of heritability. It is the doubts about the empirical sufficiency of previous estimates which have suggested their dismissal. Accordingly, it seems quite wrong to treat our findings as co-extensive with previous ones as if they were of equal empirical sufficiency. Again the Newman, Freeman and Holzinger study sample twins of a very wide range of ages and their small numbers of pairs did not allow separation of the DZ$_{os}$ and DZ$_{ss}$ pairs. Similarly, the well known Erlenmeyer-Kimling and Jarvik study includes studies of widely different measures, many with very small samples, wide age ranges, etc. Thus we dispute Francis's inference that our results, from a nationally representative group of the same age, can be explained away by 'extreme sampling'; indeed, speculation of that sort seems a pointless exercise. Of course a changing 'population characteristic', and a 'labile heritability', is a possibility, but debatable only with comparable studies; the studies of Cohen *et al.*[3] and several others, moreover, suggest that identical twins are still treated much more similarly than are fraternal twins.

Mechanism of stomatal movement

ACCORDING to Bowling's malate-switch hypothesis[1] of stomatal action, the *p*H changes in the guard cell create a gradient of monovalent malate towards either guard cells or epidermal cells causing a diffusion of K$^+$ (bound to monovalent malate) along with the gradient. His theory is based on (1) changes in *p*H of guard cells during opening or closure, (2) balancing of K$^+$ by the amounts of malate and chloride present in epidermal tissue, and (3) no change in the net amounts of K$^+$, Cl$^-$ or malate in epidermal tissue.

Changes in the *p*H of guard cells do occur[2,3], however. Malate and Cl$^-$, together, can balance K$^+$ present in guard cells[4-6]. There is also no net change in K$^+$ of epidermal tissue[7]. The replaceability of K$^+$ by Na$^+$ for stomatal opening demonstrated that a monovalent ion is necessary to increase the turgor pressure of guard cells but not necessarily K$^+$ (refs 8–10).

We cannot reconcile these data on malate with the proposals of Bowling[1]. The epidermal tissues produce appreciable quantities of malate and the changes in malate levels are closely and positively correlated with the stomatal aperture[5,6,11]. Further, the epidermal tissues contain highly active enzymes not only for malate synthesis but also for malate degradation[12,13]. The above data, together with the autoradiographic studies indicate that malate production and metabolism could occur in guard cells[2,11-13]. The general understanding is that guard cells can derive malate through phosphoenolpyruvate carboxylation and may exchange those acid ions for K$^+$. The stimulation of stomatal opening by phosphoenolpyruvate[13] supports this assumption.

In fact, no anion is required for K$^+$ uptake by guard cells since the guard cell can itself release H$^+$ ions[14]. We therefore feel that, in addition to malate, photosynthetic and/or respiratory electron transport-mediated H$^+$/OH$^-$ efflux could cause a change in the *p*H and provide the necessary H$^+$ ions for exchange with K$^+$. We have presented evidence for such light-induced efflux in guard cells[15]. An active uptake of K$^+$ is likely because the stomatal response to even CO$_2$ free air is sensitive to metabolic inhibitors[16]. Abscisic acid also interferes with energy metabolism in guard cells[17,18]. Active K$^+$ transport is, however, not ruled out by Bowling[1].

BOWLING REPLIES—In developing the malate-switch hypothesis I considered the evidence for a connection between overall malate levels and stomatal aperture quoted by Das, Rao and Raghavendra[1]. I do not think, however, that the evidence is as strong as they imply. For example, Pearson and Milthorpe[2] showed that with a malate concentration of 5 μg mg^{-1} the stomatal aperture ranges from 4 to 24 μm. Allaway[3] qualifies his conclusions by stating that his results were obtained after 3-h treatments in light or dark, and questions whether the malate–aperture correlation exists in other conditions. Willmer and Dittrich[4] found no difference in the rate of incorporation of ^{14}C into malate in the light or the dark by *Commelina diffusa*. They point out that changes in stomatal aperture seem to be much more rapid than do changes in overall levels of organic acids and other metabolic products

I put forward the malate-switch hypothesis after realising that there is a transport dimension as well as a metabolic dimension to stomatal functioning. A hypothesis which assumes that stomata open as a result of synthesis of malate in the guard cells and subsequent exchange of H$^+$ ions with K$^+$ has also to explain how K$^+$ moves to the guard cell from three cells away as it does in *Commelina communis*. An accompanying anion is surely required and on present knowledge this would seem to be malate.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature* The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

Scrotal asymmetry

FOR the record, I report that since reading Morgan and Corballis[1] on the subject of scrotal asymmetry and Rodin's dyslexia, I have made regular observations of the asymmetry in one person who is right handed, has not got situs inversus totalis (or even partialis), has never had surgical procedures on the abdomen, and has no neurological, endocrinological or psychological disorder, except a certain impatience with pretentious nonsense. My findings are that if the subject of my investigation had been the model for Rodin's *L'Age d'Airan*, Rodin would have been correct in assigning a lower position to the right testis compared with the left. I am not dyslexic.

WILEY INTERSCIENCE

TRENDS IN CHILDHOOD CANCER

edited by **M.H. Donaldson,** *University of Pennsylvania,* and **H.G. Seydel,** *School of Medicine and Albert Einstein Medical Center, Thomas Jefferson University.*

Designed to convey recent research and treatment information in symposium form, this volume includes results of clinical and basic research and comprehensive coverage of pediatric oncology. Emphasis is given to genetics and etiology of leukemia and lymphoma. (Wiley Series in Diagnostic and Therapeutic Radiology)

0471 21782 4 158 pages February 1977 £12.40/$20.95

INFANT NUTRITION

edited by **D.H. Merritt,** *School of Medicine, Indiana University.*

Over 30 articles have been selected and organized to provide a comprehensive treatment of artificial feeding of infants. Major topics of infant nutrition are covered, including modified whole milk; the hunger, energy, and metabolism bases for feeding: safety and cleanliness; and certain long-term aspects of freedom of choice on the part of the infant. (Benchmark Papers in Human Physiology Vol. 7)

0470 98918 1 448 pages December 1976 £18.65/$31.75

Published by Dowden, Hutchinson & Ross Inc., and distributed by John Wiley & Sons Ltd.

ORGANIC CHEMISTRY OF DRUG SYNTHESIS

by **D. Lednicer,** *Upjohn Company,*
and **L.A. Mitscher,** *University of Kansas.*

Brings together published syntheses from patents and journals for the majority of organic compounds used as drugs. Examines how therapeutic agents were developed, the synthetic operations used in their preparations, and the type of structures that have proved useful as drugs.

0471 52141 8 492 pages February 1977 £16.90/$27.75

TISSUE RESPONSES TO ADDICTIVE DRUGS

edited by **D.H. Ford,** *State University of New York,*
and **D.H. Clouet,** *New York State Drug Abuse Control Commission*

Presents a conference proceedings on the subject, covering what is known about pharmacology, metabolism and the presumed mode of action of a variety of opiate drugs in relation to sites of action and possible clinical complications. A broad view of the effects of addictive drugs on the brain and other tissues is described.

0470 15192 7 724 pages February 1977 £37.50/$63.50

Published by Spectrum Publications Inc., and distributed by John Wiley & Sons Ltd.

PRINCIPLES OF LASER PLASMAS

edited by **G. Bekefi,** *Massachusetts Institute of Technology.*

Thirteen self contained chapters, written by well known authorities in the gas laser field, discuss the specific area of electrical discharge of the lasing medium. The book is profusely illustrated.

0471 06345 2 716 pages February 1977 £26.00/$40.00

OPTICS AND INFORMATION THEORY

by **F.T.S. Yu,** *Wayne State University.*

This provides vital material on the development of more efficient optical communications systems and a greater understanding of modern communications data processing. Offers a thorough background in information theory and its application to problems of optical communication, with material derived from Shannon's theory, Gabor's concept, and Brillouin's entropy of information.

0471 01682 9 218 pages January 1977 £11.00/$19.00

MAGNETIC OXIDES

edited by **D.J. Craik,** *University of Nottingham.*

This book contains authoritative accounts of the different aspects of the relevant theoretical work and the practical behaviour of magnetic oxides which is the class of magnetic materials which has received the most intensive basic study and is of the greatest technological importance. The areas of the subject are covered by authors from industry and academic life, all with considerable experience in the field (bound in two parts).

0471 18354 7 504 pages April 1975 £15.00/$30.70 (part 1)
0471 18355 5 338 pages " £15.00/$30.70 (part 2)
0471 18356 3 842 pages " £30.00/$61.40 (set)

LIQUID STATE CHEMICAL PHYSICS

by **R.O. Watts,** *Australian National University,*
and **I.J. McGee,** *University of Waterloo, Canada.*

Covers the theory of liquids and the relation between this theory and the determination of intermolecular forces. Shows the comprehensive nature of modern liquid state theory by giving accounts of several different types of liquids. Presents semiempirical models for all inert gases, and discusses the role of body forces in liquids and in solids.

An Important New Series

Research Monographs in Cell and Tissue Physiology

"It is intended to publish edited monographs on selected topics which will provide the latest information gained at the molecular, subcellular and cellular levels, as well as reviews of the current situation. It is hoped that these monographs will prove particularly valuable for people working at the clinical, animal and tissue levels as well as those more closely concerned with the functions of individual cells and organelles."

J. T. Dingle, from the *Preface to the Series.*

Volume 1

Platelets in Biology and Pathology

edited by J. L. GORDON

1977. xiv + 388 pages. US $ 52.95/Dfl. 132.00
ISBN 0-7204-0601-3

Recent research has shown that, apart from their vital role in haemostasis and thrombosis, blood platelets are convenient models for investigating numerous cellular reactions and as such contribute to a variety of pathophysiological processes. The purpose of this book is to acquaint physiologists and pathologists with the diversity of biological processes involving platelets and to bring platelet biology to the attention of biochemists, cell biologists and pharmacologists, who may find platelets a valuable adjunct to (or even substitute for) more complex or less accessible cells in their research. Therefore while investigations of haemostasis and thrombosis are included, emphasis is placed on the potential roles of platelets in other biological processes, such as atherogenesis and inflammation.

Some of the most stimulating contributions are the reviews of current work on platelet membrane receptors for specific agents, and on the mechanisms regulating the responses of the cell.

Volume 2

Proteinases in Mammalian Cells and Tissues

edited by A. J. BARRETT

1977. about 780 pages. US $ 79.95/Dfl. 196.00
ISBN 0-7204-0619-6

Reasons for the continuing expansion of our knowledge of proteinases are not difficult to understand. Evidence that protein catabolism must be quantitatively an important process in normal physiology comes with the realization that the amount of protein broken down to animo acids is well in excess of that digested in the alimentary tract during the same period. This degradative activity is very precisely controlled in the healthy state, but there are many diseases in which tissue damage seems to arise from local disturbance of the process, with net loss of important protein structures. It is in the very area of control of biological processes that many previously unsuspected roles for proteinases are being discovered.

The main emphasis in this volume is on the isolation and in vitro properties of proteinases. It is at this fundamental level that the most rapid acquistion of knowledge is occurring and this handbook will stimulate new research methods needed for physiological studies.

Caricature of Darwinism

R. C. Lewontin

The Selfish Gene. By Richard Dawkins. Pp. xi+224. (Oxford University; London, 1976.) £2.95.

POWERFUL theories that offer to explain large parts of the world of appearances carry, immanent within them, their own caricatures. Indeed, their liability to absurd reduction is precisely in proportion to their original generality and power. There are inevitably those who, dazzled by the great insights of others but understanding them only superficially, push these theories far beyond their valid domain of explanation. This has been the fate of the three powerful conceptual systems that have had such an immense impact on the life and thought of the nineteenth and twentieth centuries: Marxism, Freudianism and Darwinism. Marx's historical materialism has been vulgarised by an 'economism' that attempts to explain the last petty detail of social organisation and history by direct reference to 'material conditions'. Carried away by Freud's theories of the unconscious, and especially the transformations of behaviour described as repression, inversion and sublimation, facile 'psychologism' has searched for an explanation of the French Empire in Bonaparte's relationship with his parents.

The caricature of Darwinism which sees the wonderful workings of natural selection in every aspect of the living world and its artefacts, began immediately with the publication of the *Origin of Species.* The enthusiasm that led the early partisans of Darwin to see every difference in the morphology and physiology of organisms as adaptative, also led them into speculation no different from the baroque rationalisation of Paley's *Vestiges of Creation.* Evolutionary theory was rescued from its excesses by Huxley's ideas of allometric growth which enabled us to understand that many morphological features of organisms are simply epiphenomenal consequences of relative changes in different growth fields or in different dimensions, and by Sewall Wright's demonstration that precisely the same selective forces can lead different populations to quite different phenotypic compositions because of random processes operating in a field of multiple stable equilibria. Thus, we no longer feel called on to explain in an adapative mode why the Indian rhinoceros has one horn whereas the African rhinoceros has two.

For more than forty years evolutionary theory has remained free of a naive selectionism, but in recent times there has been a return to the extreme form of the adaptationist program, as evolutionists have rediscovered behaviour. Beginning with the undoubted truth that behaviour must, like morphology and physiology, be subject to the force of natural selection, the new Panglossians end with the old error that *all* describable behaviour must be the direct product of natural selection. The scientific manifestation of this trend can be seen in every issue of say, *The American Naturalist,* which is permeated by the language, if not the formal apparatus, of game theory, and in the development of the school of 'sociobiology', among whose more extraordinary productions is a recent highly praised dissertation explaining *fellatio* and *cunnilingus* among the upper middle classes as an adaptive response to constant resources. The popular manifestation of this new caricature of Darwinism reaches its most extreme form in *The Selfish Gene* by Richard Dawkins.

The Selfish Gene is the result of Dawkins' discovery of vulgar Darwinism. "We are survival machines—robot vehicles blindly programmed to preserve the selfish molecules known as genes. This is a truth which still fills me with astonishment" (preface). I too find Dawkins' description of the relationship between gene and organism rather astonishing. The theme of our passive manipulation by our gene captors is repeated over and over. "They swarm in huge colonies, safe inside gigantic lumbering robots, sealed off from the outside world communicating with it by tortuous indirect routes, *manipulating it by remote control.* They are in you and me; they created us *body and mind*; and their preservation is the ultimate rationale for our existence. They have come a long way, those replicators. Now they go by the name of genes, and we are their survival machines" (p21). "It leaps from body to body down the generations, *manipulating body after body* in its own way and for its own ends, abandoning a succession of mortal bodies before they sink into senility and death" (p36) (my italics throughout).

The form of reasoning that leads Dawkins, or, rather, the evolutionary theorists of whom Dawkins is the enthusiastic reporter, to this view of gene and organism is exemplified in the discussion of crowding and fertility. It is observed that in some animals overcrowding reduces the birth rate. Given this observation, Dawkins then asks "Why does natural selection favour females who reduce their birth rate when the population is overcrowded?". He then contrasts a population selection argument, unfavourably, with a "selfish gene" theory. But both arguments assume without proof that females reduce their birth rate for an adaptative reason, rather than regarding lower fertility as a mechanical concomittant of the altered endocrine function that results from excitement. They also assume that at some time in the evolutionary past the ancestors of these animals did *not* respond to crowding by lower fertility and that genetic variation of just the right sort conveniently arose to allow some animals to do so. Finally, they invent a plausible story to explain why lowered fertility is a 'good thing'. With a little ingenuity, of course, such stories can always be invented, but it is not clear whether we are dealing with science or high-table wit. The realisation that he is engaged in game playing after all comes briefly to Dawkins' consciousness in his discussion of R. L. Trivers's story of reciprocal altruism. "There is no end to the fascinating speculation which the idea of reciprocal altruism engenders when we apply it to our own species. Tempting as it is, I am no better at such speculation than the next man, and I leave the reader to entertain himself" (p202).

Dawkins is not content that his readers should amuse themselves with the clever games already produced by Hamilton, Trivers and Zahavi, but introduces, in his last chapter, his own patented variant. Allowing that the details of human culture are probably not coded in our genes (we are not such robots, after all, it seems), Dawkins suggests that ideas themselves are units of reproduction and natural selection. He asserts, for example, that "The idea of hell-fire is, quite simply, *self-perpetuating,* because of its own deep psychological impact" (p212), although he does not tell us how its "deep psychological impact" provides a mechanism for its self-perpetuation. He shrugs off without analysis the much more plausible and clearly causal hypothesis that hell-fire is not *self*-perpetuating, but is perpetuated by some people because it gives them power over other people. In fact, both Dawkins' suggestion that ideas are replicating selected units and the sociologists' notion that the details of human social activity are coded in our genes and selected for maximum reproductive potential, arise from the same fallacious view of human society, which, in turn, is a reflection of their confusion between materialism and reductionism. Although it is true that human beings are material objects whose brains are the result of a developmental process under the influence of genes, it is not true that their *minds* can be understood when we understand their genes. In like manner, although human society is the product of the sensuous activity of material individuals, human society is not simply the collection of all individuals.

According to Richard Dawkins, "If superior creatures from space ever visit earth, the first question they will ask, in order to assess the level of our civilisation is 'Have they discovered evolution yet?' ". I think it more likely they will want to know whether we know the difference between properties of sets and properties of their members. □

R. C. Lewontin is Alexander Agassiz Professor of Zoology in the Museum of Comparative Zoology and Professor of Biology at Harvard University, Cambridge, Massachusetts.

Compendium of physiology

Introduction to Physiology. Vol. 3. By H. Davson and M. B. Segal. Pp. x+656. (Academic: London; Grune and Stratton: New York, 1976.) £9.80.

THE appearance of the third volume of this series so shortly after the first two (for review see *Nature* **259**, 428; 1976) is a great tribute to the industry as well as the erudition of the authors. It is a pity, even so, that they have been outpaced by inflation and the cost per page has risen from about 13p to 15p.

This third volume is devoted mainly to the homeostatic control of the principal mass-transport systems of the mammal—the circulatory, respiratory, alimentary and urinary systems. There are also sections, in the Bernard tradition, on thermoregulation, the control of plasma electrolytes and blood sugar, and a concluding one on the internal environment of the central nervous system in which the writers are, of course, very much on their home ground. Each of these topics is covered in considerable depth and the bibliography which is appended to each section is copious including virtually all workers who have achieved prominence in their respective fields over the past 20 years as well as many whose contributions are less familiar.

What seems to be emerging is a compendium of contemporary physiology rather than an introduction to the subject. The various sections, although providing detailed and thoughtful surveys of current ideas, suffer somewhat from a lack of contour lines which might help the novitiate to distinguish the salient features in the detailed scenario which is presented. The text is complemented by frequent clear and apposite illustrations, although in one instance, at least, the figure contradicts what is written elsewhere and occasional pictures of apparatus hardly merit the space they occupy. In the text itself there are some confusing and inconsistent statements but these are rare and could well result from hasty proofreading. Also from time to time an idea is tantalisingly floated without being adequately developed.

Now that the half-way stage in its production has been reached, the question must arise as to what type of user is likely to gain most from this multivolume treatise. My own impression is that it is too detailed to serve as a working source book for the average medical student who may, however, find it valuable for occasional consultation. On the other hand, Honours undergraduates in most UK universities would probably be encouraged to read original papers rather than rely on summaries, however well prepared. This leaves postgraduate students who, particularly on taught courses, could find their needs well catered for, and finally there is the harassed teacher who may be called on to give lectures or tutorials outside his own speciality. Persons in the last category should be heartily grateful to Drs Davson and Segal for having so diligently 'researched' such a wide range of important topics and having so skilfully blended and packaged the fruits of their labours.

R. V. Coxon

R. V. Coxon is Reader in Human Physiology at the University of Oxford, UK.

Isotachophoretic analysis

Isotachophoresis: Theory, Instrumentation and Applications. (Journal of Chromatography Library, Vol. 6.) By F. M. Everaerts, J. L. Beckers and T. P. E. M. Verheggen. Pp. xiv+418. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl. 160; $61 50.

THIS is an important book. Its senior author, Dr F. M. Everaerts, was introduced to isotachophoresis some twelve years ago by his PhD supervisor, the legendary A. J. P. Martin. Since then Everaerts and his group have developed the technique from a laboratory curiosity to arguably the most versatile method available for the characterisation and determination of low to medium molecular weight electrolytes. It is a method which in my view is destined to become one of the standard tools of chemical analysis.

Essentially the book is a full report of the work done by Everaerts' group; as such the treatment of the subject is uneven. The theoretical section does not provide a good introduction to the subject. The long chapter describing a mathematical model of isotachophoresis seems out of place and adds little of practical value. The qualitative aspects of isotachophoresis, however, are adequately described and the chapter on ionic mobilities summarises the variables available for exploitation by the analyst.

The section on instrumentation is by far the best. It provides a clear account of the problem of detection and of presently available solutions to it. The descriptions of the apparatus are complete enough for anyone with sufficient skill to build an analyser for himself.

The applications section is the most disappointing of all. In spite of the wealth of experimental data presented, there are no comparisons made with rival, well established techniques. A careful perusal of the separations depicted in (say) Fig. 12.4 (p 303) and Fig 15.1 and 15.2 (pp 350–351) will convince any analyst of the value of the technique.

In spite of its shortcomings this book ought to be read by all analysts of electrolyte solutions. Scientific instrument manufacturers should also find it of considerable interest, and possibly very profitable.

Frank Hampson

Frank Hampson is a Research Fellow in the School of Molecular Sciences, University of Sussex, UK.

ASA Monograph

Social Anthropology and Law

edited by Ian Hamnett

April/May 1977, x + 234pp., £5.50/$10.75 0.12.322350.4

Here contemporary social anthropologists and academic lawyers present new ideas and provide answers to some important theoretical problems in the anthropology of law. The focal point of enquiry in this volume consists of the relative importance of "norms" or "rules" on the one hand, and of "interest" or "power" on the other, in the settlement procedures of widely varying African societies. This controlling theme involves a close discussion of the role of law in society generally with particular reference to cases in which legal pluralism results in dynamic social, political and economic change.

Studies in Cross-Cultural Psychology Volume 1

edited by Neil Warren

April/May 1977, xvi + 212pp., £8.50/$16.65 0.12.609201.X

This is the first volume in a series which aims to gather together the scattered but increasingly voluminous information on the subject of cross-cultural psychology. The essays demonstrate the peculiar diversity and potential scope of cross-fertilization between anthropology, ethnology and psychology. In principle, cross-cultural psychology might address itself to problems anywhere within the psychological spectrum. In practice, however, certain areas of research lend themselves better to this approach than others, and accordingly the authors have each chosen important growth points, presenting either a report of sustained research program, or a critical review examining and developing conceptual schemes and theories.

Theory and Practice in Interpersonal Attraction

edited by Steve Duck

April/May 1977, x + 438pp., £9.80/$19.25 0.12.222850.2

This book closely examines the nature of interpersonal attraction, what it is, why we are attracted to some people rather than to others, how it is possible to measure the extent of attraction and attractiveness, and how our lives may be affected by the degree of attractiveness or unattractiveness attributed to us. The book is arranged into three sections following three fundamental questions. These are. 1) How do specialist workers explain the phenomena in the area? 2) What sorts of study do they do to investigate the area? 3) How does this area fit in with theoretical work in other areas of the subject.

Proceedings of the Serono Foundation No. 11

Prolactin and Human Reproduction

edited by P.G. Crosignani and C. Robyn

April/May 1977, vii + 306pp., £10.50/$20.50 0.12.198345.5

This book records the proceedings of the eleventh International Symposium of the Serono Foundation, held at Cernobbio in July 1976. The purpose of the symposium was to gather together experts in human prolactin that they may present and discuss recent findings concerning the influence of prolactin on the endocrine control of human reproduction. The result was a comprehensive revision of the relationship between prolactin and human reproduction.

Contents
Assay Methods. Physiology. During fetal life and development. Role in the control of fertility: in animal, in man. **Pathology.** Characterization of hyperprolactinemic amenorrhea. Management of hyperprolactinemic amenorrhea.

Proceedings of the Loch Lomond Symposium, Ross Priory
University of Strathclyde, in September 1975

Studies in Mother—Infant Interaction

H. R. Schaffer

April/May 1977, x + 478pp., £14.80/$29.00 0.12.622560.5

These papers take a lively, modern approach to the topical problem of mother—child interaction, taking care to present the relationship as a dyadic one: the effect of the child's presence on the adult is as considerable as that of the parent on the infant. The approach is marked by the adoption of microanalytic techniques of study, showing how unsuspected patterns can be revealed by close analysis of the extremely complex interactive behaviour which is in existence between mother and child long before linguistic communication develops.

ORIGINS OF LYMPHOCYTE DIVERSITY

With the publication of this two-book set, the question of antibody diversity, an already intriguing enigma when considered at the 1969 Symposium on Antibodies, has now been placed within the broader context of lymphocyte diversity, and in fact can now be discussed within the framework of almost all of immunology.

Bringing together a wide range of research done in many leading laboratories throughout the world, this symposium volume should represent for many years the most comprehensive overview of the way in which immunologists see their field evolving. It is thus sure to find a wide audience among all engaged in fundamental biology and most specifically those attempting to unravel the mystery of the immune response

1977, 1024 pp., illus., index ISBN· 0-87969-040-2 2-Book set, clothbound, $60

CONTENTS

Part 1

Introduction· The common sense of immunology (Jerne)

T-cell Markers and Differentiation

Thymopoietin and bursopoietin (Goldstein). T-cell maturation (Weissman). T-cell subclasses (Cantor). Cells in B-lymphocyte differentiation (Herzenberg). A kappa membrane antigen on B and T cells (Gottlieb). Rat Thy-1 antigens from thymus and brain (Williams). Terminal transferase (Baltimore). Virus-lymphocyte interactions (Bloom)

Helper and Suppressor T Cells and Their Products

The hermaphrocyte (Gershon). Suppressor T cells in tolerance (Basten). Two pathways of tolerance to DNFB (Claman). Heterogeneity of interactions (Feldmann). I-region expressions on T-cell factors (Tada)

B-cell Differentiation and Commitment

In vitro studies on lymphocyte diversity (Owen). Ontogeny of B-cell diversity (Cooper). Ontogeny of B cells (Melchers). B-lymphocyte development (Raff). Induction of immunoglobulin synthesis (Weimann). B-cell diversification (Klinman). One lymphocyte, two immunoglobulins (Pernis). Immunoglobulin receptors on murine B lymphocytes (Vitetta). Immunoglobulin on murine B lymphocytes (Parkhouse). Lymphocytes of the sIgA system (Cebra). B-cell activation (Möller). T- and B-cell growth in vitro (Andersson). Antigen-specific B cells (Nossal). Regulation of B-cell clones (Kincade). B-cell immunity and tolerance (Diener)

Receptors

Lymphocyte surface immunoglobulins (Marchalonis). Idiotypic T-lymphocyte receptors (Binz). Structure of the T-cell receptor (Krawinkel). Antinuclease receptors (Sachs) Rabbit Fc receptor-bearing cells (Cazenave). Heterogeneity of Fc receptors (Grey)

Structure of Molecular Products of MHC

Structure of HL-A A and B antigens (Strominger)· Structural studies of MHC antigens (Peterson) Chemical analyses and sequences of HL-A (Appella) Structural differences of H-2 mutants (Nathenson) Structure of H-2 antigens (Cunningham) Structural studies of H-2 and TL alloantigens (Uhr) Chemistry of H-2 products (Silver). Human Ia antigens (Snary) Characterization of B-cell alloantigens (Springer) The guinea pig MHC (Schwartz) Analysis of antigen expression (Hyman)

Part 2

Genetics of the MHC and Associated Products

Polymorphic B-cell determinants (van Rood) Recognition of MHC antigens (Bach) Genetics of human Ia antigens (Barnstable) Histocompatibility-2 system of wild mice (Klein) H-linked Ir and Is genes (Benacerraf) New I subregions of H-2 complex (Shreffler). Functional and genetic analysis of Ia antigens (McDevitt) Selective expression of Ia loci (Murphy)

Role of Histocompatibility Gene Products in T-cell Cytolysis

Surveillance and alloreactivity (Zinkernagel). Cytotoxicity to Hh determinants (Shearer). T-cell response to H antigens (Bevan). Antigenic requirements for virus-specific CMC (Koszinowski). H-2 gene products and T-cell specificity (von Boehmer). H-2 antigens and cytotoxic T cells (Schrader). Multiple receptors on T cells (Wilson)

Antigen Presentation and T-B Cell Interactions

Macrophage-lymphocyte interactions (Pierce). Genetic control of lymphocyte activation (Paul). T-lymphocyte activation (Miller). Response to cell-surface antigens (Lake). T–B collaboration across haplotype barriers (Swain). Genetic control of cell interactions (Katz)

Antibody Combining Site

Models of antigen binding sites (Padlan). Three-dimensional structure and diversity of immunoglobulins (Poljak). Genetic implications of V-region diversity (Haber). Antigen-binding myeloma proteins (Potter) Domain interactions in antibody (Givol)

Allotypes and Idiotypes

Rabbit immunoglobulin allotypes (Mage). V_H genes for rabbit Ig (Knight). Streptococcal hyperimmunization (Fraser) Structure and suppression of idiotypic antibody (Ju). Interactions between idiotypes and anti-idiotypes (Cosenza) Immune response to self idiotypes (Sakato). GOD in the response to phosphorylcholine (Claflin). Inheritance of antibody specificity (Mäkelä). Dissection of an immune response (Geckeler)

Generation of Diversity: 1. Biological Aspects

The life style of B cells (Askonas). Rapid diversification of lymphocytes (Cunningham). Lymphocyte diversity in amphibians (Du Pasquier). Immunoglobulin expression (Marguiles). Mutants and hybrids in tissue culture (Milstein). V_κ-region marker and Ly-3 antigen (Gottlieb)

Generation of Diversity: 2. Structural Aspects

NZB and BALB/c myeloma proteins (Hood). Genetics of variable regions (Weigert). Immunoglobulin V regions (Capra). Immunoglobulin gene diversity (Leder). Hybridization kinetics and diversity (Smith). Somatic changes of immunoglobulin genes (Tonegawa)

Summary (Edelman)

Carcinological fauna of Japan

Crabs of Japan and the Adjacent Seas By Tune Sakai Volume 1: English text+figs. Pp. i–xxix+772. Volume 2; Plates Pp. 250. Volume 3 Japanese text. Pp. 460. (Kodansha: Tokyo; Antiquariaat Junk Lochem, The Netherlands, 1976.) Dfl.550 the set

DURING the past two decades research on the carcinological fauna of Japan has made rapid progress, resulting in many additions to the species of crabs. The author of this handsomely produced, up-to-date, and definitive monograph has kept abreast with the recent literature and incorporated the results of over forty years of field work and research. Considerable changes in classification and nomenclature have therefore been made—for example, to the family Potamonidae after Bott, 1970, and to the genus *Uca* after Crane, 1975.

About 885 species of Brachyura, referable to 329 genera and 30 families, are dealt with taxonomically, and nearly all are illustrated. Numerous keys are given to the determination of most categories from superfamilies to subspecies Exceptions are, for example, species of *Ebalia,* which require revision; and genera in the Alliance Xanthoida, because Mme Guinot's investigations are still in progress. Well known species, or ones described in the earlier monograph, or in *The Crabs of Sagami Bay* (1965), are not described again.

Throughout, references and synonymies, material examined, habitat with occasional ecological notes, type locality and general distribution, are given. Mention is made of some recently described species not seen by the author. Quite a large percentage are endemic; a few are known only from Japan and some remote locality like Ceylon, or Madagascar. Many are widely distributed throughout the Indo–West Pacific.

Because of the great economic importance of some of the cold water crab-like Anomura of the family Lithodidae, fifteen species (two new to science) are described and illustrated in an Appendix. Bibliographies for the Brachyura and the Lithodidae, and a systematic index, complete the English text. The author's English is always easy to follow, and the Japanese text is apparently intended for the use of students and non-specialists.

The colour plates are excellent About 600 beautiful paintings after living or frozen crabs, specially prepared by the author's wife, are reproduced. and a number of rather striking colour photographs of crabs in their natural habitats are included The book will be useful for specialists working on the fauna of the whole of the Indo-Pacific region.

Isabella Gordon recently retired after many years as Head of the Crustacea Section at the British Museum (Natural History), London, UK

ISIS bibliography

ISIS Cumulative Bibliography. A Bibliography of the History of Science formed from ISIS Critical Bibliographies 1–90, 1913–65. Vol. 3; Subjects Edited by M. Whitrow. Pp 678. (Mansell Information: London, 1976.) £28.

THIS massive work brings one stage nearer completion a major scholarly project reviewed in these pages five years ago (*Nature*, **237**, 115–116) when the initial two volumes were published. The *Isis Cumulative Bibliography* aims to make accessible the rich information on "the history of science and its cultural influences" stored in the critical bibliographies routinely published by the official journal of the History of Science Society. Volumes 1 and 2 recovered and reorganised material under the headings of "personalities" and "institutions". This third volume deals with "subjects". "Periods" will occupy a fourth volume.

The difficulties inherent in this kind of bibliographical synthesis are commensurate with its magnitude. The abbreviations for the journals cited run to seventy-six closely-printed quarto pages The classification scheme needs ten pages of explanation That scheme allows the more than twenty thousand entries to be arranged and cross-indexed under approximately seven thousand categories In an interesting reflection of historical priorities, works on mathematics and the physical sciences occupy one hundred and twenty-three pages to a mere thirty for the biological sciences and twenty-nine for the sciences of man

The present volume allows one quickly to identify the reliable historical literature on subjects ranging from "Adsorption: Chemistry" to "Alchemists: North American: Collective Biography", and "University and Advanced Level Teaching. Mathematics: Russia" to "Writing and Reviewing: Science". Like its predecessors, this volume is an indispensable reference work for all those concerned to understand science as a human enterprise

Arnold Thackray

Arnold Thackray is Chairman of the Department History and Sociology of Science, University of Pennsylvania, and will be a Visiting Fellow at All Souls College, during 1977–78.

Underwater optics

Marine Optics By N. G Jerlov. (Elsevier Oceanography Series, No. 14.) Pp xiii+231. (Elsevier: Amsterdam, Oxford and New York, 1976.) Dfl.77; $29.75.

AT first sight this book seems to be a glossier and larger version of Jerlov's *Optical Oceanography* (Elsevier Oceanography Series, No 5, 1968), indeed the earlier book is still advertised on the dust cover of the present book, which seems a little strange A closer look shows that the number of figures has increased from 83 to 137, tables from 28 to 37, but pages only from 173 to 203. Impressively, the references have increased from 296 to no less than 548, of which nearly 200 are post-1968. This certainly confirms the author's statement that progress in ocean optics is being made at a rapid rate.

In revising the book the author has eliminated some earlier references and included many others, as well as adding so much new work. In particular one should mention the large number of Russian and eastern European references (about 70) in the recent volume, compared with about 30 in the earlier one The author's technique in revising has been mainly to repeat word for word the 1968 book, here and there inserting new paragraphs or tagging on bibliographical information. The extra 30 pages are mostly made up by the extra figures and tables.

It should be stressed there is almost no re-writing of the 1968 text and thus it becomes necessary to justify the production (and purchase) of the new volume purely on the extra information included. The price of about £18 does seem high but the eminence of the author and the assembling of so much extra material probably does justify such expenditure. The new data probably are better shown as figures and tables, but the main advances over the past eight years are more in the nature of additional data built on to old, rather than the formulation of new concepts.

One of the most valuable new sections deals with the use of underwater optics to check the movement of water masses, a valuable tool for the physical oceanographer. As in the 1968 version, however, the author disappoints the biologist reader who is looking for the application of underwater optics to such phenomena as primary production, bioluminescence and animal behaviour

J. H. S. Blaxter

GABA

GABA in Nervous System Function. (Kroc Foundation Series, Vol. 5.) Edited by Eugene Roberts, Thomas N. Chase and Donald B. Tower. Pp. xv+554. (Raven: New York, 1976.) $30.00.

THE identification of γ-aminobutyric acid (GABA) in mammalian brain in 1950 led, after a short lag phase, to a profusion of physiological and biochemical studies. Many of these were described in the only previous volume on GABA and the nervous system, published in 1960. At that time the possible neuronal inhibitory role of GABA, and its importance in epileptic activity, were the focus of attention. A subsequent period of doubt was followed by one of consolidation. An inhibitory transmitter role for GABA in the mammalian cerebellum, cortex and hippocampus is now generally accepted. Experimentally, epileptic convulsions can be induced by drugs which block the synthesis of GABA or impair its inhibitory action. It has yet to be shown, however, that epilepsy in man (except for pyridoxine-related syndromes) arises from a failure in GABA-mediated inhibitory processes.

The present volume arises from a workshop held in California in 1975. The 37 chapters are by 47 contributors (32 from North America, 10 from Japan, 2 from Norway, 2 from West Germany and 1 from Australia). The predominant emphasis is on biochemistry, cytology and cellular physiology. The last 5 chapters discuss the possible involvement of GABA in disease and therapy.

There are indications that we are entering a new growth phase in GABA research. Suggestions that abnormal functioning in GABA systems contributes to the pathogenesis not only of epilepsy, but also of Huntington's chorea, Parkinsonism, schizophrenia, senile dementia, and anorexia nervosa, are providing the stimulus.

The techniques and basic data presented in this volume provides the means. Of outstanding importance is the development of immunocytochemical techniques which, using antibodies prepared from purified enzymes (glutamic acid decarboxylase and GABA transaminase), enable visualisation of cellular structures containing these enzymes. Pioneering reports from the laboratory of Eugene Roberts, describe the light and electron microscopical localisation of these enzymes. These reports provide beautiful confirmation of neurophysiologists' earlier conclusions about which cell types release GABA in the cerebellum and hippocampus. **Brian Meldrum**

Brian Meldrum is Senior Lecturer in the Department of Neurology, Institute of Psychiatry, London, UK.

Polymerisation

Thermodynamics of Polymerization. By H. Sawada. Pp. xiii+403. (Dekker: New York and Basel, 1976.) 130 Swiss francs.

THIS book is an expanded version of the collection of articles written by Dr Sawada for *Reviews of Macromolecular Chemistry* over the period 1969 to 1974. Each chapter has been written as a separate entity so that there is inevitably a certain amount of repetition of both content and references.

The first two chapters are introductory, dealing with the general ideas of ceiling temperature, heats and entropies of polymerisation. These are followed by five chapters covering in succession anionic, cationic, radical, condensation and ring polymerisation. Next comes a chapter on polymerisations, the equilibrium positions of which have been measured, followed by two on copolymerisation. Finally there are two chapters devoted to degradation of polymers and miscellaneous topics such as tacticity and pressure effects.

The reader who comes to the subject afresh may be surprised to discover how much of the book is concerned with kinetics rather than thermodynamics. A more complete description would have been "Kinetic and thermodynamic aspects of processes relevant to polymerisation". Thus under anionic polymerisation we find a discussion of equilibrium between different types of propagating species, under cationic polymerisation an account of the thermochemistry of ionisation processes, and under radical polymerisation substantial sections on the thermodynamics of the initiation, termination and transfer reactions. The kinetic data are sometimes linked with thermodynamically-based parameters such as Hammett σ, and sometimes simply expressed in terms of energies, entropies and volumes of activation. Other times there is only the most tenuous link with thermodynamics, as in the discussion of reactivity ratios in terms of the Alfrey–Price Q,e scheme.

The chief merit of the book is that it brings into a single volume for the first time most of the available information on thermodynamics of polymerisation, and a valuable feature is the Addendum of recent publications.

Wax esters and non-polar lipids

Chemistry and Biochemistry of Natural Waxes. Edited by P. E. Kolattukudy. Pp. xx+464. (Elsevier: Amsterdam, Oxford and New York, 1976.) Dfl129; $49.75.

THIS book is dedicated to Professor A. C. Chibnall who first became interested in waxes fifty years ago and (with S. H. Piper) carried out some classical studies in this field. Significant advances in our understanding of wax chemistry and biochemistry had to await the chromatographic and spectroscopic procedures which have revolutionised and activated all areas of lipid research. The waxes (broadly interpreted) have shared in these developments, and for any who have overlooked them the record is fully documented in this book. Chemists and biochemists interested in lipid methodology, lipid structure, and lipid biosynthesis, and biologists of many kinds will want to consult this book and to have frequent access to it.

The term "wax" is not here confined to wax esters but includes a wide variety of non-polar lipids: hydrocarbons, ketones and aldehydes, primary and secondary alcohols, ethers, alkanediols, acids, wax esters of several kinds, and terpenoids. In general these may be saturated or unsaturated and straight chain or branched chain. The editor has chosen, however, to organise the chapters on the basis of the type of organism from which the wax is derived, the ten contributions being: introduction to natural waxes (P. E. Kolattukudy); mammalian waxes (D. T. Downing); marine waxes (J. R. Sargent, R. F. Lee and J. C. Nevenzel); bird waxes (J. Jacob); and their biochemistry (P. E. Kolattukudy); insect waxes (L. L. Jackson and G. J. Blomquist); plant waxes (A. P Tulloch); and their biochemistry (P. E. Kolattukudy, R. Croteau and J. S. Buckner); algal and fungal waxes (J. D. Weete); and bacterial waxes (P. W. Albro). Dr Kolattukudy is to be congratulated on securing the service of such authoritative contributors. In addition to his own writing the editor has—more or less successfully—prevented undue overlap of material between the various chapters.

At appropriate places in the text, structure and composition, structural determination and analytical procedures (chromatography and several kinds of spectroscopy), biosynthesis and catabolism, function, and taxonomy are discussed. **F. D. Gunstone**

F. D. Gunstone is Professor of Chemistry at the University of St Andrews, UK.

The Molecular Biology of the Mammalian Genetic Apparatus

edited by PAUL O. P. TS'O, *Professor and Director, Division of Biophysics, The Johns Hopkins University School of Hygiene and Public Health, Baltimore, Maryland, U.S.A.*

The intensive research carried out over the past 25 years on the chemistry and biology of nucleic acids and the molecular biology of prokaryotic cells has laid down the foundation for a concerted investigation of the mammalian genetic apparatus as a whole.

In December 1975 the "International Symposium on the Molecular Biology of the Mammalian Genetic Apparatus - Its Relationship to Cancer, Aging and Medical Genetics" was held at the California Institute of Technology. These two volumes comprise the proceedings of the symposium. They provide the most comprehensive and up-to-date treatment of one of the most important fields in modern biology and will become leading texts for biochemists, molecular and cell biologists, and also cancer researchers and geneticists.

Volume 1

Structure

1977. xx + 444 pages. US $ 56.75/Dfl. 139.00. ISBN 0-7204-0625-0

Contains contributions by over 80 scientists on the properties of histone conformation and interaction, the role of RNA and non-histone proteins in the structure of chromatin, and the various interpretations of the current data on the structural units of interphase chromatin and metaphase chromatin.

Volume 2

Part A DNA Organization and Gene Expression

Part B Relationship to Somatic Genetics, Cancer and Aging

1977. xx + 326 pages. US $ 46.75/Dfl. 114.00. ISBN 0-7204-0626-9

This volume extends the contents of Volume 1 on Structure to the organization and functional aspects of the genetic apparatus, and describes the relevance of the research in this area to the challenging problems in cell biology and biomedical science.

Part A is concerned with DNA organization as studied by various methods including electron microscopy, nucleic acid hybridization, and cloning of plasmids. In addition it contains papers on the expression of genes in terms of transcriptional control.

Part B is concerned with the relationship of the genetic apparatus to somatic genetics, cancer and aging.

obituary

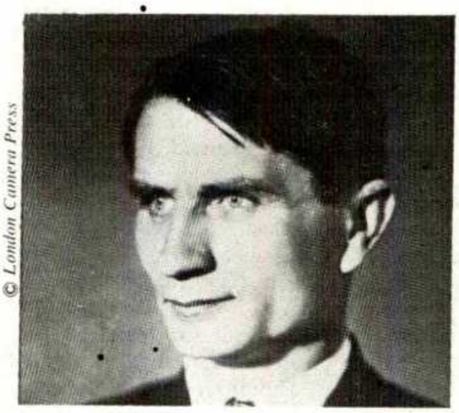
T. D. Lysenko

IT IS a paradox that Trofim Lysenko, who died at the age of 78 on November 20, 1976, was for 30 years the best known spokesman for communist science both inside and outside Russia. For he was not a member of the Communist Party, he was hardly a scientist, and of course he never left Russia. It was his part in the fluctuating relations of successive heads of the Soviet Government with science and with agriculture in the Soviet Union that aroused this world-wide interest.

What first brought Lysenko to notice was his claim in 1930, based on his work at a Ukrainian plant breeding station, that pretreatment of grain would enable Russian farmers to sow winter wheat in spring and thus to reap an increased harvest. This claim, made in the year of Stalin's 'great break', was soon linked with wider generalisations.

It was said that such treatments would change heredity, displacing the slow methods of orthodox plant breeding. Hence they would revolutionise both the practices of agriculture and the theories of biology. For sceptical observers it was not clear whether these claims were based on scientific experiment or philosophic expectation. But it was believed that they were the result of collaboration with a Marxist mentor, Professor I. I. Prezent, who for long remained in the background. Nevertheless, first scientific and then political journals in Russia began to discuss them. Eventually the newspaper *Pravda* and the whole Soviet press was seen to be accepting the evidence and propagating the arguments of Lysenko. The demand arose for a public discussion of the relative merits of Western idealistic bourgeois genetics and the new practical materialistic and Marxist science.

At this point other branches of the Government stepped in. An International Congress on Genetics which was being arranged in Moscow for 1937 by N. I. Vavilov, the President of the Lenin Academy of Agricultural Sciences, was ordered to be postponed. In its place a debate was arranged before a purely Russian and largely agricultural audience. Here the geneticists were allowed to defend themselves and there was a serious argument. But by this time Stalin's purges were in full swing and when the great man himself appeared on the platform and intervened to exclaim "Bravo, Comrade Lysenko" it was obvious how the argument would be settled.



© London Camera Press

Vavilov had been removed from some of his offices before the meeting. After it was over the leading geneticists, one by one, disappeared. Those who were members of the Party were shot. Vavilov himself was not arrested until 1940. He was then sentenced to death as a British spy (having been a frequent visitor to Britain). He was reprieved but later died in prison. Lysenko took over his chief posts and these he continued to hold for twenty-five years.

News of what had happened leaked out of Russia only after the war. By 1946 critics in Britain and the United States were beginning to make serious charges. Lysenko and the Soviet Government were accused of collusion in scientific fraud and political murder. Lysenko's second active phase then began. He denounced the critics abroad, and any who might support them at home, as enemies of the people.

To make it clear what this meant, a second debate was now arranged. The battle lines were laid down in advance. On the Marxist and Leninist principles of struggle and partisanship, two biologies were seen to be implacably opposed. On one side was Lysenko's own science, honest, creative and revolutionary, marxist and materialist, proletarian and patriotic. On the other side were the false and futile works of the Mendelist–Morganist Weismannists who were hardly human and almost entirely foreign.

The meeting took place in August 1948. Again it was at a time of crisis, the battle over Berlin. A few surviving supporters of genetics were allowed to speak, heckled and ridiculed from the floor. Lysenko's followers filled the hall. They also filled the pages of the proceedings with long citations from Marxist authorities. What their statements amounted to in a positive sense was simple but comprehensive. It was the assertion that the inheritance of acquired characters must be the basis of all plant and animal improvement. From this immense generalisation only man was excluded, eugenics and medical genetics having been abolished in the 1930s. In a negative sense there was another conclusion which could also be put in a nutshell. As Lysenko said: "No efforts of the advocates of the chromosome theory of heredity . . . to lend their theory a materialistic appearance can change the character of the theory which is essentially idealistic" (*Applause*). The obstinate material character of the chromosomes and heredity, which had been unknown to Marx, was thus shown never to have existed.

The climax of the meeting came when Lysenko announced that his report had been examined and as was to be expected, approved, by the Central Committee of the Party (*Stormy Applause, Ovation, All Rise*). After Stalin's death Lysenko added the footnote that his patron had most diligently edited the report before approving it. Well he might, for the 631 pages of the Proceedings translated into many languages were ordered to be circulated in well-bound editions at home and abroad.

At the end of the meeting three professors of genetics admitted their errors and promised to follow Lysenko's guidance in future. Those whose honesty and courage forbade submission were degraded and dispersed. By a series of decrees all teaching and research in genetics, agricultural or medical, was suppressed. Books were destroyed, type broken up and libraries purged throughout the Soviet Union. There followed a period of idolisation of Lysenko. He was now a Hero of Socialist Labour with nine Orders of Lenin. His statue appeared in public places and the State Chorus sang his praises.

Lysenko's career, so far, had been sustained by a stream of projects, like his first proposal, to parallel the work of collectivisation in revolutionising Soviet agriculture. Vernalisation of wheat was followed by inherited vernalisation. Hybridisation within varieties was followed by pollination without hybridisation and hybridisation without pollination. Summer potatoes in the North were followed by spring wheat in Siberia; by a *tour de force* wheat became rye and by love-marriages extraordinary fruit hybrids became fertile, while under the master's hand a hazel sprouted from a hornbeam.

During Stalin's lifetime the succession of claims was too rapid to disprove and too dangerous to contradict. But when he died critics raised their heads. And when Khrushchev, three years later, announced a thaw, they dared to open their mouths. The fact that none of Lysenko's claims had ever been vindicated might now, it seemed, prove to be his undoing. But matters of state are not to be so easily disentangled. As can happen even in a free world the industries of communication and education were now implicated with the establishment in a general deception. They were also infiltrated by the secret police. What was worse, it turned out that the successor, Khrushchev himself, liked Lysenko; not as Stalin did, for his theory but for his earthy language and proverbial wisdom.

So it was that Lysenko enjoyed one last spell of power. The virgin lands of Kazakhstan and the novel possibilities of cattle breeding offered him new fields to conquer. The two men embarked on these ventures in partnership and their failure seems to have contributed to the downfall of both. For Zhores Medvedev's exposure of this failure in *Samizdat* led to his confinement in a psychiatric clinic. But it had been known to the Praesidium before it deposed Khrushchev on October 14, 1964. The customary newspaper campaign followed. But now, for the first time, it was turned *against* Lysenko. He was dismissed as head of the Academy's Institute of Genetics on February 1, 1965. And the Institute itself (not for the first time) was dissolved.

News of these developments was released abroad. But the Russian public were only by rumour allowed to perceive that a great pillar of the state had somehow been withdrawn; and to feel that two systems of belief, abandoning the struggle to the death, were to be allowed to shake down together. When summer arrived, sure enough, the Academy in Moscow was allowed to celebrate the centenary of Mendel's paper and to dispatch to Brno in Czechoslovakia seventy geneticists, the largest of all delegations, to lay a wreath on the Abbot's monument.

Thus everything, it seemed, could now be amicably and democratically arranged. Lysenko, for his part, could remain a member of three academies. He could keep his titles and pension, his following of university professors, his journal regularly published and his Experiment Farm in the Lenin Hills. And the grateful geneticists were free to pick up what they could, first in medical, then in animal, and ultimately in plant genetics, from the ruins that Lysenko had left them. Meanwhile the Government could forget that it had ever interfered in these academic matters.

Outside Russia, however, the damage that had been done to the relations between scientists and communism could never be repaired. The view of communism as meaning the liberation of science, held in the 1920s had been turned inside out. With this painful reservation, inside Russia, it is a hopeful sign that the restored geneticists are proposing to hold in Moscow in August 1977 the International Congress on Genetics so tragically abandoned forty years ago. The history, the theory, and the philosophy of genetics are not among the 35 headings proposed for discussion. But, no doubt, the names of the men whom Lysenko destroyed will be discreetly remembered.

One more question should be asked: was Lysenko a charlatan? It is an important question because fraud is always, and in all countries, bound to collect in the wide fringes of science. He was obviously ill-educated, quite shallow, very cunning and a little deranged. As Vavilov put it, privately, he was "an angry man" of a kind we all know. And he found his anger brought him great rewards. On the other hand, his followers were far from angry. They had calculated the rewards that a corrupt system had to offer them.

It remains to say that the world of science owes a debt to three bodies of men in connection with Lysenko. There were those like Vavilov who died in fulfilling their duty. There are those like Andrei Sakharov and Zhores Medvedev who resisted and survived. And there are those devoted scholars outside Russia, notably David Joravsky and Loren Graham, who have enabled us now to understand so much of what happened. *C. D. Darlington*

S. B. Pessôa

The death of Professor Samuel Barnsley Pessôa, removed the grand master of parasitology from Latin America, a region where the subject has flourished vigorously throughout this century. His predecessors in Brazil included H. de Beaupaire Aragão, Carlos Chagas, H. da Rocha Lima and Oswaldo Cruz. Pessôa himself founded a school of workers who have penetrated into all corners of South and Middle America. The training of the first generation stemmed from their close association with German, French and Italian scientists either directly in the New World or during their own visits to Europe in pre-world war days. Pessôa's monumental book, *Parasitologia Médica*, has gone through many editions and is in constant use in Portuguese and Spanish speaking countries.

Pessôa was born in São Paulo on June 4, 1898, the son of Leonel Pessôa and Anna Barnsley, who was of English descent. He spent the greater part of his life in São Paulo, and died there on September 3, 1976.

After qualifying in medicine, he entered in 1925 the General Prophylactic Service of the State of São Paulo as an experimental officer attached to the Institute of Hygiene. His work took him far afield and he quickly became acquainted with the severe sanitary problems of the rural areas as well as those of the city. The distress and poverty of so much of the population transformed him into an ardent fighter for the abolition of the system, which accepted this situation with equanimity, and his ideas became increasingly revolutionary.

His abilities were quickly recognised both in the academic and in administrative fields: he was appointed to a Chair in the Faculty of Medicine of the University of São Paulo in 1931 and was later made Director General of Health. In the latter role he entirely re-organised the service by starting large scale campaigns against endemic diseases and initiating research projects. He took an active part in the latter and made many original contributions notably in muco-cutaneous leishmaniasis, trachoma and schistosomiasis. His observations on espundia and on the transmission of this form of leishmaniasis were fundamental. He studied the epidemiology of Chagas' disease and disentangled some of the problems of the cardiac complications and other phenomena of 'mega'.

Pessôa's reputation was so great that he was appointed to numerous chairs throughout Brazil and even in his last years, he was still commuting between different universities from one end (e.g. Goiás) of Brazil to the other (e.g. Santa Catarina). Pessôa never hesitated to express his views and he was often threatened with prison or dismissal. In the last 15 or 20 years of his life, he became entranced by the parasitic protozoa of snakes and lizards, working both at the Institute of Butantan and in the field on these parasites, which had always attracted Brazilian scientists; he disclosed many new species and methods of transmission by leeches and other invertebrates.

Pessôa was a colourful character, always welcome in international gatherings, where his astute and original mind was much appreciated. But above all, he was revered by his past pupils who could count both on his loyalty and protection during trials and persecutions, and invaluable advice regarding their scientific problems.

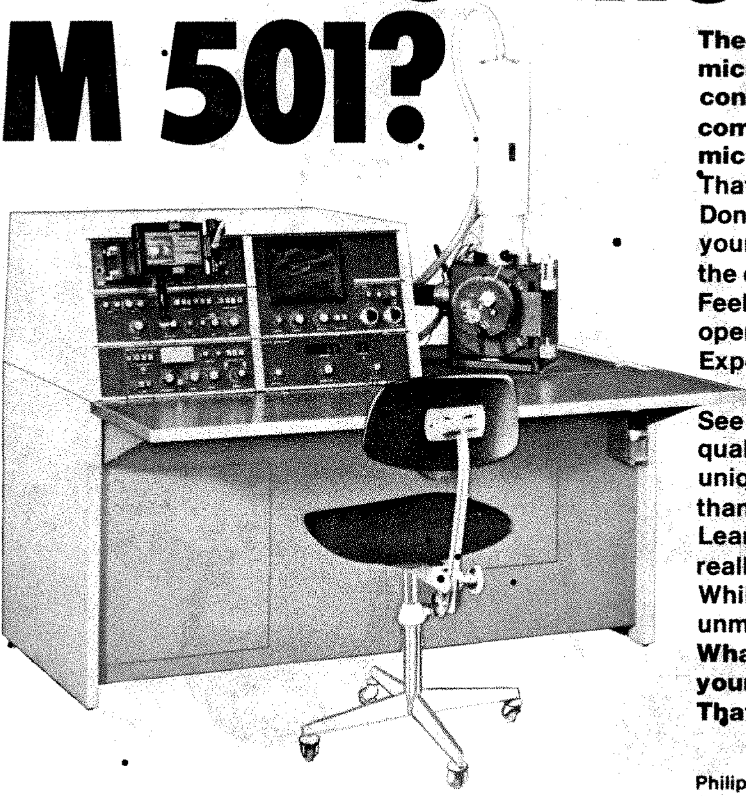
Why believe all our claims for the new SEM 501?



The new SEM 501 gives you better micrographs, consistently, more conveniently than with any other competitive scanning electron microscope.

That's our claim.

Don't believe it until you prove it for yourself. Bring your own samples. Sit in the driver's seat of our SEM 501.

Feel for yourself how convenient it is to operate.

Experience for yourself the benefits of a built-in eucentric goniometer.

See for yourself the uncompromised quality you get from the videoscope and unique greyscale generator. . . and better than 70 Å resolution time after time.

Learn for yourself what SEM versatility really means!

While you're here, learn about our unmatched total support service.

What you see in our lab you'll get in your lab.

That you can believe!

Philips Industries, Electron Optics Department,
Building TQ III-2 Eindhoven, The Netherlands.

Just sit in this driver's seat!

Seeing is believing!

☐ I'd like to sit in the driver's seat of your new SEM 501 Please contact me for a personal demonstration.
☐ For the time being, full documentation will do.
☐ Put me on your mailing list for technical/application bulletins.

For the city and for the world

PROFESSOR Daniel Bell of Harvard and sabbatically at the London School of Economics was lecturing last week at the United States Embassy in London on social institutions in post-industrial society. It was Daniel Bell, of course, who all but invented the term 'post-industrial society' and who has written extensively on the subject of a world in which knowledge is the major resource. He contends that the scale of many of our institutions (in tune, perhaps, with earlier days in which the major resource was land or machinery) is not necessarily in very good register with the sort of demands that will be made in a post-industrial society. An organisation that is co-extensive with a nation or a state may be too large for some purposes, too small for others.

In Professor Bell's *The Coming of Post-Industrial Society* (Heinemann, 1974) it was the scientists and the somewhat quaintly labelled 'research men' who would become the dominant figures where the landowners, the military and, more recently, the businessmen had once been. It follows, then, that the scale of organisations which sponsor, stimulate, monitor or control science is as much in question as in the scale of other social and economic institutions. Is there such a thing as a right size for administering science? This question has been raised recently in Scotland, as Martin Goldman remarked in last week's *Nature* (page 208), but it is not simply one of being ineffective if below some supposed critical mass; on the contrary it may be that the United States, Britain, Scotland, even the Greater London Council are too big for some purposes.

At this small end of the spectrum the local problem with a scientific content has frequently been sadly neglected. Polytechnics do what they can within the heavy teaching load, but universities rarely have much sense of springing from the local community, the academic staff are unlikely to be of local origin and the administration is likely to be more worried by the changing scene in the capital city than in the local town hall. As a result, peculiarly local questions of health, environment, resources and stimulation of enterprise are frequently passed over; besides, scientists are rewarded more by fame than fortune, and you don't get many people receiving wide acclaim for solving a problem at the local quarry or sewage works. There seems to be a whole range of scientific questions on this small scale needing small institutions to initiate them.

But, some will argue, if we are weak at the small scale, we are at least capable of operating, when needed, at the supranational level. Look at CERN IPOD, ESA, ILL; all institutions which work quite well on an international basis. Certainly scientists, when the financial pressure is on, find little difficulty in sinking national differences. This is hardly surprising since scientific knowledge, of necessity, transcends national frontiers. But what is surprising is that this great international spirit has still made precious little impact at the science policy level. One example would be in the field of medical research. Every developed country must be seen to be funding a coherent programme to fight cancer just as it must have its own airline. The health problems of the developing world, arguably much more pressing than those of the developed world, receive a few per cent of our attention and yet we know full well that developing countries are unlikely to have the resources to support adequate research themselves.

There have, of course, been tentative efforts towards regional science policies and talk by individuals of something resembling a global science policy, but as yet the power and pride of nations has not allowed much progress along a direction which is going to cut across a lot of autonomies and cosy relationships. Maybe pressure in this direction will eventually come from the financial problems of supporting extensive national scientific programmes. One would hope, however, that pressure might come from scientists themselves for international decision-making and international programmes over a very wide range of disciplines.

Daniel Bell's challenge is this: to ensure, as knowledge becomes the major resource, that it is sought in the areas where there is greatest need and is distributed fairly and rapidly. We would do well to ponder whether our present institutions are best organised for this task. □

A fair exchange?

Philip Hanson assesses the balance in the East–West transfer of technology

THE technological relations between the West and the Soviet bloc are curious. The United States and the Soviet Union spend huge sums on military R&D, primarily to maintain their abilities to blow one another to pieces. Yet at the same time Western businessmen are eagerly selling know-how and high-technology products to the USSR and Eastern Europe; and there is also a certain commercial flow of technology—of more modest dimensions—from East to West.

These transactions, of course, are in principle restricted by strategic embargoes to non-military purposes; yet the technologies transferred quite often originate from military R&D. In any case the civilian–military distinction is somewhat artificial: in the long run any new technology that makes the civilian economy more productive makes it easier to enlarge the resources allocated to the military. And even if there were no military considerations, economic competition between communist and capitalist countries is part of their general competition for power and influence, and so much technical assistance among competitors—even at a price—is at first sight rather odd. Altogether it is not surprising that East–West technology transfer is politically controversial.

The recent growth of Soviet–US trade, in particular, has prompted economists to look more closely than before at East–West technological relations. They have focused, naturally enough on commercial transactions. Obviously there are many ways in which knowledge about new products and processes travels from West to East without any commercial exchange, but these are not discussed much because most of them are not amenable to control by governments. The screening of Western technical literature by Soviet specialists, for example, and the gleaning of information from visits and conferences are beyond the influence of all but the most provocative action by governments.

East–West trade, however, provides a number of channels of technology transfer: notably, the sale of products embodying new technology; turnkey projects; licencing; know-how sales; and technical assistance and training. Some of these transactions simply provide cost-saving machinery and other products (for example wide-diameter pipe for gas pipelines) without transmitting the know-how to make the product in question. Other transactions, however, such as licence deals with technical assistance, or joint design work, may transfer such capabilities.

An interesting example is the Pullman-Swindell contribution to the huge foundry complex at the Soviet Kama River lorry works. Over a period of three years a total of more than 150 Soviet engineers worked with Pullman-Swindell on the detailed design and equipment ordering. The knowledge they acquired must have been considerable. How far it would enable the Russians to repeat the exercise for themselves probably depends on the extent to which these particular engineers can be kept together as a design team.

Most Western governments subsidise export credit as they compete against one another to promote exports and they thus ease the terms on which technology is transferred. Is this really in the interests of the West as a whole? Would it be wiser not to encourage such transfers, or even to restrict them? What is or is not wise in this context is largely a matter of political judgment: in other words, nobody really knows. The economics of East–West technology transfer, however, are more susceptible to measurement, and a good deal of measurement has accordingly been going on. The aim is to quantify the economic costs and benefits to Western and Soviet-bloc countries of transactions by which technology is transferred.

The starting point is the well established fact that in most fields Soviet and East European civilian production lags technically well behind that of the West even though these countries maintain large R&D establishments and are strong in many areas of basic research. Heavy military priorities, semi-isolation from Western technology and the lack of competitive pressures and incentives, however, have resulted in a generally poor performance in the creation and diffusion of new technologies. They therefore stand to gain a good deal from the acquisition of Western know-how.

Clearly Western firms also gain from selling this know-how. A recent survey of 168 US firms selling to the USSR found—in contrast to what some economists had predicted—that about three-quarters of them considered their activities to be profitable. The position of West European firms, who have had more experience of dealing with the Russians, is probably more favourable.

Novosti

West–East: Fiat's USSR showroom

The transfer that is going on, whether by means of product or of know-how sales, is predominantly of proven technology. In electronics, for example, Western firms quite often sell their latest products or the know-how to manufacture their less advanced products, but they seldom transfer the know-how to manufacture their latest products—let alone those currently under development. There is also, in the case of the Soviet Union, evidence that absorption and utilisation of imported technology is slow by Western standards. As a result, there is so far no very obvious narrowing of East–West technology gaps as a result of transfer.

Western firms, in other words, have not gone into Eastern markets in order to establish Eastern competitors for themselves. It is rather odd that anyone should ever have expected them to. Since they could not set up wholly- or majority-owned subsidiaries in any Comecon country, they have mostly been careful to hand over technology in measured doses: in products, in licence deals subject to market restrictions, and so on. More than a hundred companies, mostly big multinationals, have signed technological cooperation agreements with the Soviet State Committee for Science and Technology, but exchanges of information under many of these agreements have been minimal.

Production benefit

There is a good deal more, however, to the economics of East–West technology transfer than the question of its commercial profitability. Much of the debate in the West concerns the impact of imported Western technology on Soviet production, and this raises some quite different questions. To begin with, there is the question whether imports of Western technology are really of more than marginal importance to the Soviet economy. The USSR has traditionally been highly self-sufficient. Only a very small percentage of its consumption and investment needs are met by imports. Less than half of these imports, moreover, have been from the West, and of this, capital goods—the main vehicle of international technology transfer—have generally comprised about a third. This means that in 1976, for example, imported Western machinery was almost certainly not more than 6% by value of total machinery installed. (The large differences between Soviet domestic prices and the prices of imports make precise comparison impossible.)

At first sight, this suggests that imported Western technology cannot have more than a very minor effect on Soviet output. If the growth of production depends on the growth of the labour force, the growth of the capital stock and technical change, then the technical change embodied in a very tiny part of the increment in the capital stock must surely make only a tiny contribution to that growth.

This need not follow, however, if the technology embodied in the imported machinery has significant indirect, as well as direct, effects. The direct effect of the imported technology is the extra output attributable to it, over and above what would have been produced with the same resources of capital and labour with the technologies already in use inside the country. But this same technology will also have indirect effects insofar as it is successfully diffused (for example by building Soviet machinery to the same design) and insofar as it enables improved producer goods (such as compound fertilisers) to be made which themselves raise productivity in other lines of production.

East–West: exporting machine tools

NOVOSTI

Soviet machinery and know-how imports have been strongly concentrated in certain fields: the main recipients have been the chemical industry, the motor industry, computerisation, shipping, and oil and gas pipeline transport. The planners have identified areas where there was a considerable technology lag: in other words, areas where the direct and indirect impact of technology would be considerable. The production of fertilisers and pesticides is an example: the backwardness of both the Soviet chemical industry and Soviet agriculture promised high returns to hard-currency spending on imported technology.

Some recent estimates suggest that the returns have indeed been high. One tentative estimate for the mineral fertiliser industry is that by 1975 the technology embodied in about $2,000 million worth of installed Western equipment was yielding, directly and indirectly, some $4,000 million worth of extra agricultural output per annum, over and above what the same resources would have produced in the absence of the imported technology. Part of the gain came from the diffusion of Western phosphoric acid and compound fertiliser technology to Soviet built plants.

A global estimate has been derived from an econometric model of the Soviet economy. The conclusion in this case was that, of an overall increase in Soviet industrial output of 32.1% be-between 1968 and 1973, 2.5% could be attributed to an acceleration of the import of Western machinery over that period. The acceleration was such that the stock of installed Western machinery was about a fifth higher in 1973 than it would have been if the rate of growth of imports had remained unchanged. Like the estimate for the mineral fertiliser industry, this entails a very high rate of return.

On the other side of the scale, the contribution of East–West technology transfer to Western GNP is very small indeed. The Soviet Union has probably made slightly over 200 licence sales to Western firms in recent years, mostly unaccompanied by machinery, and often requiring development and adaptation in the West. And the employment associated with Western capital-goods sales to the Soviet bloc is probably less than 0.5% of total employment in most OECD countries.

According to the conventional wisdom, Western governments should not worry unduly about all this because the Soviet economic system is relatively poor at using and diffusing new technology, and this fundamental lack of technological dynamism will keep the level of Soviet civilian technology generally below that of the West, even if the import of Western technology and know-how continues to grow strongly.

One way street

This may well be so. But if the two estimates just described are anywhere near correct they put this conventional wisdom in a somewhat changed perspective. They suggest that, while the Soviet economic system may be slower than Western economies in using and diffusing new technologies, it nonetheless does get a fair mileage out of imported technology. Where there is a particularly large backlog to be exploited, the impact on production can be dramatic.

This means that those who see East–West technology transfer as a 'one-way street', in which the benefits go mainly from West to East, have a serious case. It may be true that imported Western technology is not enabling the USSR to catch up and overtake the West in areas of advanced technology, but it is probably making a significant contribution to Soviet productivity levels, and thus reducing the pressure on Soviet policymakers to divert resources from military to civilian purposes.

Similarly, the firms selling the technology are no doubt doing so on commercially acceptable terms. On the other hand they are generally competing with one another to extract extra revenue from products and processes whose development costs have already been written off; they are therefore unlikely to charge prices that would come close to reflecting either the cost to the Soviet-bloc purchaser of replicating the development work for himself or his gains in output from using the technology.

The balance of economic advantage, then, in East–West trade in machinery and know-how seems to be strongly in the Soviet bloc's favour. From a conventional Western point of view this is not a welcome conclusion. Further evidence might possibly alter it, or it might be made more palatable by clear indications that the growth of East–West trade was linked with political advantage for the West. If not, a rather awkward question arises: is there anything much that Western governments can do about it? ☐

USA

After the carrot, the stick

Colin Norman reports from Washington on the moves to introduce legislation to control recombinant DNA research in the United States

JUST two years ago, at the now famous Asilomar Conference, a group of scientists was discussing a set of proposed guidelines for experiments involving the powerful new recombinant DNA genetic engineering technology Joshua, Lederberg, a Nobel Prizewinner from Stanford who had been sounding ominous warnings about threats to free scientific inquiry, gloomily told his colleagues that there was "a graver likelihood of (these proposals) crystallising into legislation than some of us would like to think" That likelihood is now a virtual certainty.

Last week, the health subcommittee of the House of Representatives held three days of intense public hearings to examine a number of bills, including one proposed by the subcommittee chairman Paul Rogers, which seek to regulate all recombinant DNA experiments in the United States. Next week, the House subcommittee on Science, Research and Technology will begin its own set of hearings. On April 6, the Senate health subcommittee, chaired by Senator Edward Kennedy, will hold a hearing to discuss various legislative proposals already introduced into the Senate, and Kennedy will probably subsequently offer a bill of his own. And legislation which will soon be proposed by the Carter Administration is now taking shape (see below)

Thus, what Lederberg correctly perceived as an inexorable march toward federal legislation is now entering the home stretch It will take several weeks, perhaps months, for a final bill to emerge from Congress, however, and the debate is likely to turn on a relatively small number of issues.

First, it should be noted that Congress is unlikely to try to rewrite the guidelines issued last year by the National Institutes of Health (NIH). Though it is possible that some legislators will offer proposals to ban the research entirely—Representative Richard Ottinger said at last week's hearings, for example, that he is considering offering a bill declaring a moratorium and calling for an international meeting to develop a better understanding of the hazards—it is unlikely that such a move would succeed.

The most probable outcome is that Congress will direct the Secretary of Health, Education and Welfare (HEW) to develop regulations based on the NIH guidelines Both the Rogers bill and the Administration's draft bill take that approach, and Kennedy said in a statement last week that "we must assure sufficient and meaningful involvement of laymen and the general public in the formulation of regulations by the Secretary", thus indicating that he is likely to support that approach as well.

A second point to note is that the final regulations will apply equally to research supported by public and private funds, and that the legislation will establish a mechanism by which the controls can be enforced. Those two elements are missing from the NIH guidelines, and the need to extend and enforce the guidelines is largely responsible for the momentum now behind the development of federal legislation

The coming Congressional debate is thus likely to centre on four areas:

- **The extent to which the federal regulations will override state and local controls.** Many scientists who were once opposed to federal legislation now support it because several state and local governments, led by the City of Cambridge, are developing their own controls on recombinant DNA experiments, thus raising the possibility that a patchwork of regulations of varying strictness will be adopted throughout the United States Most scientists are consequently hoping that federal regulations will specifically prohibit local governments from setting their own controls on the research.

The Administration's draft bill would

A committee of government officials, representing 16 federal agencies, last week urged the Carter Administration to draft legislation to control all recombinant DNA research in the United States, and the committee sketched out the chief elements which it believes should be included in such a bill. As soon as the committee's report landed on his desk, the Secretary of Health, Education and Welfare (HEW), Joseph A. Califano, announced that his department would promptly transcribe the recommendations into formal legislation, noting that "such a measure is necessary not just to safeguard the public but also to assure the continuation of basic research in this vital scientific area".

The bill is expected to be ready early in April, when it will be submitted to Congress with an endorsement from the White House. It is likely to be particularly influential as Congress grapples during the next few weeks with the complex problem of how recombinant DNA research should be regulated.

The inte-agency committee, chaired by Donald Fredrickson, Director of the National Institutes of Health (NIH), began last November to seek ways to extend NIH's own recombinant DNA guidelines to cover experiments supported by other government agencies and by private industry. Though other agencies have since adopted the NIH guidelines, the committee decided that new legislation is needed to ensure compliance by everybody conducting recombinant DNA experiments in the USA

The committee consequently recommended that the Administration's bill should contain the following provisions. The Secretary of HEW should issue regulations based on the NIH guidelines, "with such clarifications and modifications as the Secretary determines to be necessary" All recombinant DNA experiments should be conducted at facilities licenced by HEW, the licence being issued only when the Secretary is satisfied that the facility will be operated in accordance with the regulations. Researchers would have to register their experiments with HEW. The committee suggests, however, that the Secretary could exempt from licencing and registration requirements "categories of activities which he determines pose no unreasonable risk to health or the environment"

To ensure that the regulations are being followed, HEW would have the authority to inspect facilities, conduct environmental and health monitoring, and require that reports and records be kept. The Secretary would have power to halt experiments if necessary, and violations of the regulations could incur loss of a facility's licence. In the event of injury to people or the environment, actions and damages would fall under state and local laws.

The committee suggests that all reports submitted to HEW by experimenters and officials in research facilities should be made available to the public on request, except for information likely to cause loss of proprietary rights Before information is released, researchers would be able to identify material which they believe should be kept confidential, but the final decision on disclosure should rest with the Secretary of HEW.

In what may turn out to be one of its most controversial recommendations, the committee suggests that federal legislation should specifically pre-empt all state and local regulations regarding recombinant DNA research The only exception would be if a state passes a law imposing requirements identical to those contained in the federal legislation, the Secretary of HEW could enter into an agreement with the state to carry out the inspection, monitoring and enforcement responsibilities. In other words, such a clause would rule out the setting of state and local controls of varying stringency.

Finally, the committee recommends that the legislation should contain provisions protecting the rights of employees who blow the whistle on their superiors, and it also suggests that the legislation should lapse after five years unless further action is taken by the Congress indeed pre-empt local moves, though it would allow the Secretary of HEW to enter into agreements with state governments under which local agencies would enforce the federal regulations. The Rogers bill, however, would allow the Secretary of HEW to approve state regulations which are at least as strict as the federal controls, and Kennedy said last week that "we must carefully assess the wisdom of totally pre-empting state and local laws regulating the recombinant DNA research and applications given our concern to assure the involvement of the general public in these issues".

The crux of the issue is how the federal government can ensure the adoption of uniform regulations without throttling public debate and without cutting off legitimate community interest in what universities are up to.

- **The nature of registration and licencing schemes.** It is likely that the final version of the legislation will establish a mechanism through which researchers or research facilities would be licenced and research projects would be registered with the federal government. There is a significant difference in approach between the Administration's draft bill and the Rogers bill, however, and it is not clear which approach will prevail.

The Administration's draft bill, in short, would require that facilities housing recombinant DNA experiments be licenced by HEW and that individual research projects would simply have to be registered with HEW. The Rogers bill, on the other hand, would require researchers themselves to obtain licences from HEW before embarking on any recombinant DNA project, and the licence application would specify the nature of the project and the safeguards to be employed. The difference between the two approaches represents a very significant difference in the focus of control and the complexity of the licencing process. Kennedy has so far made no statement on that aspect of the legislation.

- **The extent to which proprietary information can be protected from public disclosure.** There is a clash of interests between the need on the one hand to provide full public information on recombinant DNA experiments and the need on the other hand to protect proprietary information from public disclosure. That dichotomy is sure to generate a good deal of Congressional debate. The Administration's draft bill and the Rogers bill deal with public disclosure in slightly different ways, though both leave to the Secretary of HEW the ultimate decision on what information should be made public. The Rogers bill essentially requires the Secretary of HEW to publish in the *Federal Register* details of research projects for which he has issued licences, though he would simply exempt from disclosure proprietary information. The bill under consideration by the Administration, however, would require the Secretary of HEW to make information public only on request and after the researcher involved is given a chance to object if he believes that disclosure would jeopardise commercial interests.

- **The nature of sanctions if violations are discovered.** It is likely that the legislation which will eventually emerge from Congress will empower HEW to inspect facilities, and require reports, health monitoring and so on. The legislation is likely to give the Secretary of HEW the power to revoke licences if violations of the regulations are discovered, and he would also be able to halt projects deemed to present an imminent hazard. As for the question of liability, the Administration's draft bill would leave that up to state and local laws, while the Rogers bill would allow imposition of a $1,000-per-day fine for each violation.

Those areas are likely to be the chief focus of discussion in the next few weeks as Congress goes through the unprecedented process of setting federal regulations on an area of basic science. One thing is already clear from the public debate so far, however. As NIH Director Donald Fredrickson put it during last week's hearing: "biomedical research is entering a new era in its relationship to society. It is passing from an extended period of relative privacy and autonomy to an engagement with new ethical, legal, and social imperatives under concerned public scrutiny". ☐

NIH grants: OK, but . . .

After a two-year study of the system used by the National Institutes of Health (NIH) to parcel out more than $1,400 million a year in research grants, an internal NIH committee has concluded that the system is working well, but would benefit from a few changes.

NIH now handles about 15,000 grant applications a year, and funds less than a third of them. They are reviewed first by a study group consisting of a number of scientists working in related fields, which rates the proposal according to its scientific merit and which takes into account such considerations as the track record of the applicant. The proposal, together with the study group's rating, is then passed along to the advisory council of the Institute to which the application has been referred. The council goes into such matters as whether the proposal fits in with the priorities of the Institute, and it recommends whether or not the grant proposal should be funded. The final decision is made by NIH officials. Clearly, the most influential stage of the review is the initial evaluation of the study group.

At present, study groups meet behind closed doors and their recommendations are exempt from general public disclosure. The committee has recommended that the groups continue to deliberate in private, but it has suggested that the groups' conclusions and recommendations routinely be communicated to grant applicants as soon as the Institute's Advisory Committee has completed its review.

On the question of confidentiality, the committee has also expressed concern about the fact that grant proposals, once they are funded, must be made available to the public, on request, under the Freedom of Information Act. The committee urges passage of legislation protecting grant proposals from public disclosure.

As for the support of unorthodox research, some concern has been expressed that the peer review system favours traditional, conservative research at the expense of creative, unorthodox research. The committee therefore suggests that applicants identify innovative aspects of their research proposals. It also suggests that the study groups prepare a statement pointing out the innovative aspects of a grant application.

Finally, the committee recommends that a formal appeals system be established in NIH through which applicants can appeal the assignment of their proposals. It suggests that an ombudsman be appointed to adjudicate disputes over the handling of grant proposals, and that a Permanent Grants Peer Review Appeals Board be established under the chairmanship of the ombudsman.

The committee's recommendations are now being considered by the NIH Director, Donald Fredrickson. He is expected to endorse most of them.

Colin Norman

EUROPE

First meeting

THE problem of disclosure of information emerged last week as the most immediate obstacle to progress in formulating European guidelines for recombinant DNA research when representatives of bodies in some 15 European countries concerned with its regulation met in Strasbourg under the European Science Foundation's wing.

The meeting, the first of the newly established European Committee on Recombinant DNA, was from all accounts very useful and friendly but far too short to allow adequate discussion of a heavy agenda. The disclosure issue concerned the details which need to be revealed about particular projects in order that guidelines might be formulated and containment procedures applied without the applicant surrendering scientific or commercial advantage.

The simple origin of the problem is the recommendations of the committee's predecessor. This concluded last year that the recommendations and code of practice of the British Williams report should be adopted as guidelines for recombinant DNA research in Europe. The difficulties arise because those recommendations are general rather than specific, emphasise physical more than biological containment, and operate in a country where agreed standards of confidence obtain and certain patent laws operate.

Since only a body of case law can fill in the grey areas created by the lack of specificity, the argument goes, access to full details of particular cases becomes necessary for everyone using the guidelines, particularly where biological containment allows a drop in the level of physical containment. The trouble is, in Britain disclosure of such detail apparently means forfeiting the right to apply for a patent, and the hard-to-win cooperation of such companies as ICI with Britain's Genetic Manipulation Advisory Group (GMAG) must be on the understanding that revelations to it will not constitute disclosure.

Whether that means that without full disclosure the Williams guidelines could not operate fairly is unclear, but it is apparent that Britain's patent laws, interpreted in this way, could create a problem nationally and certainly internationally. The position is different in the United States, where application for a patent can be filed up to 12 months following disclosure.

In Strasbourg the French and Swedish representatives urged full disclosure, and the representative of Britain's GMAG was not in a position to agree. That means that answers are needed on the precise meaning of Britain's patent laws as they relate to recombinant DNA research before the next meeting expected in September.

No one seems to doubt that there should be a full exchange of information for any European guidelines to work properly. But the potential economic rewards of the work (the bad experience of penicillin is not lost in Britain) are also recognised, and if industry is to be incorporated in the whole scheme without resort to legislation, it may be at the price of not having full disclosure. In that case, the idea of using paradigmatic cases will gather support.

BRITAIN

Sea-bed disposal: safe after all?

An optimistic assessment of the radiological consequences of disposing of solid high-level radioactive waste on the ocean floor is published this week. Chris Sherwell reports

IMAGINE it is the year 2010. The world's nuclear power programme, consisting entirely of light water reactors, had an installed electrical generating capacity ten years earlier of 2,500 GW. The high-level waste produced by that programme has since been cooling in ponds at a reprocessing site, and has now been glassified and put into stainless steel cylinders with 'waste oxide incorporation'. The cylinders—all 72,000 of them—are about to be dumped on the floor of the North Atlantic, in one operation. What will happen over the next 1,000 million years?

An attempt to answer that question is contained in a report out this week from the National Radiological Protection Board (NRPB)* and prepared for British Nuclear Fuels Ltd (BNFL). The subject is especially controversial at the moment in Britain where, apart from the decisions being sought on the choice of the next generation reactor and on the commitment to the fast breeder, the matters of oxide fuel reprocessing and of high-level waste disposal remain unresolved issues.

Just last week, for example, the UK Atomic Energy Authority (UKAEA) attached great importance to the words of Dr Frank Feates, head of Harwell's Environmental Safety Group, at a public meeting in Scotland. The search now being conducted was not for dumping grounds in any particular area, he said; it was to see if unfissured granite, no matter where it was, was a safe structure for high-level waste disposal.

The idea of underground burial, which is being investigated in other countries too and focuses on salt and clay as well as granite, is only one of three options. The others are burial under the ocean floor and placement on the ocean floor, and it is the consequences of the latter alone which the NRPB study examines, even though the London Convention of 1972, which came into force in 1975, expressly forbids such disposal—a point the study mentions in an appendix.

The report endeavours to model the ways in which material deposited on the ocean floor will re-enter man's immediate environment, especially via his food. The principal route of return it uses is via dispersion in the deep ocean, physical transport to the productive surface layers, incorporation in marine food chains and the consumption of contaminated seafood, but it also considers radiation doses arising from contamination of beach sediments.

Although the report emphasises that only broad conclusions should be drawn, it states that "no overriding reason connected with radiological protection considerations has been identified which would preclude the disposal of suitably conditioned high-level waste on the ocean floor". Other points:

- All the vitrified waste may be expected to be dissolved in about 3,500 years. The heat generated by the wastes would not give rise to "any significant vertical transport mechanism". The amount of activity removed from the water by adsorption onto sediments will not be the major fraction of the total amount released, and will not significantly deplete the quantity of activity in the water, for 10^5–10^6 years.
- Assessments, for each of the many nuclides involved, of their changing concentrations over time in surface and deeper waters, and of how these are take up by plankton, molluscs, crustacea, fish and eventually man, show the relative importance of different routes. The ratio of intake to the maximum permissible annual intake (I/MPAI) attains its highest value for consumption of deep-ocean fish or plankton (neither of which routes currently exist) at times of either 50–100 years or 500–2,000 years. The ratio is 10^{-2}; for surface fish, the order is 10^{-4}; other ratios are below 10^{-5}.
- The largest annual collective dose is due to consumption of surface fish (the only intake route actually established), at about 4×10^4 man rems at 50 years from ^{137}Cs and ^{90}Sr taken together. Collective doses at longer times will be of the order of 10^2–10^3 man rems per year. The figures would be larger if plankton was established as a major direct food source.
- Predictions of nuclide levels in the sea water do not exceed the level of the nuclides known to be present in sea-water naturally or through fall-out.

The study emphasises that different conclusions might be reached if the waste was separable into short- and long-lived fractions, if a different composition (or even monolithic) glass was available, if better containment materials than steel were used, or if additional barriers, including even the sediment itself, were employed.

---

*P. D. Grimwood and G. A. M. Webb, *Assessment of the Radiological Protection Aspects of Disposal of High Level Waste on the Ocean Floor.* **(NRPB-R48, HMSO, 50p).**

● Conservation is one of the strongest refrains in the UK Department of Energy's (DEN) efforts to produce an orchestrated energy policy. Straightforward measures like fuel pricing policy and speed restrictions have been buttressed by various schemes like the Save It campaign, the Industrial Energy Thrift Scheme, the Energy Audit Scheme and the Energy Survey Scheme; a recent report on Energy for Industry from Cambridge Information and Research Services has emphasised the importance of conservation in any future strategy; a DEN report on energy elasticities published last week speaks of the savings to the balance of payments through cutbacks in consumption; ministers—last week it was Peter Shore, the Environment Secretary—regularly stress the importance of conservation. And on the international front Britain is now taking part in two of four R&D programmes on conservation through the Paris-based International Energy Agency.

To some it is obvious, to others exotic, but one of the more ambitious schemes mentioned in Britain to encourage conservation has now received an official judgment. It comes from a working party of a special group set up under the aegis of the DEN's Advisory Council on Research and Development (ACORD). The group is the Combined Heat and Power Group and the working party's focus was its domestic application—that is, district heating. The group's main report, which is unlikely to be out this year, will cover industrial applications.

No one has doubted that changing the operation of a conventional power station to produce vast quantities of hot water but less electricity can allow substantial energy conservation. The problem is whether it can be done economically, and last week's report, *District heating combined with electricity generation in the United Kingdom* (HMSO, £3.75), gives a carefully quantified response.

The difficulties in making calculations are enormous. One reason is that it would take some 15 years to develop a heat load suitable for connection to a combined heat and power (CHP) plant. Moreover, a new and expensive system of lines would be necessary to distribute heat to consumers; and even then a great deal depends both on the demand from them (what will their standard of living be?) and their distance from the power station (what planning policies will apply?). The future cost and availability of alternative fuels and the development of alternative technologies such as heat pumps is also important. So, although the savings in energy are clear and the engineering involved is established, the assumptions that are made when using standard discounted cash flow techniques are critical.

For all this, the working party concludes that with present fuel prices and fuel availability, and with the test discount rate used by the Treasury of 10%, there is no economic incentive to introduce CHP and district heating save for limited high density areas. CHP could be more economic with a reduced discount rate, however, or if fuel prices rose, or both. Fuel saving would amount to 20 mtce compared with the 1972 fuel consumption pattern if CHP plant supplied 25% of the population.

At the turn of the century, on the other hand, when oil and gas will be scarce and expensive, CHP and district heating would be economically attractive compared with direct electric heating or with substitute natural gas produced from coal. About 25 GW less capacity of nuclear power stations would be required compared with direct electric heating if CHP plant supplied 25% of the population, and fuel savings would be somewhere between 7 and 30 mtce.

But if a significant amount of district heating network is to be installed by the first decade of the next century, the working party says, it is necessary to start now, and that means selecting a pilot city for conversion; strong government initiatives are essential if CHP is to develop significantly. Last week, however, Dr John Cunningham, the minister with responsibility for conservation, and Dr Walter Marshall, chief scientist at the DEN, were both at pains to emphasise the political sensitivity of embarking on such a course without proper consideration of the people affected.

● The trouble with the report out this week from the Wellcome Trust covering the 1974–76 period is that there is no indication of the price levels to which its figures refer. Thus the Trust says it allocated over £8.5 million to research in human and animal medicine, which is some 91% higher than the nearly £4.5 million it allocated in the previous 1972–74 period. Inflation was such that £1.35 million of the increase went to meet salary increases for people the trust supports. And it expects an income of £5½ million in 1976–77. But are these and other figures at 1974 or 1976 prices? Answer: the figures are at prices at the time referred to.

The present strength of Wellcome, which is the largest endowed charitable trust supporting medical research in the United Kingdom, is, according to the report, "the result of the expansion of the international pharmaceutical company, the Wellcome Foundation Limited." For the 1976–77 allocation it has had to make a choice between deliberate support of special objectives and *ad hoc* selection from the applications the trustees received. It has opted for a more selective policy for 1977 focusing on such relatively neglected areas as ophthalmic medicine, the vascular system of the human brain in relation to disease, the metabolic effects of infection and the pathology of trauma. There is no increase in funds for projects submitted for *ad hoc* consideration.

● Participants in this weekend's conference in Aberdeen on the changing sea-bird populations of the North Atlantic will gather just five weeks after the latest serious incident involving oil pollution. To the concern of many, at least 700 oiled birds, and possibly twice that number, came ashore near the sites of Yorkshire's cliff-nesting seabird colonies. Faced with the argument that official maps showed no vulnerable bird concentration in the area for that time of year, the Royal Society for the Protection of Birds had to organise its own aerial survey to find and size the oil slick responsible; and the RSPCA actually destroyed some live oiled birds instead of sending them to a new and costly rehabilitation centre. The adequacy of existing maps and the criteria for bird rehabilitation remain important issues to ornithologists. With the subject of pollution on the conference agenda, there could be a bit of a flap in Aberdeen.

Chris Sherwell

Quality control

Vera Rich writes on the reorganisation of higher degrees in the Soviet Union

THE Soviet media are at present conducting a major campaign eulogising Soviet achievements, as part of the build-up to the forthcoming 60th anniversary of the October Revolution. The achievements of Soviet science feature conspicuously in this campaign. In one field, however, there is little cause for rejoicing, and the press notices strike a critical note—the training of the next generation of scientists and the awarding of higher degrees.

In the Soviet Union, the degrees of Candidate (roughly equivalent to a PhD) and Doctor of Science are awarded not by the universities, but by a special body, the Higher Qualifications Commission (*Vysshaya Attestatsionnaya Kommissiya*, VAK) of the Ministry of Higher Education. At the beginning of 1976, new regulations for higher degrees came into force, setting new, higher standards and reorganising the structure of VAK. In its new form, VAK consists of a 'Plenum', a 'Presidium' and a 'College', with 34 'councils of experts' dealing with the principal lines of research, and 500 'specialist councils' for assessing degree theses, 150 of these councils being entitled to deal with doctorate theses.

Under the new regulations, a higher standard is demanded, both in the theses themselves and also in the official opponents against whom the theses must be defended. Postulants for a higher degree have, in addition, to fulfil certain non-academic requirements; according to Professor V. G. Kirillov-Ugryumov, the Chairman of VAK, they are expected to "combine a profound professional knowledge with a mastery of Marxist–Leninist theory and with the convictions of an active builder of communist society."

In spite of this emphasis on *partiinost'* (Party-mindedness), the changes were primarily intended to improve the standards of scientific manpower. The first year's work of the reorganised VAK has, however, failed to effect this improvement, and the overall picture suggests incompetence and inadequacy.

According to *Pravda*, a number of the degree councils have not been observing the proper procedure for the defence of theses and have been deliberately lowering their standards for reasons ranging from "bonds of friendship" to the "exploitation of official status" by the postulant. Twenty-one degree councils have been suspended as a result of such infringements. Nevertheless, during the year, almost 20% of doctoral theses were rejected by VAK.

Theses appear to be of a low standard because more than half the postulants come from industry, having carried out their research while working in jobs which may not necessarily be closely related to their academic work. This is a somewhat delicate matter to broach in the media; Soviet policy constantly urges a closer contact between research and industry, and even so eminent a body as the Siberian Branch of the Academy of Sciences of the USSR was recently censured for slackness in establishing and maintaining such contacts.

However, Moscow radio recently hinted at some of the difficulties facing the young graduate who goes straight into production and attempts, while working, to obtain a higher degree. Those who embark on such a course, suggested the commentator, should be "surrounded by care and attention". In plants where this had been done, working scientists had obtained degrees not only at the Candidate level but even at the Doctor level. Directors who failed to cherish in this way their ambitious young scientists "display shortsightedness and lack of foresight". The difficulties of combining research with a job, even a job in one's chosen field, were considerable, and accordingly, while in no way overtly criticising official policy, the commentator urged that special attention should be paid to ensuring that more young graduates gain their research experience in the most authoritative establishments.

The current Five-Year plan is aimed at increasing efficiency and quality in all sectors of production, including the higher education 'industry'. The reorganisation of VAK was but one aspect of this drive towards quality. The first results of the new system show that it is not easy to achieve higher standards simply by legislation. □

More give, more take

DR Mikhail Shtern was unexpectedly released last week from the labour camp where he was serving an eight-year sentence for allegedly accepting bribes. The official TASS statement on his release maintained that the sentence was "correct", but claimed that acting on considerations of socialist humanity, and in view of Dr Shtern's poor state of health, the Supreme Court of the Ukrainian SSR had decided to reduce the sentence to two years and nine-months—the term already served.

After his release, Dr Shtern told foreign reporters that he was "absolutely not guilty of anything", and that the accusations against him were made in reprisal for his sons' application to go to Israel. Dr Shtern's release followed a worldwide protest campaign which involved fifty Nobel Prize winners. A special tribunal to examine the Shtern case was scheduled to open in Amsterdam this week.

Dr Shtern's release, however, does not appear to augur a relaxation of pressure on the refusniks. In Moscow, Yosif Begun, an electrical engineer, is in prison awaiting charges of "parasitism", that is, being without visible means of support—a charge which has not been brought against any refusnik for some time. On 15 March, the day after Shtern's release, Anatolii Shcharanskii, the mathematician who has acted as press agent for the Azbel' Seminar and is closely associated with the Moscow 'Helsinki monitoring group', was arrested while actually in the company of two Western journalists who were interviewing him about the Shtern case. Shcharanskii's family has been told that he may be accused of "crimes against the State", an accusation which could lead to a show trial.

Jewish activists in Moscow see the arrest of Shcharanskii as part of a growing campaign of repression against the refusniks. Although there have been recent attacks in the media on other dissidents too, the campaign against the Jews who simply wish to leave the Soviet Union is far more aggressive than that against the Russians, Ukrainians, Lithuanians and others who also urge change.

The anti-refusnik campaign has been particularly directed against the scientists and academics. Searches of unprecedented severity have taken place at the homes of several of them, resulting in the destruction of their books and the confiscation of all papers. At the time of his arrest Shcharanskii, together with Professor Aleksandr Lerner, a cyberneticist, and Vladimir Slepak, an engineer, were attempting to bring a libel suit against the government newspaper *Izvestiya*, which had accused them of spying for the CIA.

Vera Rich

COMECON

● The first meeting of the Heads of the Academies of Science of the Comecon countries took place last month in Moscow. All nine Comecon members were represented, and also Vietnam. Yugoslavia, however, which has a special relationship with Comecon in a number of fields, including science and technology, was not represented. The meeting consisted of an exchange of views on the development of cooperation in solving key problems of "the building of socialism and communism", and increasing the efficiency of scientific research and the implementation of research results in production—this last being the most pressing problem for R&D in all Comecon countries.

Examples of cooperation to date were discussed, including joint programmes for space research, earth sciences, physics, chemistry, and biology. Special attention was given to the role of the scientists in détente and the duty of scientists "recognising their responsibility before history" to use their influence in support of non-proliferation and disarmament. The scientists of Comecon, it was stated, are ready to unite their efforts with those of the scientists of all other countries to work on "major problems of concern to all mankind", such as energy, raw materials, environment, the rational use of ocean resources, and epidemiology. Suiting his tone to the occasion, Mr Brezhnev, in welcoming the delegates to a Kremlin reception, proposed a law of composition for scientific cooperation between socialist countries—individual efforts, he asserted, were not added but multiplied together.

● The recent Romanian earthquake has raised certain doubts concerning earthquake prediction. This is an important topic of research in the Soviet Union, and the countries of Eastern Europe have watched developments in the field closely. In 1976, a Soviet team produced a seismic map of the Balkans predicting probable epicentres for the next 100 years. It would seem, though, that the foretelling of natural disasters is a mixed blessing.

The suggestion of American seismologists that an earthquake of the same magnitude with its epicentre in Romania might be repeated within a few weeks was denounced on Bulgarian radio as "an act . . . beyond all bounds of the admissible and even of the inadmissible in inter-State and inter-human relations", being designed to "create a panic among ordinary people". Whether the Romanians coping stoically with the aftermath of the disaster were alarmed by the American predictions, or even had the opportunity to hear them, is a moot point; but in Yugoslavia considerable alarm was created in the Krusevac region by radio hams who predicted that an earthquake of even greater intensity was imminent.

The only predictions that have not been pilloried by the East European media have been the non-alarmist ones—that of the Institute of Geophysics of the Bulgarian Acadamy of Sciences, which announced comfortingly that the periodicity of an earthquake of this magnitude was of the order of 50 years, or that of Professor Bruce A. Bolt of the University of California who, after visiting the site of the Romanian earthquake, pronounced that present scientific methods do not allow one to say whether such a phenomenon might occur in the near future.

According to Dr Negmatullyaev, director of the Soviet Institute of Seismic-Resistant Construction and Seismology, who is at present working on earthquake prediction in Tadzhistan, current Soviet methods, using boreholes and gas-analysis, allow earthquakes to be forecast with the greatest degree of accuracy. Reactions to the Romanian disaster would suggest, however, that until prediction can be backed up with prevention, the publication of predictions may present a problem in public relations and media management.

Among the victims of the Romanian earthquake were Professor Florin Ciorascu, Corresponding-Member of the Romanian Academy of Sciences; Academician Paul Petrescu, a physicist; Professor Carli Marcu, a pharmacologist; and Professor Marin Lupu, Rector of the Bucharest Academy of Economic Sciences. Major scientific installations damaged included the National Physics Centre in Bucharest, the Faculties of Chemistry and Medicine at the university and an 'atomic centre'.

● Since the May 1974 visit to Britain of Academician Vladimir A. Kirillin, Chairman of the State Committee for Science and Technology of the USSR, when he declared that industrial fast-breeder generators would not be a practical possibility before the mid-1980s, Western commentators have from time to time suggested that long-range Comecon planning in nuclear power generation is committed to fast-breeders. Such speculations were recently revived at a press conference which Kirillin gave to the heads of foreign missions in Moscow. On this occasion, after referring to the successful operation of the pilot fast-breeder reactor at Shevchenko, Kirillin stated that such reactors would be in industrial use within the next ten years.

Such estimates, however, seem over-optimistic. The recent meeting of the Comecon Permanent Commission for the Peaceful Uses of Atomic Energy in Riga, which reviewed progress to date and approved future plans, paid special attention to the designing of 1,000 MW water-moderated water-cooled reactors. Since this is above the capacity of any reactor scheduled for production in the plans to 1980, any major changeover to fast breeders cannot be expected in the present planning period.

One of the major topics of discussion at the meeting of the Commission was specialisation by the member countries in the production of isotopes, instruments, and equipment for power generation. Yugoslavia, although not a member of Comecon, has a working arrangement by which she participates in a number of Comecon projects, including the Interatomenergi programme for the construction of nuclear power station equipment. Several engineering plants in Yugoslavia are already participating in this construction, including the Litostroj combine in Ljubljana. Litostroj has designed a special circular crane, to operate in complete isolation inside a reactor, to charge it with nuclear fuel and remove the waste products. The equipment is intended for power stations in the USSR; a recent report on Yugoslavia's energy resources and demands makes no mention of nuclear power, but stresses the importance of home-produced coal as the basis of the electrical generating industry.

Vera Rich

IN BRIEF

German nuclear problems

The domestic and international aspects of Germany's activity in the nuclear field have both come in for further dispute recently. Following the visit of the US deputy Secretary of State to Germany a fortnight ago, and the visit to Washington last week of Germany's Foreign Minister, the German position on its controversial nuclear deal with Brazil apparently remains one of determination to fulfil its obligations, in spite of US objections.

Domestic developments have proved less restrained. Violent demonstrations occurred at the weekend outside a nuclear plant in Lower Saxony; and news of a third court case on the construction of a nuclear plant, this time in northern Bavaria, followed the decision last week of an administrative court in Baden-Württemberg to withdraw the construction permit for a plant on grounds relating to safety. A Schleswig-Holstein court blocked construction of a plant at Brokdorf last month.

Press statement

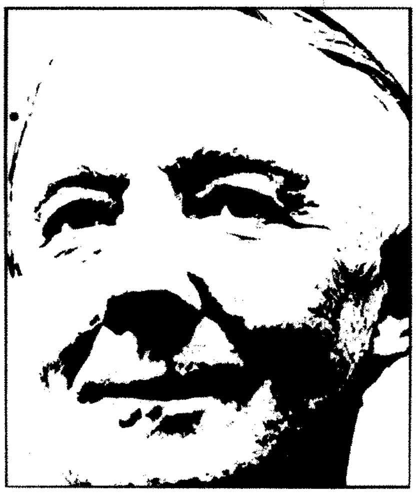
The long-awaited official announcement finally came late last week: Frank Press, Professor of Earth Sciences at MIT, has been named Director of the White House Office of Science and Technology Policy (OSTP) and science adviser to President Carter. The appointment must be confirmed by the Senate, but no problems are anticipated there. Press's appointment has been a certainty for the past month, but the official announcement was delayed by a lengthy series of security and other background checks which President Carter has insisted be made on top officials in his Administration. Press has been working at the White House, however, attending meetings of Carter's advisers and helping select candidates for other top research jobs in the government.

NSF budget change

In an unusual move, the House Committee on Science and Technology has restored some of the cuts in the budget request for the National Science Foundation (NSF) made by the subcommittee on Science, Research and Technology. The subcommittee had voted to hold NSF's budget increase for fiscal year 1978 to about 7% compared with the 11% boost requested by the Administration. The full committee has restored about half the cuts made by the sub-committee in NSF's basic research and Research Applied to National Needs (RANN) programmes, additions which would give NSF a 9% increase.

According to staff aides on the committee, the full committee took the unusual step of overturning the subcommittee's recommendations because of recent projections that the inflation rate will be higher than the subcommittee had assumed.

Fishing line



KENNETH MELLANBY

THE most impressive success story in conservation is the recovery of the population of the Antarctic fur seal, described by Nigel Bonner of the British Antarctic Survey in a recent *NERC News Journal*. Before 1791, when the first sealing expedition went to South Georgia, these animals existed in millions. By 1830 they were so scarce that the fur sealing industry stopped. However, they survived in small numbers, perhaps less than a hundred animals, and were officially protected by the British administration of South Georgia in 1907. Most zoologists thought this action was too late and that the species was doomed. But now estimates for 1976–77 suggest that there are over 300,000 and that the population has increased annually by at least 17% for the past 20 years. The seals should soon reach their former level of abundance.

One reason suggested for this phenomenally rapid increase is the ample food supply. Fur seals feed mainly on krill, the shrimp *Euphausia*. This is also the food of the whales which have been so severely reduced in numbers. Successful whale conservation could leave less food for seals. However it seems more likely that man will soon compete for krill, and this could affect both whales and seals. It is therefore interesting to assess the value of this new human food. Would the gain in human nutrition be sufficient to make it worth putting these marine mammals at risk?

The world catch of marine fish for 1974 was estimated at 60 million tonnes. Biologists believe that it would be possible to harvest almost as great a biomass of krill—at least 50 million tonnes per annum. This would seem at first to add greatly to the food resources available for the growing world population. The ocean's contribution to man's food is surprisingly small. Much of the fish is used to feed livestock and pets. When fed to farm animals, the wastage is considerable, and broiler fowls and pigs yield much less protein and energy than the fish supplied to their diet. Even when eaten by man, much of the carcass is wasted. Probably less than 30 million tonnes of actual fish flesh is eaten by humans each year. Even with the krill, the actual consumption would be unlikely to exceed 50 million tonnes. In terms of energy (calories or megajoules) the total world fish catch would satisfy some 30 million people—less than the annual increase in global population. Even the krill would be consumed by a few month's increase.

Of course, this calculation is, or should be, absurd. Fish is a rich source of high class protein, and the annual catch could supply the protein needs of a tenth of the world's population, and the krill could meet the demands of a further two hundred million individuals. Unfortunately, it is unlikely that it would do so. It is rare for fish to be eaten except by those whose diet already contains sufficient protein. Those who live on staples low in protein, including cassava, plantains and yams, seldom obtain much fish, and it is unlikely that they would benefit from krill. Fish would almost certainly go to increase the luxury eating of man and beast in the richer countries.

We should therefore be cautious before encouraging the exploitation of krill. We see that many of our traditional fisheries are overexploited, and may be destroyed unless internationally conserved. We are very ignorant about the interdependence of krill, seals, whales and man. As the oceans, in spite of overexploitation, are making such a trivial contribution to feeding the world's increasing population, we must realise that most of the food needed must be grown on dry land.

correspondence

Science with public appeal

SIR,—I think your criticism of the BBC's programme, *The Key to the Universe* (3 February, page 393) was unfair to say the least. Nigel Calder did not make any "fundamental mistakes", especially in underestimating the serious mindedness of the audience. Indeed his refreshing attitude encourages the public to take a greater interest in science—we would soon fall asleep (at least I would) if the programme was presented in the way you implied in the article. These two-hour programmes are occasional. they are not the same as *Horizon* and they add a new look to the debate.

I think you are making the fundamental error by assuming that "the uninitiated 99.9% of the audience can only have been thoroughly confused . . . ". I did not find the order in which the programme was presented at all confusing. Your leader writer should watch it again as a member of the public and not as a cynical critic.

G. MARKS

Harrogate, UK

SIR—In your editorial, "That was the weak force, that was" (3 February 1977), you make a strong criticism of Nigel Calder's two-hour BBC2 brainteaser, "The Key to the Universe." You ask, in effect, not only whether it was worth the resources devoted to it, but also whether it might not contribute to the further alienation of many people from science.

These are important questions to which we have no answer. In this regard the BBC fails us entirely. We are not told how much in financial terms such a two-hour programme costs; we do not know whether the key criterion of 'worth' may not be measured solely by audience ratings; and we are completely in the dark about the effect of such programmes on the general viewing audience. That Calder's book of the same title is high in the *Sunday Times* best-seller list tells us nothing about the TV programme except that it surely helps to sell the book.

The non-scientists with whom I watched the programme confessed that apart from the presentation of the 'black holes,' they were baffled. I found the jargon familiar, but I disagreed with some of Calder's emphases. I think he made too much of the tentative, of the as-yet unaccepted, as in Salam's exposition for example. In that sense, it was difficult to distinguish the 'real' from the 'unreal.'

I have said before that the populariser of science, as he functions today, cannot disseminate the subtle ideas of science; that these really cannot be understood without hard, disciplined effort. We need a research programme on this thesis. The BBC (and ITV) might consider funding that part of it concerned with the presentation of science on TV and radio. Such a proposal concerns the key question of what the presenters of science are really providing, not only in terms of good, entertaining viewing, but also in their contribution to general understanding *en route* to involving thep ublic in decision-making about the use and impact of science in everyday life.

Tidal energy

SIR—Your leading article (10 February 1977) refers to the 'severe defect' of the periodicity of the tides being not always in phase with the daily load cycle, but nearly 40% of our electrical energy is used for space and water heating where the 'defect' is not at all severe. The use of blocks of tidal energy produced in regular and predictable amounts, both in time and quantity, is now perfectly feasible in the British system, and as installed capacity increases (if indeed it does increase), will become easier rather than harder to absorb. This is without the addition of any further pumped-storage capacity.

The reasons why the French have not proceeded with the Iles de Chausey scheme have nothing to do with the foregoing point, since La Rance incorporates a pumped-storage capability to provide power capacity in phase with peak-demand—if that is what the operators require. (Incidentally La Rance is presently using peaking system energy to pump on those occasions when so doing produces more energy overall.) The reasons are both economic and oceanographic, since the inclusion of sophisticated pumped-storage facilites made La Rance so expensive as to discourage further investment in tidal energy, coupled with fears that a much larger scheme might have reduced the tidal range.

The defects of pumped-storage in estuarial schemes are primarily cost, since such facilities can be provided more cheaply on land (as at Ffestiniog or Dinorwic) or underground, and secondly because the important function of system spinning reserve is unavailable from a tidal pumped-storage plant without loss of available energy. The arguments are all developed in the technical literature and it behoves your leader writer to give it more than a cursory examination before committing himself to a particular solution.

The proposed Severn scheme your article describes is one of at least six proposals made in the last few years, all of which deserve examination in the light of system requirements. It will do the cause of tidal energy no good if a scientific journal of your reputation appears to be prejudging the solution to what is a most complex problem.

Geothermal electricity

SIR—Recent studies of potential UK geothermal heat sources (for example, Oxburgh *Nature* **262**, 526, 1976) have been virtually unanimous in stating that temperatures greater than 200 °C would be required from sources intended for electricity generation. A report produced by Patscentre International has shown that, contrary to this general view, it may well be possible to accept a much lower temperature limit. If it can be combined with a fossil-fuel source in an existing or purpose-built power station, geothermal heat in the temperature range of 100–200 °C could be economically used for electricity generation.

In modern steam plants most of the feedwater heat is supplied by low-

Correction

A bad telephone line helped to produce three errors in the article 'Give us a call, says NASA' (10 March, page 112). The Viking chief project scientist is Dr Gerald A. Soffen, not Dr Soffes; the Kioto meeting will be in the first week of April, not in June, and will be organised by the International Society for the Study of the Origin of Life; and the Tel Aviv meeting in June is the COSPAR and not the pulsar meeting. Sorry.

temperature steam from the turbines. However, this steam, which in a conventional station has been heated by a high-grade fossil fuel, is diverted from work-producing duties in the turbine. If low-grade geothermal heat is used for feedwater heating, the steam could be retained in the turbine, thus increasing both the work output and the cycle efficiency relative to the fossil fuel. The resulting capitalised fuel saving (for the normal rated output) can then be used to pay for the necessary geothermal plant. (I have discussed a similar use for low-grade waste heat in MHD power generation in *Energy Conversion* **8**, 177; 1968.) The amount of geothermal heat that would be usable in this system, which could be applied to either an existing or a purpose-built station, is no more than about 15% of the total heat input; that is, about 200 MW(t) could be accepted by a 500 MW(e) steam plant using geothermal heat at 125 °C. This would give a fossil-fuel saving of 5%.

An alternative purpose-built combined plant, in which the geothermal heat predominates, would use fossil fuel for superheating only. In this case, efficiencies in the region of 100% (relative to the fossil fuel) become possible. For example, 100 MW(e) output could be obtained from 100 MW(t) fossil fuel combined with 360 MW of geothermal heat at 185 °C. This method also has the advantage of low steam wetness, thus appreciably reducing turbine blade erosion, which could occur in a plant that is predominantly geothermal.

The cost benefit analysis proceeds as follows. The present saving on fossil fuel is determined from an annuity-type calculation, taking into account, among other factors, the current fuel cost, inflation of real cost of fuel, interest rate, plant life-time, and increased load factor allowed by increased efficiency. Thus a capital allowance (per kilowatt of geothermal power) is obtained which can be compared with estimated specific costs of geothermal plant for various conditions.

Results for a purpose-built plant based on a modern conventional power station illustrate the operation of the first system. With the plant situated on hot dry rock supplying feedwater heat at 125 °C, a fossil fuel cost of 9p a therm, and a load factor of 80%, the capitalised fuel saving over 20 years, with a basic interest rate of 10% a year, is £62 per kilowatt of geothermal power. This equals the (1974) cost of the associated geothermal plant (well-head equipment and so on) calculated from fairly conservative data supplied by the Energy Technology Support Unit (Harwell) for a site having a temperature gradient of 45 °C per km. For a similar station situated on an aquifer, the available cost of £62 per kW(gt) would pay for geothermal plant in the upper half of the range of calculated aquifer costs. Of course, the capitalised fuel saving increases with the fossil-fuel cost, the fuel inflation rate (in real terms), and the load factor. Figures for the second type of plant, using 185 °C geothermal heat, show that its unit electricity costs are comparable with those of conventional power stations.

The Patscentre study has shown that geothermal sites that coincide with, or are accessible to, fossil-fuel sources could be of special interest for electricity generation. For instance, the nearness of the Durham hot rocks (granite) to the Durham coal fields should be noted, and coastal sites on the Hampshire sedimentary basin could also be of interest.

Management courses

Sir,—I have long felt it appropriate that the likeness that accompanies Kenneth Mellanby's articles should be as black and white as the views he expresses! However, the truth about management courses for scientists may not be quite as black as his article (3 March, page 11) might suggest. Five years ago A. J. Lockwood and I started a course in research management (*R&D Management* **5**, 235–238; 1975) for heads of research sections at the Building Research Establishment. It has been held annually since then and now draws participants from a wide range of government research laboratories (both civil and defence). Those who attend appear to find it helpful.

The course was started because many section heads felt the need for some help with the management aspects of their work, a need that was understandably not met by the more general management courses that were then available—and it may be that Professor Mellanby's strictures were directed at such courses. Our courses are deliberately designed for those leading research teams Perhaps the secret of whatever success the courses have achieved lies in the very fact that we deliberately refrain from any attempt at 'training'. Rather, we try to make available to participants a wide range of conceptual material and practical experience on which they can draw for use in their own circumstances. More important still, we devote about half the course time to fostering, within a carefully thought out series of syndicate exercises, the exchange of the management experience that participants will have accumulated during their working lives. Just as scientists profit considerably from an exchange of their scientific experience, we have found that they can and do receive considerable benefit from an exchange of their (often unrecognised) management experience.

Competition 12.
A chair in bio-aeronautics has recently been established in the UK. Its occupant is an expert in crop spraying. £10 for the best real or fictitious professorial title. Entries by 20 April to Competition 12, *Nature.*

Competition 11. Readers' contributions offered humorous associations with the work of scientists. Thus: 'Faraday was incapacitated', and so on through a deluge of awful puns. Jim Watson, according to most competitors, had a guess-what in his neck. Two winners, one brief, one less so.

Brahe thought the paper by Copernicus revolutionary, but pointed out that his argument was essentially circular (M. C. Thorne, Harwell, UK).

On the first day Rutherford reported an immediate disintegration of the Symposium catalysed by Brønsted's acidic comments on Madame Curie's radiant attire. Drs Barnard and DeBakey were further disheartened when Van de Graaff generated a separate reaction from Schiff by referring to her attire as basically colourless. Bragg viewed things from another angle as did Roentgen who saw through it all Compton recoiled at the prospect of making any statement while Planck and deBroglie also went to some lengths not to make waves—an attitude that Moseley called uncharacteristic. Wegener asserted that if the rifts continued to grow things would drift further apart. As usual, Heisenberg was uncertain but Coulomb and Nobel were positive that such a charged situation was potentially explosive. Kelvin and Boyle advised that a cooling-off period might reduce the pressures that were building up Bell thus called on Hubble and Doppler to focus their attention on shifting the emphasis to a series of higher-level discussions as earlier suggested by Balmer and Lyman. Newton seconded the motion and, being short of time, Einstein tried to apply a constant and massive attempt to bring the entire matter to a close. The following day Watson and Crick happily reported that things were taking a turn for the better. (K. M. Towe, Smithsonian Institution, Washington, USA).

Molecular charmonium?

from Frank Close

A YEAR ago most high energy physicists were agreed that charmed particles must exist, the only problem was that nobody could find any. Then in a study of the debris produced in annihilation of electrons and positrons, charmed mesons called D (1.86 GeV in mass) and D^* (2 GeV) were at last found in the spring of 1976 (see *Nature* 262, 537). Once it was known what had to be looked for and where it could be found old data were studied again and new experiments performed. We now have the surprising result that sometimes too much charm is being found, specifically that when electrons and positrons annihilate at just above 4 GeV an anomalously large production of pairs of charmed D^* mesons is seen. What makes this so remarkable is that the energy of the colliding beams is only just sufficient to produce a pair of 2 GeV mass particles. It is as if the moment that the energy was sufficient to produce them, they just poured out. Why should this be so?

A group of workers at Harvard (de Rujula *et al. Phys. Rev. Lett.* 37, 398; 1976) had earlier suggested on statistical grounds that the relative production rates of $D^*\bar{D}^*$:DD^*:$D\bar{D}$ should be 7:4:1 (there are more degrees of freedom for high spin particles and so the spin 1 D^* is more readily produced than the spinless D). The observed rate of $D^*\bar{D}^*$ production is far in excess of this and so it seems that there is something in the underlying dynamics of the production process that is enhancing the D^* pairs.

When this discovery was reported at a seminar at Harvard, two groups of theorists suggested that charmed molecules might exist (de Rujula *et al. Phys Rev. Lett.* 38, 317; 1976; P. Cox *et al* Harvard preprint, 1976) Their idea was that in the electron–positron annihilation, in addition to resonances of charmed quarks and charmed antiquarks (like the ψ meson at 3.1 GeV mass) there might be found resonances of charmed mesons and their antiparticles. If such a $D^*\bar{D}^*$ resonance occurs at 4.03 GeV, then this could explain the copious production of D^* and $\bar{D}^*$ at this energy.

But critics say that this is tautology. To say that there is a $D^*\bar{D}^*$ resonance is simply equivalent to saying that the $D^*\bar{D}^*$ are produced more often than expected. Since no completely satisfactory mechanism has yet been given for producing such a resonance the copious production of D^* pairs has still not been explained. Supporters argue, however, that the idea can be tested and so has some merit. If energies away from 4.03 GeV are looked at the D^* should be less copiously produced.

Whether or not the idea is right it has suddenly gained wide attention in the high energy community although it is by no means new. Several papers have appeared during the past two years and been largely ignored. They have implied or explicitly suggested the existence of charmed molecules as the consequence of investigating the broader issue of the binding of quark states, and it is in connection with this broader issue that the above discoveries might turn out to be significant.

Multiquark hadrons

Mesons are formed when a quark (q) and an antiquark ($\bar{q}$) bind together with orbital angular momentum (L). The mass of the resulting meson can be estimated from the rough rule that each quark or antiquark contributes around 300 MeV and each unit of L-excitation gives around 500 MeV. The quark has spin 1/2 and so the quark and antiquark can spin parallel (spin 1) or antiparallel (spin 0). Then, just as in atomic physics, the spectrum has the form $^1S_0$, $^3S_1$; $^1P_1$, $^3P_{0,1,2}$ and so on, and a hyperfine splitting causes the singlet states to be lighter than the triplets (for example, the pion $^1S_0$ is lighter than the ρ $^3S_1$)

These rules mean that the lightest vector particles will be around 700 MeV since they are the $^3S_1q\bar{q}$ states. Of particular interest are the scalar states $^3P_0$. From our rule these states will have a mass around 900 MeV since the hyperfine splitting has pulled them down relative to the average mass of about 1,100 MeV for the P-wave $q\bar{q}$ system. Hence roughly half of the mass has arisen from the two quarks intrinsically and half is from the P-wave excitation.

One can also form scalar states (0^+) from $qq\overline{pp}$ where now all of the quarks are in S waves. The extra mass of 600 MeV associated with the two additional quarks is compensated for by the absence of the P-wave excitation and so the mass of this four quark scalar meson can be comparable to the two quark state. In fact the hyperfine splitting in the four quark state tends to be larger than in the two quark and an explicit calculation by R. Jaffe of MIT (*Multiquark hadrons*, SLAC Publications, 1772, 1773) found that the $qq\overline{qq}$ 0^+ is lower in mass than the $q\bar{q}$. Astonishingly he presented a good case for believing that the familiar 0^+ mesons are really four quark states and not $q\bar{q}$! The implication is that four quark states have to be taken seriously.

For states containing a charmed quark (c) the same rough and ready rules seem to apply except that one has to allow 1.5 GeV for each charmed quark instead of 300 MeV. The lightest mesons $c\bar{q}$ will be expected around 1.8 GeV and the lightest charmonium states $c\bar{c}$ around 3 GeV. Both of these are realised in the data. Furthermore the P-wave $c\bar{c}$ states $^3P_{0,1,2}$ do seem to spread around 3.5 GeV in line with the rules.

Now replay Jaffe's game but with charmonium. The 0^+ ($c\bar{c}q\bar{q}$) state could be as low as 3.5 GeV (comparable to 0^+ ($c\bar{c}$) at 3.4 GeV). It is possible that a mysterious state at 3.46 GeV could be such a beast. The states that will be produced in electron–positron annihilation are vectors (spin 1, negative parity). If made from four quarks then a P-wave excitation is required and hence the mass rule implies another 500 MeV compared with the S-wave $c\bar{c}q\bar{q}$ (3.46 GeV?) or 800 MeV above the S-wave vector $c\bar{c}$ at 3.1 GeV. Either of these estimates suggests that the 4 GeV region is the place to look.

Very soon after the ψ was discovered Iwasaki in Japan suggested that $c\bar{c}q\bar{q}$ states might exist and even predicted a $c\bar{c}c\bar{c}$ at 6 GeV. The possible existence of such a state is controversial. When the plethora of dips and bumps were discovered in the 4 GeV region of the e^+e^- annihilation cross section, Rosenzweig (*Phys. Rev. Lett.* 36, 697; 1976) and also

Bander *et al.* (*Phys. Rev. Lett.* **36**, 695; 1976) independently suggested that four quark states $c\bar{c}q\bar{q}$ had been manifested. At the time of these works the charmed states $c\bar{q}$ had not been isolated!

After the D and D* charmed particles had been found with masses around 2 GeV, Nussinov and Sidhu at the Fermi National Accelerator Laboratory near Chicago explicitly investigated the possibility that charmed mesons might bind together in a manner analogous to the way that nucleons bind to form deuterium. Their explicit calculations (Fermilab preprint, August 1976) indeed showed that a loosely bound $D\bar{D}$ state could exist near to 4 GeV and they speculated that a similar occurrence might also happen for DD* and $D^*\bar{D}^*$. In the light of the recent developments a report on their calculations of the $D^*\bar{D}^*$ possibility is eagerly awaited.

If $c\bar{c}q\bar{q}$ states are indeed around the 4 GeV mass region then several questions come to mind. Once formed how do they collapse? Is the decay to $c\bar{q}$ and $q\bar{c}$ preferred to $c\bar{c}$ and $q\bar{q}$? The latter decay pattern has been called "charm burning" and has been investigated in particular by Okun and Voloshin in the Soviet Union. There is no obvious presence of $\psi(c\bar{c})$ in the debris produced at 4 GeV so this latter mechanism may be unimportant. Is this a problem? In the absence of dynamical information on the binding of the four quark states this is perhaps an open question. Are the four quark states (cc)$(q\bar{q})$ necessarily the same as $(c\bar{q})(q\bar{c})$?

If the quark model is relevant to nature then these four quark states seem to be unavoidable. With all the current interest in the 4 GeV region of energy in electron–positron annihilation one might hope that the first evidence for them may show up here. If the ideas of Iwasaki, Rosenzweig, Bander and many others are right, then it is possible that such a state has already been seen, in which case a whole new spectroscopy of molecular charmonium awaits discovery in addition to the "traditional"(!) charmonium now being unravelled. □

Versatile polysaccharides

from R. D. Preston

THE recent explosion of information on the detailed structure of a variety of polysaccharides, largely at the hands of four groups of workers, provides a salutary reminder, for those who need it, that these substances are to be reckoned with as well as proteins and nucleic acids. Broadly speaking, polysaccharides serve two main functions in living organisms. They largely determine the mechanical properties of supporting tissues, such as cell walls in plants and connective tissue in animals, and on the other hand, serve as recognition and receptor sites, a function particularly well-studied in bacteria, in which polysaccharides may be involved in recognition and adsorption of bacterium and phage, and of bacterium and host.

It is this function of polysaccharide that has attracted the attention of two groups of workers, D. A. Rees and colleagues in the UK and S. Arnott and coworkers in the USA. Two recent publications present the first detailed conformation of branched polysaccharides and give structural information relevant to their function as agents of recognition (Moorhouse *et al. J. molec. Biol.* **109**, 373; 1977; Morris *et al. J. molec. Biol.* **110**, 1; 1977).

Structural information on polysaccharides has been scanty until comparatively recently because no polysaccharide gives enough X-ray evidence to allow a complete determination of structure. The recent spectacular advances stem, not from advances in the technique of X-ray analysis itself, but from a combination of X-ray data with conformation theory as developed by Ramachandran and his colleagues and modified particularly by Arnott and his group (Ramachandran *et al. J. molec. Biol.* **7**, 95, 1963; Arnott & Wonacott *J. molec. Biol.* **21**, 371; 1966; Arnott & Scott *J. Chem Soc. Perkin* 324; 1972; Arnott *et al. J. molec. Biol.* **90**, 253; 1974). Both Moorhouse *et al.* and Morris *et al.* use this approach in defining the structure of their polysaccharides and, with the former, in presenting computer-drawn models complete with the necessary hydrogen bonding within and between the molecular chains and the positions of included water and anions.

Moorhouse *et al.* deal with a capsular polysaccharide from *Escherichia coli* strain Bi161/42(09:K29(A):H) in the form of chains of hexasaccharide repeating units [-2-α-mannopyranose-(1 → 3)-β-D-glucopyranose-(1 → 3)-β-D-glucuronic acid-(1 → 3)-α-D-galactopyranose-(1 →] with a disaccharide [β-D-glucopyranose-(1 → 2)-α-D-mannopyranose] attached by a 1 → 4 link from the mannopyranose residue to the glucuronic acid. Pyruvate is attached to every terminal D-glucose residue. This polysaccharide has been isolated from the serotype K29 and from two mutants, M13 and M41. The structure turns out to be the same for the mutants as for the wild type. The unit cell of fibres maintained at 92% R.H. is orthorhombic with dimensions a = 2.030 nm, b = 1.178 nm, c (fibre axis) = 3.044 nm. This contains four hexasaccharide units, one along each c edge and one central, and the space group $P2_12_12_1$ dictates that the central chain lies antiparallel to the side chains. The conformation of the chain is presented in Fig. 1. The main chain lies in a two-fold helix and the side chains are folded back to lie parallel to the main chain. Of the 15 potential hydrogen donors in each asymmetric unit, only five have been explicitly identified as participating in hydrogen bonds within and between chains. Presumably the other 10 may represent hydrogen bond bridges utilising a single water molecule between the chains. When the fibres are dried over silica gel, the unit cell is reduced in volume by contraction in a (to 1.73 nm) and b (to 1.02 nm) and then several of these bridges appear to be converted into direct intermolecular hydrogen bonds. *In vivo*, this highly hydrated polysaccharide is attached to the exterior of the cell in all three forms either as a capsule or contributing to long loose strands which project outwards.

Its functions seem to be many. *E. coli* phage 29 is highly specific for this capsule, cleaving β-D-glucosido-(1 →3)-D-glucuronic acid bonds exclusively and is dependent on the presence of the pyruvate ketal. The authors consider that the viral glucanase may move along the polymer strands, cleaving the glycosidic bonds and thereby opening a path for the phage head. Some particular conformational aspect of the polysaccharide, still to be determined, may then direct the phage to a particular site. Otherwise, the capsular polysaccharide prevents bacteriophages specific for cell wall receptors from infecting the cell and protects the bacteria from phagocytosis by macrophages; the structure so far elucidated gives no clue to the molecular mechanisms involved.

Although Morris *et al.* (*op. cit.*) refer to the structure determination of the polysaccharide they discuss, the details have not yet been reported and their paper deals exclusively with the behaviour of the chain molecules in solution, as judged by temperature effects on optical rotation, circular dichroism, proton magnetic resonance and viscosity; to this extent it complements the findings of Moorhouse *et al.* They deal, however, with different polysaccharides, the extracellular polysaccharides of *Xanthomonas* spp., pathogens responsible for blight disease of a number of important crop plants. These have a range of distinctive rheological properties which give them a variety of industrial uses. The primary structure consists of a backbone of repeating [→4)-β-D-glucopyranose-(1 →4)-β-D-glucopyranose(1 →] as in cellulose, with a substituent [3 →1)-α-D-mannopyranose-6-O-acetate-(2→1)-β-D-glucuronic acid-(4→1)-β-D-mannopyranose] on every other glucose residue. Each side chain appears to carry O-acetate, but in addition pyruvate is found attached to mannose residues though only to about one third of this extent.

The crystallographic evidence (not yet reported) is said to imply that the side chains, like those of the *E. coli* polysaccharide, fold down to form favourable noncovalent interactions with the main chain, and the molecule as a whole constitutes a five-fold helix in the form of a rigid rod. All the spectroscopic evidence with solutions points to a change from an ordered form to a disordered form as the temperature is raised. The transition temperature is independent of concentration and from this it is argued that the ordered form is a single-chain species (though it is agreed that this is not yet completely certain) and that this ordered form could have the same conformation as in the fibre This last consideration is one that vexes all attempts to understand solution properties, and properties *in vivo*, in terms of the conformation of the solute molecule when in a crystallite, and it cannot be said that the authors give direct proof of this correspondence. If the correspondence is acceptable, then the rheological behaviour can be understood in terms of weak interactions between rigid rods forming a tenuous three-dimensional network which is dispersed as the temperature rises.

A clue to the function of the polysaccharide of this pathogen is given by the observation that when mixed with even low concentrations of galactomannan the mixture may gel even though neither polysaccharide alone does so. The interaction is thermally reversible, and the gel is stronger when the ratio of mannose to galactose is 4:1 than it is at a ratio of 3:1, and when the ratio is 2:1 the mixture does not gel at any temperature. From this it is deduced that noncovalent binding occurs between the unlike chains of 'cellulose' and mannan. This could be regarded as 'recognition' of one polysaccharide by another. The interaction is not confined to galactomannans, however, but occurs with other polysaccharides with the β-1, 4-linked backbone including cellulose derivatives (Dea, Morris & Rees, in the press). There are therefore in the walls of the host plant a number of polysaccharides to which the bacterial polysaccharide might become attached and the suggestion made by the authors that this might constitute a molecular 'holdfast' securing the pathogen to the cell surface is not without its attraction. In going further by suggesting that this mechanism might ensure recognition of particular sites on particular plants the authors are, however, clearly going beyond the evidence. There seems no reason at the moment to believe that this association between polysaccharides would confer sufficient specificity and further evidence is needed on the polysaccharide composition of cell wall surfaces in host and non-host plants before accepting this as 'recognition'.

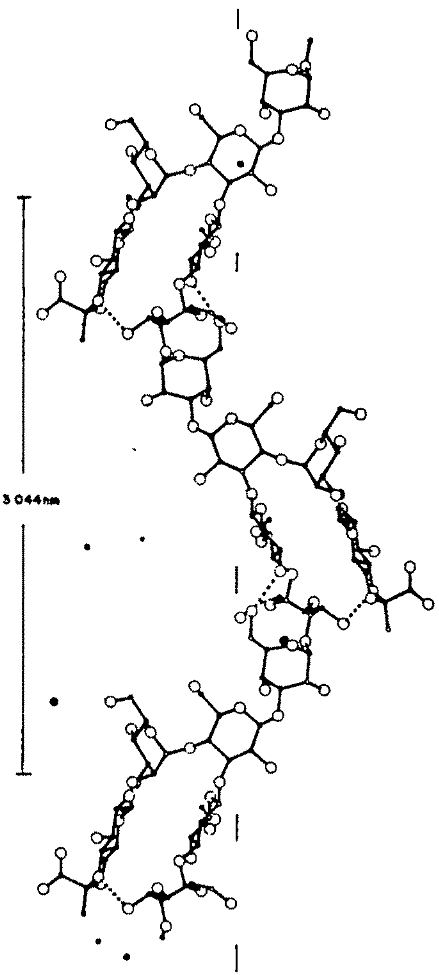

Fig. 1 Molecular conformation of the M41 polysaccharide. Open circles, oxygen; hydrogen omitted. Broken lines denote hydrogen bonds.

It is welcome that two groups of workers have now delineated the conformations of two branched polysaccharides and that, in spite of the different chemistry, there is an overall similarity between them. This will one hopes stimulate closer attention to the other partner in the proposed recognition mechanisms, namely to the possibility of variations in the matrix substances of the walls of host and non-host cells, and, for *E. coli*, to the structure of the viral glucanase of phage 29 as a check on its compatibility with the function claimed. More remotely from the field of the present two papers, but of equal urgency, success with these two polysaccharides should stimulate attempts at the conformation of branched polysaccharides in higher plant cell walls, to the benefit of cell wall mechanics both in cell growth considerations and in, for example, timber technology. The importance of these papers ranges well beyond the confines of bacterium/host recognition.

Laser dissociation

from Graham Richards

LASERS offer to chemists the possibility of controlling the specificity of chemical reactions by choosing the energy of the laser beams so as to cause the rupture of particular chemical bonds. Most attractive from this point of view is the prospect of isotopic separation by laser dissociation of polyatomic molecules. Powerful CO_2 infrared lasers have been used successfully to produce enrichment of boron isotopes from BCl_3, sulphur from SF_6 and more recently amongst heavier nuclei, osmium from OsO_4 (Ambartzumian *et al.*, *JETP Lett.* **22**, 43; 1975) and molybdenum from MoF_6 (Hudson *et al.* *Electro-Optical Systems Design Conference*, 1976). The hope is that the technique may lead to a method of separation of uranium isotopes by laser action on UF_6.

The dissociation of a molecule by infrared radiation, whose photons have enough energy to increase vibration but far too little to break a bond, can only succeed if many photons are absorbed so rapidly that energy is not lost on collision between molecules. The high power density of the CO_2 laser enables these conditions to be met. The sharp frequency of the laser may fit with a vibrational frequency of one isotopic species, but not with another since in molecules, as in all vibrating systems, the vibration frequency decreases with increasing mass of the oscillator. Once started up the vibrational ladder by absorbing several photons, one isotopic molecular species may be decomposed leaving an isotopically enriched mixture.

Despite a great deal of work, many questions about the mechanism of this potentially valuable technique remain. How can a molecule absorb a number of quanta of the same energy even though the vibrational energy levels converge as dissociation approaches? It could be due either to multiphoton absorption (several photons absorbed at the same instant) or to the use of rotational energy levels which give fine structure to the vibrational energy ladder. Theoretically the former hypothesis seems more likely (Bloembergen *Opt Commun.* **15**, 416; 1975), but even in the case most studied, SF_6, the mechanism of multiphoton absorption is far from completely understood. What are the dissociation products; how many photons can a single molecule absorb beyond the dissociation limit, and how is the excess energy distributed among the fragments? What is the effect of molecular collisions and is there an activation energy barrier beyond dissociation? Many of the unanswered questions are clarified by the elegant experiment of Coggiola *et al.* (*Phys. Rev. Lett.* **38,** 17; 1977) on the multiphoton dissociation of SF_6. They establish that the molecule does accumulate energy by sequential absorption of photons and provide many details of the mechanism.

Their experiment involved crossed molecular and laser beams; an SF_6 beam formed by expansion was crossed with a pulsed CO_2 laser beam (1 J per pulse). The fragments produced by multiphoton dissociation of the SF_6 were analysed with a quadrupole mass spectrometer whose position could be varied to measure the angular distribution of fragments.

The observation of dissociation products from the beam interaction region confirms that the multiphoton molecular dissociation is indeed a unimolecular process since there is no possibility of collision.

The SF_5^+ ion signal is always the most intense and no F_2^+ was detectable. Ions with one, two or three fluorines removed and F^+ all have the same parent molecule, SF_5. The major products are thus SF_5+F, rather than SF_4 and F_2. The possibility that clusters or van der Waals dimers of SF_6 are the origin of the fragment signals was ruled out by studying the dependence of the SF_5 signal as a function of SF_6 beam saturation pressure when no increase in intensity beyond that due to increased beam flux was seen.

The translational energy released in the dissociation was found from the angular distribution of products using conservation of energy and linear momentum. It proves to be very small (< 6.3 kJ mol^{-1}), implying that there is no substantial barrier beyond the dissociation limit. The activation energy required beyond dissociation is less than 70 cm^{-1}.

The laser affords the possibility of varying intensity, power, polarisation and wavelength, and the SF_6 beam may be excited both vibrationally and rotationally. Further experiments should thus yield detailed information about dissociation dynamics and internal energy distribution and energy transfer of an excited molecule before dissociation. This should in future give a much better understanding of the mechanism of multiphoton dissociation. □

Specificity of chromatin transcription

from Stewart Gilmour

MUCH of the information about gene regulation in animals has come from experiments in which chromatin is transcribed *in vitro* with exogenous RNA polymerase. In many cases *Escherichia coli* RNA polymerase is used and it is pertinent to ask whether the transcriptional patterns reflect the regulatory features of chromatin or an incompatible marriage of bacterial polymerase and animal chromatin. Could it be that a bacterial enzyme may not recognise some active sequences in chromatin or perhaps transcribe other sequences which are normally inactive *in vivo*? An insight into this question has been provided recently by Parker and Roeder (*Proc. natn. Acad. Sci. U.S.A.* **74,** 44; 1977) for the particular case of 5S RNA gene transcription in isolated *Xenopus* oocyte chromatin. Normally *in vivo* these reiterated genes are transcribed by RNA polymerase III and in immature oocytes this accounts for a substantial proportion of the total RNA synthesis. The spacer region between the gene copies is apparently not transcribed.

In these experiments chromatin isolated from immature *X. laevis* oocytes was transcribed *in vitro* with exogenous RNA polymerase I and III from *X. laevis* ovaries, polymerase II from mouse plasmacytoma cells and *E. coli* RNA polymerase. The authors devised a hybridisation assay which analysed the fidelity of the chromatin transcripts with respect to sense strand, anti-sense strand and spacer region copying of the 5S gene. This was achieved by two separate hybridisations. First, transcripts labelled with ^{3}H–UTP were hybridised to plasmid DNA containing homologous *X laevis* 5S DNA in the presence and absence of saturating amounts of unlabelled 5S RNA. The levels of hybridisation in the two cases indicated the degree of sense and antisense strand copying and by simultaneous inclusion of standard ^{32}P–labelled 5S RNA in the hybridisation reactions an accurate estimate could be made of the total 5S RNA transcript synthesised. In the second analysis transcripts were hybridised to plasmid DNA containing 5S DNA from *X. mulleri.* Since only the 5S gene regions and not the spacer regions are homologous between *laevis* and *mulleri* any aberrant transcription of spacer will not score as hybrid in this case.

Incubation of *X. laevis* chromatin without additional polymerase reveals endogenous polymerase III activity. About 40% of the transcript is 5S RNA transcribed from the sense strand. In control experiments where only ^{3}H–UTP is present some terminal addition to 5S RNA occurs and an appropriate correction has to be made. The addition of exogenous polymerase III results in a <50-fold increase in 5S RNA synthesis; the percentage of 5S RNA in the transcript is about the same as for the endogenous activity and is asymmetric. In contrast exogenous polymerase I did not stimulate 5S synthesis even though there was a net stimulation of total RNA synthesis above endogenous levels. In all cases a small but indeterminate amount of spacer transcription is seen. It is clear that the transcription of 5S RNA from *Xenopus* chromatin requires the mediation of a specific polymerase. This conclusion is reinforced when chromatin is transcribed with mouse plasmacytoma polymerase II and *E. coli* RNA polymerase. In neither case is there a specific stimulation of 5S RNA synthesis.

In another series of experiments purified *X. laevis* DNA was transcribed in identical conditions with *Xenopus* I, III and *E. coli* polymerase. In each case only about 1% of the transcript was 5S RNA and copying was symmetrical. Taken together these findings suggest that chromatin-associated proteins are required for the selective and asymmetrical transcription of 5S RNA genes in amphibian oocytes and that a specific polymerase is required to effect this. It is clear from the data that a high degree of proper initiation and termination occurs. The situation with other cell-free systems is unfortunately not so precise. A number of laboratories are currently investigating the control of specific genes in a variety of animal systems (such as globin, ovalbumin and histone genes) by analysing the *in vitro* transcripts from isolated chromatins.

In nearly all cases *E. coli* RNA polymerase rather than the homologous polymerase II is used because of the relative inactivity of the latter when added exogenously. The transcripts are usually analysed by hybridisation to complementary DNA made from the appropriate mRNA. It could be argued that the analysis is geared to the biological expectation of the template rather than to the fidelity of the polymerase, however it is clear from these experiments that bacterial polymerases can transcribe chromatin in a tissue-specific fashion. The question of how specific the overall transcription process is in these systems has been studied recently by Biesmann *et al.* (*Biochemistry* **15,** 4356; 1976) by transcribing *Drosophila* chromatin with *E. coli* polymerase and hybridising the RNA to cDNA made to the polyadenylated nuclear RNA of the tissue. In summary these results showed that while most of the sequences represented in the cDNA probe were also found in the transcript some aberrant transcription also occurred. While it is possible to demonstrate a fair degree of the *in vivo* transcription pattern *in vitro* by this approach it has to be conceded that some genes, like the 5S gene, may be subject to finer levels of control which may not be recognised by heterologous polymerases. Gross controls such as heterochromatisation, acting at the structural level, might determine which tissue-specific genes are transcribed from chromatin *in vitro* and may require little discrimination on the part of the polymerase for the selective transcription of these genes.

Triassic extinction or Jurassic vacuum?

In his article "Triassic extinction or Jurassic vacuum?" (*News and Views* **265**, 402; 1977), Milner refers briefly to my work on a Middle Jurassic microvertebrate locality in Oxfordshire. (*Science* **194**, 1053; 1977). He expresses hope that it and other new localities in Queensland, India and the Isle of Skye may provide data on the times of extinction of the procolophonids, rhynchosaurs, thecodonts, dicynodonts and temnospondyl labyrinthodonts, all of which are conventionally supposed to have died out at the end of the Triassic.

The Oxfordshire site has yielded isolated bones and teeth of mammals, therapsids, theropods, ornithischians, ?sauropods, pterosaurs, crocodilians, lepidosaurs, chelonians, anurans and actinopterygians, but in spite of a deliberate search, no teeth of labyrinthodonts have yet been found. The fragmentary condition of the material would not permit ready identification of the other Late Triassic groups to which Milner refers even if these were present. The diversity of the vertebrate fossils from Oxfordshire indicates that a wide range of vertebrate palaeoenvironments fell within the catchment area of the deposit, and that therefore the absence of the labyrinthodonts in the Late Bathonian is real rather than apparent.

Difficulties in solving heparin structure

from Edward A. Johnson

Heparin has now been in clinical use for 40 years, but the achievement of anything like a complete understanding of its anticoagulant action still seems a long way off. The difficulties centre on our ignorance of the structure of heparin; or perhaps one should say structures, for it is clear that not only is the most thoroughly purified material a mixture of many compounds, but various components of the mixture exert different effects within the coagulation 'cascade'—that insecure sequence of enzyme reactions which may sometimes begin with the activation of Hageman factor and (with more confidence) may be said to end with the cross-linking of fibrin by activated fibrin stabilising factor to form an insoluble clot.

A matter in dispute since the discovery of heparin is its native form in tissue; more specifically, in the granules of mast cells which are its only certain source, although Jaques and coworkers (*Lancet* **i**, 411; 1977) have recently suggested that it may be present in other kinds of cell. Silbert, Austen and coworkers (*J. biol. Chem.* **252**, 518; 1977) have now consolidated earlier work by Horner (*J. biol. Chem.* **246**, 231; 1971), confirming that, in some tissues at least, native heparin has a high molecular weight of the order of 750,000 to 1,000,000. These large molecules are made up of a number of chains more nearly the size of commercial heparin (5,000–40,000) linked to a common core of uncertain character by polypeptides which, surprisingly, are resistant to all the proteases to which they have so far been exposed. However, treatment with aqueous alkali, a procedure often used in commercial heparin extraction, readily releases the chains from the core to give a product which is presumably the equivalent of the heparin of commerce.

Heparin, as a strongly anionic polysaccharide, exerts its effects by binding specifically to basic regions of certain proteins, in particular to antithrombin III (see Seegers, Rosenberg and other workers in *Adv. exp. Med. Biol.* **52**, 1975), the inhibitory action of which on serine esterases in the coagulation cascade is thereby greatly accelerated. It is reasonable to suppose that binding will depend on the presence of appropriate sequences peculiar to the heparin chains, since related acidic glycosaminoglycans and other polysaccharides, whether artificially sulphated or not, are all far less effective than heparin in the test systems used. The difficulties of identifying these sequences are very great, principally because heparin is always heterogenous, a complete obstacle to the quasi-statistical methods used in sequencing proteins. Also, hydrolytic degradation is invariably accompanied by far more damage to the released fragments than occurs with peptides, and enzymic methods have to be used.

Useful initial fractionation may be carried out by making use of protein–heparin binding, and, by adsorption on matrix-bound antithrombin or by related procedures, several groups of workers (Lam *et al. Biochem. biophys. Res. Commun.* **69**, 570; 1976, Höök *et al. FEBS Lett.* **66**, 90; 1976; Andersson *et al. Thromb. Res.* **9**, 575; 1976) have concentrated heparin fractions with strong antithrombin binding from various commercial preparations. Such high-affinity material has been called, too loosely, 'active' heparin in contrast to the more weakly bound 'inactive' heparin (which seems to be indistinguishable in its general physicochemical properties), but it has yet to be proved that antithrombin-binding capacity *in vitro* is the only significant criterion for anticoagulant activity in heparin. It may be important; but there is certainly evidence that, at least *in vitro*, the antithrombin-binding capacity of certain heparin fractions does not follow their activity in other and presumably unrelated stages in the coagulation cascade (Andersson *et al. Thromb. Res.* **9**, 575; 1976). High-affinity heparin is still very heterogeneous, but Lindahl's group, with Linker (*FEBS Lett.* **69**, 51; 1976), has taken a further step by adsorbing heparin fractions on antithrombin–Sepharose and incubating the complex with heparinase. The segments of the heparin chains bound to the protein were not attacked, but could be displaced in the usual way by increasing the ionic strength. The material isolated in this way had molecular weights of 2,000 to 5,000 (6–16 monosaccharide units), depending on the heparin starting material, but was still heterogeneous.

This kind of approach, ultimately identifying and comparing the heparin segments that are most strongly bound to various proteins involved in coagulation, is difficult and laborious; few of the other relevant proteins are as easy to isolate or as stable as antithrombin III. Nevertheless, it is probably the best hope so far of gaining a proper understanding of heparin anticoagulation. Additional help can come from fluorescence and circular dichroism effects of heparin–protein interactions and also from X-ray diffraction studies on heparin salts—which may give some insight into heparin conformations in solution—but so far as can be seen the obstacle of heparin heterogeneity must in every case limit the information that can be gained. Any useful procedure should include studies of heparins from different tissues and species; lung and mucosal heparins have been known for many years to differ chemically to a small but consistent extent (do the mast cells differ?) and, since this difference is now known to be paralleled by differences in relative activity at different stages in the coagulation cascade, its significance needs to be examined.

One of the driving forces behind this work has been the importance of heparin in clinical practice, including, especially, its use for antithrombotic prophylaxis following major surgery (see *Heparin*: *Chemistry and Clinical Usage* (eds Kakar and Thomas) Academic, London, 1976). It is generally agreed that in this context, where prevention of venous thrombosis must not be accompanied by a tendency to haemorrhage, antithrombin potentiation, as determined by the so-called anti-Xa assay, is as yet the best criterion of efficacy. A recent observation of Thomas and coworkers (*Lancet* **i**, 120; 1977) is therefore disturbing; it demonstrates that a semisynthetic heparin-like compound, which has negligible anti-Xa activity *in vitro*, nevertheless shows excellent antithrombin potentiation in the human subject. In heparin therapy the correlation of assay results *in vitro* with consequences *in vivo* has been taken on trust perhaps more than in other fields, and this will also need reconsideration. □

Probing facilitated transport

from S. J. Smith

INSULIN acts on fat cell plasma membranes to promote glucose uptake and its stimulation of the utilisation of this sugar seems to be amplified by the production of a 'second messenger'. The glucose transport system in adipocytes has been well characterised as a carrier-mediated facilitated diffusion mechanism which shows bidirectionality, stereospecificity and saturation kinetics. However, little is known about the system in structural terms.

Aryl azide derivatives provide a powerful technique—photo-affinity labelling—for identifying sites of biological importance. Irradiation of the probe causes photolysis of the azido moiety producing a highly reactive nitrene, which can react covalently with any groups that lie within reach. In order to provide any interpretable information, the reagent must be shown to bind at the required locus before photolysis. Singer and coworkers have recognised the possibility of 'pseudo-affinity' labelling, which could occur, where the photolytic intermediate is able to bind reversibly to and dissociate from the active site before a covalent bond is formed. In such cases, the process would be analogous to affinity labelling. Attempts have been made to use this technique to label biological receptors in various systems.

Recently, a photoreactive aryl azide derivative of glucose, N-(4-azido-2 nitrophenyl)-2-amino-2-deoxy-D-glucose has been used to label adipocyte membranes (Trosper & Levy *J. biol. Chem.* **252**, 181; 1977). In the absence of light it has been shown to inhibit the uptake of D-glucose and 3-O-methyl glucose competitively, and conversely, the uptake of the probe is decreased in the presence of glucose. Measurement of the initial uptake of the probe gave values for K_t and V_{max} similar to those obtained for glucose in identical conditions, suggesting that both sugars are being transported by the same system. When intact adipocytes were treated with the radiochemically-labelled derivative, on photolysis only, four hot membrane components could be identified in SDS polyacrylamide gels of the purified plasma membrane fraction. When homogenised material was used most of the membrane proteins become labelled. Two of the specifically labelled components were found to be glycoproteins with apparent molecular weights 100,000 and 81,000. In the presence of glucose, labelling of these components was significantly reduced, suggesting their involvement in the glucose transport system. Two lower molecular weight proteins, located on the external surface of the adipocyte membrane were also modified, but substrate protection could not be demonstrated.

The participation of membrane phosphorylation in the regulation of permeability has been implicated in, for example, toad bladder and rat brain synaptic membranes and two reports suggest that this process may be involved in modulating the effect of insulin on glucose uptake. Cuatrecasas (*J. biol. Chem.* **249**, 3170; 1974; **249**, 6854; 1974) reported that low concentrations of exogenous ATP can inhibit insulin-stimulated glucose transport and that this effect is associated with the phosphorylation of two membrane components of molecular weights 22,000 and 16,000 which can be separated from unlabelled components by SDS polyacrylamide gel electrophoresis. Phloretin, a strong competitive inhibitor of glucose transport, can protect cells from the ATP effect with concomitant reduction in the phosphorylation of both these components. In these experiments the binding of ^{125}I-labelled insulin was unaffected, as was the anti-lipolytic effect of the hormone. In further studies, it was found that in the presence of cyclic AMP, but not cyclic GMP, the same membrane proteins were rapidly phosphorylated, and a Ca^{2+}-sensitive cyclic-AMP dependent kinase was isolated from purified adipocyte plasma membranes. This system could not be found in guinea pig adipocytes, where glucose transport is not sensitive to insulin. The physiological importance of these findings is difficult to assess, particularly as no direct effects of insulin or adrenaline could be obtained by pretreatment of the cells with hormone before purification of the membranes.

However, more recently Avruch *et al.* (*J. biol. Chem.* **251**, 1511; 1976) have shown a significant increase in the phosphorylation of a 26,000 molecular weight component of adipocyte plasma membrane, in the presence of adrenaline (even at physiological concentrations) and it seems that this effect is reversed when insulin is also present. The relation, if any, of this protein to that described by Cuatrecasas is obscure. Higher molecular weight membrane components (79,000 and 62,000) could also be phosphorylated, but the extent of this was not hormone sensitive.

The development of the aryl azide derivative of glucose, which seems to be a potential probe for the facilitated glucose transport system provides an obvious strategy for the next step, determination of whether these phosphorylated proteins are involved in the regulation of glucose uptake. □

Plugging the gap in the astronomical spectrum

from a Correspondent

THE last gap in the electromagnetic spectrum available for observation by astronomers seems likely to be plugged in the near future, with the development of instruments purpose built for operating in the 1 to 10 mm band, between infrared and radio astronomy. One such instrument, with a dish 10 m across, has been proposed by observers at CalTech, where a small test dish has already been built. At the meeting of the Royal Astronomical Society on 11 March R. E. Hills, of the Mullard

Radio Astronomy Observatory in Cambridge described plans for a proposed UK instrument, with a dish 15 m across and designed to operate down to 0.8 mm.

This project—at least as a design exercise—got off the ground 18 months ago when the Science Research Council set up a steering committee, chaired by Anthony Hewish and managed by members of the Appleton Laboratory, with Hills as project scientist. The product now available is a fairly advanced design and specification for an instrument intermediate between a conventional optical telescope and a radio dish, requiring its own technology but incorporating ideas from both those areas.

Hills explained that the lack of observations in the millimetre gap has been due to inadequate technology; the photons in this band each carry too little energy to trigger the kind of detector used in, say, X-ray work, but the wavelengths are small enough to make observation by standard radio techniques difficult. With infrared observers pushing one way—stretching their instruments beyond their original design capability—and radio astronomers pushing the other, the gap has shrunk, and now the technology is available for purpose built instruments to complete the job.

Why should astronomers be so keen to plug this gap, when already today they have access to far more information, across a broader band of the spectrum, than ever before? Primarily, the prospects are exciting because this band corresponds to emission from cold material, at about 10 K, and therefore provides a window to view the very substantial fraction of matter in the Universe that is now known to exist in cold clouds. Star formation regions, cool envelopes surrounding old, evolved stars, the distribution of cold matter across individual galaxies, and the differences between galaxies, could be probed with the new telescope and there is also the prospect of penetrating deeper, in observational terms, into the dusty, active regions at the centre of many radio galaxies and similar objects.

How is this to be achieved? The instrument described by Hills, although larger than any existing optical telescope, would still be housed in a dome, but a dome with a rather large aperture in order for the large dish to have an unobstructed view. This would raise problems with wind blowing into the dome, which might be overcome by providing a screen of material, transparent at millimetre wavelengths, across the 'slit'—something suitable might be sailcloth backed with polythene. The instrument itself, the steering committee suggests, should be parabolic, designed on the homology principal which has proved so successful with some very large radio telescopes. This technique allows the instrument to bend under its own weight as it is moved into different orientations, but the design ensures that it always bends into a paraboloid; the effect is to shift the focus of the instrument, but it is much simpler to move the detectors sited at the focus as necessary than to attempt to keep the whole dish rigid.

Such a 15-m instrument should give 13 arc s resolution (better than single radio dishes; worse than optical telescopes) and would need a pointing accuracy of 2 arc s to make best value of the resolving power. The estimated cost of such a facility is £3.5 million, enough to make the SRC blanch at the present time, no doubt, but not so great as to make this an obviously 'pie in the sky' project. The instrument would, of course, have to be built at a high site free from obscuring water vapour—the criteria are essentially the same as those which make Hawaii the site of the UK infrared telescope—and this would certainly mean that it would be run as a national facility for use by many teams, as large optical telescopes are, and would not be the raison d'etre of a single group, as has generally been the case with large radio observational facilities. There is no doubt that the need for the facility exists, since nothing else now being planned will observe below 3 mm, and since most other planned instruments are restricted because they are to be built inside fixed radomes, with no opening slit. But any project requiring millions of pounds of new money today must have only slender prospects of realisation.

Pluto: the little-known planet

from David W. Hughes

PLUTO, the ninth and most distant planet in the Solar System has been and still is an object of considerable mystery and controversy. In 1930, when it was discovered, people were worrying about what to call it, Minerva and Pluto leading the field. Pluto, the brother of Jupiter and Neptune, won. Today, 47 years later, controversy still rages over its most fundamental physical parameters, its diameter, mass, density, surface covering and spin axis direction.

The first measurement of Pluto's diameter was made by Kuiper in 1950. Observing with the Hale Observatories 200-inch telescope at Mount Palomar during a period of excellent seeing, Kuiper compared the planet's image with that produced by a "disk meter", a device which produces an artificial image of adjustable brightness, colour and diameter. He obtained an angular diameter of 0.23 s of arc equivalent to a planetary diameter of 5,900 km. Unfortunately the systematic errors in such measurements of marginally resolved images are rather large. The fact however that Pluto did not occult a specific star in 1965 gave an upper limit to the diameter of 6,800 km.

An indirect approach to the diameter can be made by measuring the brightness of the planet and the albedo (or reflectivity) of its surface. Cruikshank, Pilcher and Morrison of the Institute for Astronomy, University of Hawaii, used the 158-inch Mayall telescope at Kitt Peak National Observatory to measure the reflectance of Pluto in the near infrared (1.2 to 2.2 μm). They used standard JHK filters and two specially made narrow band filters centred at 1.55 and 1.73 μm. Their results are reported in *Science* (**194**, 835; 1976).

The most likely constituents of the surface of the outer planets of the Solar System are the ices or frosts of water, carbon dioxide, ammonia and methane. Water ice has already been found in the rings of Saturn, on four of Saturn's satellites and also on the Jovian satellites Europa and Ganymede. Fortunately reflectance measurements between 1.4 and 1.9 μm can distinguish between CH_4, H_2O and NH_3 and Cruikshank *et al.* find that the ratio between the flux at a wavelength of 1.55 μm and that of 1.73 μm is especially useful diagnostically. For Pluto this ratio is 1.6 ± 0.1 which they interpret as indicating that CH_4 frost is the dominant reflecting material on Pluto's surface. The observations rule out the existence of large quantities of H_2O or NH_3 frost and of CH_4 hydrates. The CH_4 frost is probably mixed in with silicate or carbonaceous material.

There are two possible sources for this solid methane. First the temperature of the pre-planetary nebula could have dropped below 40 K at Pluto's distance from the Sun leading to the direct condensation of solid CH_4. Standard equilibrium condensation models would then indicate that Pluto has a mean density of 1.2 g cm^{-3}. Second, CH_4 8 H_2O could have condensed out at nearer 70 K, internal heating in the planet leading to the outgassing of CH_4 which subsequently froze on reaching the surface.

The brightness of a planet is proportional to d^2a/R^2 where d is the diameter, a the albedo and R the distance between the planet and the observer. Rocky planets and satellites (Mercury, Mars, Moon) have low albedoes (0.056, 0.16, 0.067), frost covered satellites (Europa, Ganymede, Rhea, Dione and Tethys) have albedoes in the range 0.4 to 0.6. The presence of CH_4 frost on Pluto would put its albedo into this range too. Assuming that Pluto has an albedo of 0.4 and a mean opposition magnitude of 14.90, the diameter would be 3,300 km. An albedo of 0.6 implies a diameter of only 2,800 km. Both these values make Pluto smaller than our Moon (diameter 3,476 km).

But Pluto is not completely covered with CH_4 frost. If it were its brightness would be constant. Between 1952 and 1955 the magnitude varied asymmetrically by about 0.11 with a period of 6 d 9 h 17 min, this being the rotation period of the planet. The brightness fluctuations are caused by successive passages through the meridian of regions of differing reflectivity. Andersson and Fix (*Icarus* **20**, 279; 1973) found from observations made between 1971 and 1973, that the amplitude variation is now larger (0.22 mag) and the mean magnitude fainter (15.1). This is thought to be due to a change in the aspect of the planet as it moves round its orbit. The equatorial plane of Pluto is probably inclined at over 50% to orbital plane and the decrease in brightness is thus due to the sub-Earth point on the planet moving towards the equator during the past 40 yr, the polar regions having a higher albedo than the equatorial regions.

The mass of Pluto has been obtained from observations of the perturbations that this mass induces in the orbital motions of Uranus and Neptune. Seidelmann *et al.* (*Astr. J.* **76**, 488; 1971) obtained, for example, a value of 0.11±0.02 Earth masses (6.6×10^{26} g). However Ash, Shapiro and Smith (*Science* **174**, 551; 1971) found that the value obtained for the mass of Pluto is extremely sensitive to the choice of perturbation data and parameter sets and that this mass cannot be determined with any certainty from this source.

If the density and size of the planet are known the mass can be easily estimated. The surface of Pluto inferred from the observations of Cruikshank *et al.* is exactly that to be expected for a large object which condensed at low temperatures in the outer solar nebula. Its composition is probably dominated by frozen volatiles, just like most outer planetary satellites. (Remember there is a distinct probability that Pluto used to be a satellite of Neptune, but escaped during some encounter with Triton in the early times of the Solar System). If this is so its mean density is likely to be between 1 and 2 g cm^{-3}. Combining these with Cruikshank *et al.*'s values for the diameter (3,300 km if $a=0.4$, 2,800 km if $a=0.6$) gives mass values in the range 1.2×10^{24} to 3.8×10^{25} g, about 1/250 the mass of Earth. This mass is much too small to perturb Uranus and Neptune in a measurable fashion, a conclusion which leads to two interesting consequences. First Clyde Tombaugh's discovery of Pluto must have been to a great extent fortuitous, the result of a diligent search and not an accurate, mathematically-derived, prediction as to the planet's position. Second if Pluto is not responsible for the perturbation of the orbits of Uranus and Neptune, something else must be; another planet or the cometary cloud perhaps? ☐

Palynology at Lucknow

from Peter D. Moore

> The 4th International Palynological Conference was held at Lucknow on 29 December 1976–5 January 1977. The Proceedings are to be published.

OF particular interest at the conference were the accounts given of recent vegetation history in the tropics and subtropics, based upon studies of subfossil pollen grains stratified in peats, lake sediment and salt lake deposits. In contrast to the temperate areas of the world, the lower latitudes have been neglected and their recent environmental history is consequently little known. The work of J. R Flenley (University of Hull) in New Guinea and A. P. Kershaw (University of Canberra) in north-eastern Australia has shown that tropical rain forest has not had the long uninterrupted Quaternary history which was once imagined. On the Atherton Tableland of Queensland, Australia, at an altitude of over 700 m, Kershaw has shown that the vegetation changed gradually from a microphyll vine forest to sclerophyllous woodland at about 25,700 b.p , which could have been due to increasing aridity or to the influence of early man, using fire. The development of rain forest at the site did not occur until about 7,000 b.p.

Within India itself, the work of G. Singh (University of Canberra) and others has been of considerable value in elucidating the history of the deserts of western Rajasthan. The study of dry salt lakes in this area has shown that between 10,000 and 4,000 b.p. the sites were occupied by freshwater lakes and the pollen contained in these sediments demonstrates a development through *Artemisia* steppe to savannah vegetation with trees and shrubs. Desert encroachment followed this phase and is considered to be the product of climatic rather than cultural changes.

The argument about human involvement in recent vegetational changes is never easy to resolve. The presence of cereal pollen is often taken as evidence of human settlement and cultivation and therefore human potential for habitat modification. Cereal type pollen grains (40–50 μm) were found in the Rajasthan desert as far back as 9,300 b.p. and V. Mittre (Lucknow) reported even earlier finds of large Gramineae pollen in India. The Middle East records of cereal pollen were collated by A. Leroi Gourham (University of Paris); in Iran cereal pollen has been found in deposits going as far back as 60,000 b p., thus demonstrating the existence of, presumably, the wild progenitors throughout the last glacial climatic episode. In Lebanon and Syria, herbaceous pollen was low during the forested times of the last glacial, but increased with forest decline (here cereal pollen is defined as being in excess of 60 μm).

The recognition of true cereal pollen, however, is not a matter over which all palynologists agree. Size criteria are most frequently used, but it is well known that mounting media can alter the sizes of pollen grains, they may swell in the course of time, and also some wild grasses have large pollen grains. E. Kohler and E. Lange presented some preliminary data on scanning electron microscope studies of grass pollen in an attempt to define cereals on more reliable morphological grounds. Only four genera (12 spp.) have been examined in detail so far, but four distinct types of sculpture have emerged. Sculpture alone however, does not provide a means of separating cereal from wild grass pollen. It is hoped that combinations of size, pore and sculpture type criteria will permit a more critical definition of pollen types within the Gramineae. Such a definition is vital to the furtherance of the study of primitive agriculture, its extents and its influence upon vegetation in the Middle East and India. ☐

review article

Modelling the structures of amorphous metals and alloys

J. L. Finney*

The application of random packing models to amorphous metals and metal–metalloid alloys is discussed, with particular reference to the effects of soft potentials, boundary conditions, and density. The local atomic organisations found leads to structural speculation concerning the glass transition, and the existence of 'amorphous polymorphs'.

SINCE the late 1950s when Duwez developed his 'splat-quenching' technique for the rapid cooling of liquids[1], a range of non-equilibrium, solid metallic alloy phases have been produced. Many such materials, and others produced by sputtering, and by electro-, chemical, and vapour deposition, exhibit interesting and potentially useful mechanical, magnetic and corrosion-resistant properties More recently, amorphous (pure) metals have been prepared by vapour deposition on cold substrates[2–4].

Many (though by no means all) of these materials are non-crystalline[5]. This non-crystallinity raises severe problems when we try to understand their structure–property relations. The absence of a regular underlying lattice organisation makes it difficult (and often dangerous) to apply many of the powerful methods of solid-state physics to such systems. Their structural characterisation is related more to dense liquids than crystalline solids. Rapidly quenched liquids at least might be directly related to the liquid organisation from which the 'glassy' solid is formed; thus there is little reason even to expect crystal nucleation to have taken place.

Use of models

This conceptual and mathematical vacuum—the absence of mathematical formalisms capable of dealing adequately with dense, non-crystalline aggregates of atoms or molecules—has been partly filled by the development of methods of structural modelling. Models of particular non-crystalline atomic or molecular aggregates can be built both in the laboratory[6–14], and on a computer[15–28]. Properties predicted by such (numerical) models can be compared with those observed experimentally, and disagreements used to improve the original model. Such modelling techniques were used extensively in the early days of crystallography. The question was asked: 'what structural arrangement of molecules can I construct which is (1) consistent with what I know about the way these molecules interact, and (2) consistent with the existence of a regular, repeating lattice in three dimensions?' Thus, the crystal chemist explained the structures of the rare gas solids in terms of close-packing of hard spheres, or ionic structures in terms of charge and size effects, and of diamond in terms of tetrahedral covalent bonding. Such explanations began as 'ideal' structures, which were later improved by taking into account more subtle effects such as the detailed nature of the potential function, polarisation and three-body interactions

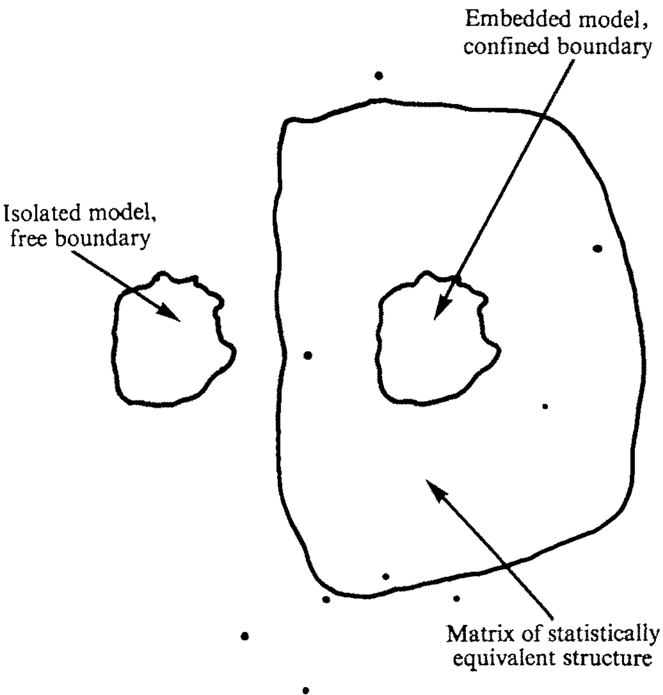
Modelling techniques as applied to non-crystalline solids are in principle similar. We ask a slightly different question: 'What structures can I build which are (1) consistent with the interactions between molecules (the 'potential function') but (2) not constrained by a regular lattice? As in the crystalline case, we establish first an 'idealised' structure of our amorphous metal or alloy. This idealised structure should relate to the real structure as an idealised crystal structure (such as a cubic close-packing of hard spheres) relates to the real crystal. The idealised structure is then improved upon to explain in more detail the structure and properties of the real non-crystalline material.

Such modelling techniques have been applied specifically to a variety of non-crystalline solids, for example, silicate and other oxide glasses[6–8], amorphous Si and Ge (refs 10, 26, 27), amorphous ice[29], and chalcogenide glasses[30–32]. Although different systems present different problems to the modeller, the principles—and the pitfalls—are essentially similar in all cases. The structures of amorphous metal films (for example, Co, Ni (refs 2, 4) and glassy transition metal–metalloid alloys (NiP (ref. 5), CoP (ref. 28)) have been explored extensively by modelling and illustrate the principles and problems particularly well

Specific application

To answer the model-builder's question above, we need first to strip the potential function down to those aspects which we think are structure-determining, and second to devise a method of

Fig. 1 The embedding problem. The structure of our finite model must correspond to that structure which would be consistent with its embedding in a matrix of (statistically) equivalent structure.



Embedded model, confined boundary
Isolated model, free boundary
Matrix of statistically equivalent structure

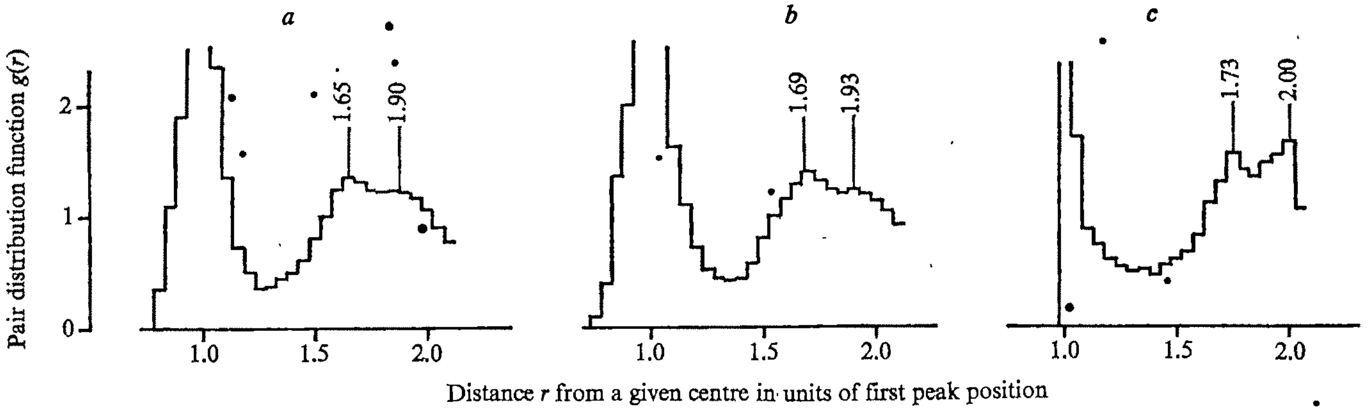

Fig. 2 Pair distribution functions of *a*, an amorphous bulk $Ni_{76}P_{24}$ alloy[5], *b*, vapour-deposited amorphous Co (ref. 2), *c*, a random close-packed assembly of hard spheres[14]. $g(r)$ is the probability of finding an atom at distance r from any atom. The packing density of (*c*)—the ratio of total volume occupied to the total volume of spheres—is 0.6366 ± 0.0004 (ref. 14). The relative positions (r_2/r_1 and r_3/r_1) of the two components of the split-second peak are indicated.

building an array of a large number of such simplified molecules, consistent with what we otherwise know of the real system. In the metallic case, we simplify our atoms initially to hard spheres, expecting the structure to be determined largely by the repulsive core of the real potential function, as is known to be the case in crystals and liquids[12,33-35]. However, when we try to put our idealised atoms together into a non-crystalline dense assembly, we run into difficulties which we must examine.

Boundary problems

Consider for example a hypothetical bulk amorphous metal. Any model we build can represent no more than a small sample of the bulk material However, the model must be capable of extension indefinitely in three dimensions, without any significant change in structure. This gives rise to what might be called the 'embedding problem' (Fig 1). An adequate model must be consistent with its infinite extension, the model boundary must therefore be consistent with the constraints that would be imposed by the presence of similar arrangements of molecules at that boundary. This is particularly relevant when we consider the variety of methods used to prepare amorphous metallic assemblies. The growth process and the boundary conditions operative during the sequential deposition from the vapour of a thin film of amorphous cobalt are very different from those relevant to the production of an amorphous alloy by rapid quenching of the liquid *A priori* there is no reason to assume identical structures will occur in these two extreme cases. A multiplicity of different amorphous structures may well exist, depending on the material and how it is prepared. Our modelling procedures should be capable of handling these possibilities

Experimental comparisons

A general problem of characterising the structures of non-crystalline materials concerns the relatively low information content of the usual structural measurements. X-ray and neutron scattering from crystals can give a relatively vast amount of very specific spatial and dynamic information. In non-crystalline materials the spatial information obtainable is limited to a statistical average projection of the structure on to one dimension. By carefully Fourier transforming the coherent scattered radiation we can obtain a pair distribution function (PDF) (see Fig. 3). This tells us the probability of finding an atom at a distance *r* from any given atom. It is the crystallographer's Patterson function projected on to one dimension. This PDF is a relatively insensitive structural measure but because it is easily accessible from both real materials and model coordinates, agreement of the model and experimental PDFs is an essential filter for postulated models. Agreement is a necessary, but far from sufficient condition which a successful model must fulfil. Because of the series termination problems inherent in the Fourier transformation of the scattering function[36], it is often preferable to compare real scattering functions with those predicted by a given model, especially when considering refined models. However, the structural reasons for disagreements between model and experimental scattering functions are not obvious in the scattering functions themselves. Thus, in what follows, we will use the PDF filter to examine postulated models and refinements, together with the densities of model and real material This somewhat old-fashioned property is often easily measured, and provides an additional powerful filter which leads to rejection of many postulated models The relatively high densities of amorphous metals and alloys are, in fact, not easily reproduced in model structures, because of the imperfectly understood packing restrictions in non-crystalline dense assemblies

Early models

The first model to be widely applied to amorphous metals and alloys was constructed in the laboratory by packing together as densely as possible a large number of equal steel spheres, taking precautions to prevent ordering effect at the boundaries[14]. This work was initiated by Bernal in the late 1950s (refs 12, 13) to try to elucidate the geometrical nature of the liquid state. Similar work was performed independently by Scott in Toronto[14] Cohen and Turnbull suggested[37] such models might be applicable to the then still hypothetical amorphous metal. However, its first specific application was to electrodeposited $Ni_{76}P_{24}$, whose X-ray scattering could not be reconciled with any realistic model based upon microcrystalline units[5].

Fig 2 compares the PDFs of electrodeposited $Ni_{76}P_{24}$, vapour-deposited amorphous Co (refs 2, 3), and the model dense hard-sphere packing out to two sphere diameters Qualitatively, the agreement of both real systems with the model is good The second peak is split in all three cases; at the time the hard-sphere model alone was able to account for this peak splitting. Moreover, the densities of model and experiment are of the same order, although precise quantitative comparisons are difficult as there is a degree of freedom in scaling the model to the real assemblies

However, the quantitative agreement is far from perfect. The relative intensities of the two components of the split-second peak are predicted the wrong way round, and their relative positions r_2/r_1 and r_3/r_1 (measured with respect to the position of the 1st peak r_1) are slightly discrepant (Fig. 2). Moreover, how justified are we in applying such a simple single component model to both (1) a binary alloy stable in the bulk, and containing a slightly smaller atom of different chemical nature (the 'glass former' phosphorus), and (2) a thin film of material containing only one metallic component, and produced by sequential vapour deposition? We cannot really ignore the effect of a glass former, which may induce specific local structuring effects in bulk NiP case, even though the effect on the PDF may be small. Nor should we necessarily expect the film material, prepared by sequential deposition from vapour, to have a structure similar to that of a model prepared to simulate specifically a bulk system.

Nevertheless, this agreement of PDF and density was sufficiently good to encourage proceeding on the postulate that the idealised hard sphere model incorporated the essential geometry of both types of system. We can now consider possible improvements to this idealised structure by examining the effects on it of, for example, different building methods, binary and more complex mixtures, different potential functions, and variations in boundary conditions. We are thus able to relate the above idealised structure more closely to that of the real materials.

Model refinements and alternative structures

Building and measuring large physical models in the laboratory is a painstaking business, and involves several imperfectly-controllable variables. Transferring the model-building to a computer facilitates tighter control of these variables, and enables structural variations to be investigated relatively rapidly. Nevertheless, there are severe restrictions on computer modelling. For example, it is very difficult to program those collective rearrangements of molecules that are necessary in order to reproduce the high densities obtained in laboratory models and the real materials, especially if large models are required. On the other hand, subtle structural effects of different potential functions can be readily examined, as can the effects of boundaries. Molecular dynamics simulations can generate structures consistent with external thermodynamic constraints in a way that both 'static' laboratory and computer building cannot hope to do. Even so, the long relaxation times of non-crystalline or glassy materials, compared with the elementary molecular dynamics time step, presently limit full simulation calculations to quenching rates much higher than those achieved in the laboratory; hence these methods can produce little more than configurationally arrested liquids. However, taking together these three building methods, we can tackle effectively many of the interesting static and dynamic problems of glasses and non-crystalline solids.

Laboratory models

Little further laboratory modelling of amorphous metals and alloys has been reported. A recent study of 60:40 binary mixtures of hard spheres, size ratio 4:5, by Scott and Koniuk (personal communication) does show a reversal in the split-peak intensities, and also a reduction of the r_2/r_1 ratio to 1.89, much closer to the real $Ni_{76}P_{24}$ value. The r_2/r_1 ratio, however, remains unchanged at about 1.73.

Computer algorithms

Various procedures have been used to build hard-sphere packings both in the bulk and as thin films. The most widely used is the sequential building method of Bennett[15], where each sphere is added in turn to a previously-existing tetrahedral site. The choice of site can be varied. Bennett originally used both 'global', and 'local' criteria. In the former scheme, a sphere is added at that site closest to the centre of the existing cluster, while the 'local' criterion chooses that tetrahedral site nearest to the plane of the three

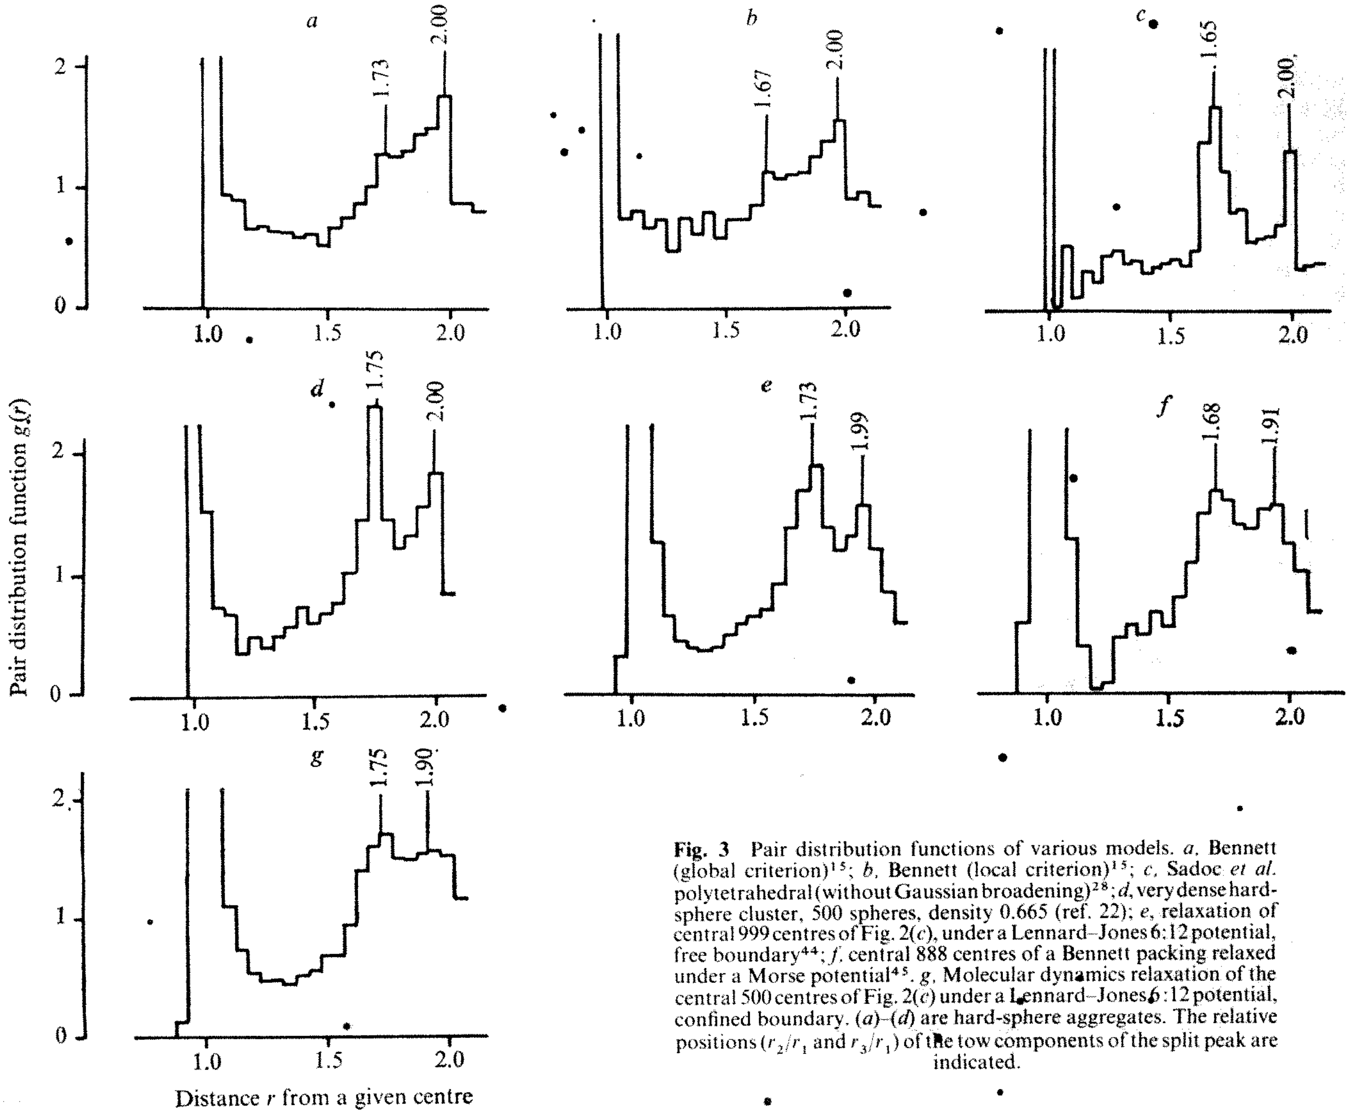

Fig. 3 Pair distribution functions of various models. *a*, Bennett (global criterion)[15]; *b*, Bennett (local criterion)[15]; *c*, Sadoc *et al.* polytetrahedral (without Gaussian broadening)[28]; *d*, very dense hard-sphere cluster, 500 spheres, density 0.665 (ref. 22); *e*, relaxation of central 999 centres of Fig. 2(*c*), under a Lennard-Jones 6:12 potential, free boundary[44]; *f*, central 888 centres of a Bennett packing relaxed under a Morse potential[45]. *g*, Molecular dynamics relaxation of the central 500 centres of Fig. 2(*c*) under a Lennard-Jones 6:12 potential, confined boundary. (*a*)–(*d*) are hard-sphere aggregates. The relative positions (r_2/r_1 and r_3/r_1) of the tow components of the split peak are indicated.

spheres defining it. Clusters of up to 4,000 spheres were built, and densities, extrapolated to infinite volume to eliminate size and boundary effects, were significantly lower (about 4%) than achieved in the laboratory packings. Sample PDFs are shown in Fig. 3(*a* and *b*). In both cases, the peak splitting is incomplete, reflecting the lower model densities. The peak positions of the 'global' model remain as in the laboratory packing, while for the 'local' model, r_2/r_1 alone is at 1.67 in better experimental agreement.

The Bennett procedure is very simple and fast, and has been used extensively with different boundary constraints, and with varying criteria for sphere additions[15–21,25]. Several of these models reproduce r_2/r_1 relatively well, but fail to bring r_3/r_1, closer to experimental values. Moreover, and more seriously, the densities of such models are low. It seems that for hard spheres at least, reproducing the positions and relative intensities of the experimental split second peak components requires a model whose density is too low. The packing constraints in a sufficiently dense model seem to be inconsistent with the adequate presence of those local geometrical structures which are consistent with the experimental split-peak component intensities and positions. This density–local structure problem is illustrated further by the polytetrahedral model of Sadoc *et al.*[28]. The algorithm used tries to reproduce the structural effects of the glass-former phosphorus in an amorphous Co–P alloy. In crystalline Co_3P each phosphorus is surrounded by 9 cobalt atoms in an incomplete icosahedral organisation. Sadoc's algorithm attempts to reproduce this icosahedral organisation, albeit slightly distorted from ideality. In Sadoc's resulting 'polytetrahedral' model, the relative peak heights are reversed, and the r_2/r_1 ratio is brought down to 1.65; r_3/r_1 remains at 2.00 (Fig. 3*c*).

However, this model also is not densely packed, having an average density 18% lower than random close packing[38]. It can be considered as an aggregate of dense, distorted icosahedral units, with considerable void space between them[38]. Thus, although the PDF of this inhomogeneous, clustered polytetrahedral model is qualitatively better than the homogeneous hard-sphere model, a consequence of forcing this clustering is, through the packing constraints, to prevent the achievement of a sufficiently dense assembly.

As long as we use hard spheres, the local structure which can explain the split second peak seems inconsistent with the high densities obtained in real materials. This is further underlined by an entirely different construction algorithm which simulates the compression of a hard sphere gas[22,24]. Here, collective rearrangements can be (rather laboriously) programmed, and very high densities achieved provided a free boundary is maintained. Figure 3(*d*) shows the PDF of such a 500-sphere cluster of packing density 0.664 (ref. 22). This is 4.2% higher than the 0.637 maximum obtained in the laboratory, a density which is thought to be the upper limit for a bulk random packing[14,39–41]. Here again, although we can reverse the split-peak intensities, we cannot budge their position[5]. From an examination of the nature of local clusterings, an interesting result arises. As density increases, the proportion of distorted icosahedral clusters—Sadoc's polytetrahedral clusters—increases slowly, although constituting barely a few per cent of the volume of the array[22]. Above a density of about 0.63, however, these 'spherically-polytetrahedral' units are forced out, demonstrating further that such locally dense clusters are indeed inconsistent with an overall high density.

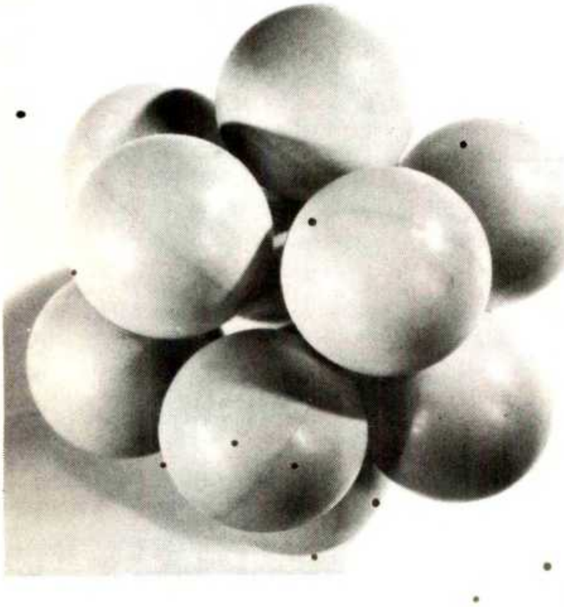

Fig. 4 Icosahedral arrangement of 13 spheres, related directly to the local geometry in 'spherically-polytetrahedral' models. This arrangement is that of minimum potential energy for soft spheres with a free boundary.

This result is not surprising for hard spheres. The geometry of the icosahedron is such that the 12 surrounding spheres have some freedom of movement on the surface of the central one (Fig. 4). For soft spheres—more like the real molecules—the 'squashiness' of the atoms would be expected to stabilise considerably such local units (Hoare and McInness, personal communication). The question thus arises as to the interplay of increased icosahedral stability at the local level and the overall packing constraints in a real dense structure. Are the two tendencies more mutually compatible when the artificial infinitely–hard repulsive core is softened?

Computer refinements and molecular dynamics

The effects of softer potentials have been examined by (1) relaxing laboratory or computer-built hard-sphere models under various soft potentials[43–46], and (2) very rapidly quenching liquid configurations by molecular dynamics[41,47–50]. The results from both approaches are in excellent agreement, and give good second-order models directly related to the first-order idealised hard-sphere model. However, various questions about local geometry, and their relevance to the glass transition in metallic systems, remain to be answered fully[38,51]. In one such relaxation calculation, the central 1,000 sphere coordinates in the laboratory-built hard-sphere model (Fig. 2*c*) were scaled to a Lennard Jones 6:12 potential and allowed to relax towards a potential energy minimum, in free boundary conditions[44]. Movements were generally small, being limited by the high density of the starting configuration. Fig. 3*e* shows the relaxed PDF. the split-peak intensities again reversed, and only a small inward movement of r_3/r_1 was observed. r_2/r_1 was unchanged, and it was suggested from geometrical arguments that this peak position should be sensitive to the softness of the repulsive potential. The degree of local distorted icosahedral clustering increased, but only slightly. These results are in close agreement with recent simulated Lennard–Jones glasses produced by almost instantaneous liquid quenching[41,48,49].

Slightly different results were obtained in a series of molecular dynamics calculations with confined irregular boundaries using the same potential and starting configuration[46]. Again an intensity reversal in the PDF was observed (Fig. 3*g*), and the inward movement of r_3/r_1 under the much higher pressure was significant. However, the degree of local 'spherical polytetrahedrality' was very low, such clusters having been presumably squeezed out under the very high pressure. Similar PDFs were obtained using a simulated harmonic potential[23]; the local geometry was not examined.

The Lennard–Jones 6:12 potential is thought to have too hard a repulsive core for realistic metallic atoms. Hence a relaxation of a hard-sphere packing under a soft Morse potential (unfortunately again in free boundary conditions) is of particular interest[45]. The PDF peak intensities reverse, and both r_3/r_1 and r_2/r_1 fall to values closer to the experimental (Fig. 3*f*). Thus, the position of the first component of the split peak does indeed seem sensitive to the softness of the potential. Such a relaxed model gives relatively good PDF and density agreement for amorphous metallic films. The agreement with the binary metal-metalloid alloys is less good. The relation of the r_2/r_1 shift to the local cluster arrangement is as yet uninvestigated in such very soft sphere assemblies.

Conclusions

The work discussed above is, because of the widely varying conditions, and assumptions made, difficult to assemble into a coherent and water-tight picture[52,53]. We can, however, make several generalisations about random packing, its application to real non-crystalline metallic alloys, and the problems and future prospects for modelling amorphous solids in general. We can also speculate a little about structural aspects of the glass transition and crystal nucleation.

We now have a much better idea of the nature of random packing. For hard spheres, a maximum packing density of about 0.637, is now well established for both modelling[14,39] and molecular dynamics extrapolations[40,41]. This maximum density can be achieved only by a relatively homogeneous assembly, with very little clustering into local icosahedral structures. Such clustering is prevented by the overall packing constraints. The homogeneous model is, however, polytetrahedral in that 70% of the assembly consists of relatively perfect tetrahedra[13]—naturally the densest local arrangement possible for four spheres. These tetrahedra are organised, however, not in the spherical clusters related to the stable icosahedral arrangements (Fig. 4) found in isolated atomic clusters[38,42,51,54], but in the twisted spirals of Bernal's 'pseudonuclei' (Fig. 5)[13].

In adequately dense packings of slightly soft spheres, the tendency towards local 'spherically polytetrahedral' clusters (Fig. 4) increases, but only slightly[44]. This increase is certainly very much less than that suggested in the much less dense specifically polytetrahedral models. 'Spiral-polytetrahedrality' (Fig. 5) is more stable under the local packing constraints found in dense assemblies. As long as the overall density remains high, there is insufficient volume available to allow the formation of many disorted icosahedra and their associated inter-cluster voids. It would seem that for molecules such as the rare gases where a Lennard–Jones 6:12 potential may be reasonable, the glass transition might more realistically be associated with the formation of relatively stable 'spirally polytetrahedral' clusters[13] than the 'spherically polytetrahedral' ones stable in isolation[38,42,51].

For even softer potentials, the situation may be different. The extra freedom conferred by the softness of the potential may change the relative stability within a dense packing of spherical against spiral tetrahedral assemblies. A detailed geometrical analysis of such a relaxed assembly would help clarify this point.

The hard sphere packing provides an idealised model of the structure of several amorphous metal films and metal–metalloid alloys. All modifications made to achieve a better model result in improved intensities of the split second peak of the PDF (Fig. 3)[22,23,43–45]. Only very soft potentials improve the position of the first component of the split peak (Fig. 3g)[45]. The relaxed hard-sphere model is indistinguishable from a Lennard–Jones glass[48], while the hard-sphere model itself is indistinguishable from a hard-sphere glass as produced by molecular dynamics[41].

The structural effects of boundary conditions can be significant[38,44,46]. Thus we should not necessarily expect vapour-deposited materials to have the same structure as those produced by liquid quenching. Moreover, a splat-quenched structure and vapour-deposited structure may well not be mutually accessible directly. This underlines the possibility of 'amorphous polymorphs' of the same substance, and the possibility of different amorphous structure for different substances[38]. Thus it would be interesting if amorphous phases of the same material could be produced by different routes, and their structural differences examined in detail, together with the possible routes for transformation between them[51,52]. The clustering effects of glass-formers are likely to be significant though they are not well worked out.

Future modelling work on amorphous assemblies of spherical atoms must take adequate account of both the local effects of the potential functions and the overall packing constraints as reflected in the density and the boundary conditions. Structure can be very sensitive to both these factors. As a filter of possible model structures, agreement with the PDF is a necessary though far from sufficient condition. More attention should be paid to the old-fashioned property of density—qualitative agreement with PDF is hardly convincing if the density is unrealistically low.

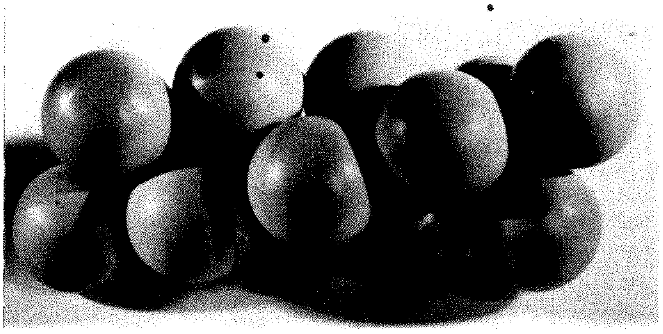

Fig. 5 A 'spirally-polytetrahedral' arrangement of 13 spheres, the so-called Boerdijk spiral of face-sharing tetrahedra. Such arrangements occur frequently in random packings of hard spheres.

The necessity to achieve high density models—and structural consistency with a bulk structure—raises severe difficulties for sequential building methods. These are basically unable to account for the high densities of real amorphous metals and alloys. Full molecular dynamics calculations can help overcome this, although the method is restricted severely by real time limitations. Although it is relatively straightforward to simulate a very rapidly-quenched liquid, the computer time required to simulate a quench on a realistic laboratory time scale, or a vapour deposition, is presently prohibitive. Thus, the detailed structural nature of the glass transition is not directly accessible thereby. Progress might be made by combining molecular dynamics with energy minimisation techniques[52], as has been done for the much more difficult but related protein folding problem[55,56]. These comments apply in general to the modelling of other glassy systems. Modelling is, however, still an inadequate substitute for more analytical approaches to the problems of local correlations in very dense, disordered systems. Although the last fifteen years of modelling a variety of amorphous solids, from the metallic systems considered here to oxide and chalcogenide glasses, has drastically increased our understanding of various non-crystalline systems, the methods become rather cumbersome when looking at refinements of first-order models. Moreover, especially in chalcogenide and more complex metallic alloy systems, the constraints that should be applied to the model-building may be insufficiently well formulated for the resulting models to be realistic. The interplay between the predicted properties of a postulated model, comparison with the real material, and feed-back to improve the model can be exceedingly time-consuming, and perhaps inconclusive once the basic idealised structure has been established. As the real amorphous systems we are interested in become more complex, the more difficult it becomes to handle, by simple modelling, the possible variables and possible heterogeneity of the structure. In some ways it is too easy to build models. To do it realistically, to represent a bulk system with adequate density, PDF, and density fluctuations in ill-defined or complex mixed systems is very difficult. And rather than turning a handle *ad infinitum* to improve marginally our models of simple systems whose basic structure we understand, we should pay more attention to the absence of an underlying theoretical framework, an absence which made modelling necessary in the first place. Only when such an adequate analytical approach to very dense, non-crystalline systems has been established—without the problems attached to integral equation approaches to the liquid state—will a full understanding of the complexities of these amorphous structures, their dynamics, their glass transitions and nucleation process, be realised. Data from models will have a role in the development of such techniques[57].

New palaeomagnetic evidence fails to support rotation of western Newfoundland

E. R. Deutsch & K. V. Rao

Geomagnetic Research Laboratory, Department of Physics, Memorial University of Newfoundland,
St John's, Newfoundland, Canada

Palaeomagnetic results from Ordovician to late Precambrian rocks in western Newfoundland are inconsistent with Wegener's hypothesis that the island has rotated 30° anticlockwise. Previous evidence apparently supporting this hypothesis is shown to be inconclusive.

WEGENER[1] proposed that Newfoundland has rotated 30° anticlockwise away from Labrador, implying a nearby pivot. A palaeomagnetic test of this motion is, in principle, straightforward, provided that test sites are carefully chosen (Fig. 1). Even so, the resolution obtainable may be small or zero, being a function of both the rotation angle R and the angular distance θ between pivot and ancient pole. Figure 2 illustrates this for Newfoundland ($R=30°$), where values of P ('resolution') approaching 30° are obtainable at Lower Palaeozoic sites suitable for testing possible Devonian or later rotations. Hence a near-optimum test is feasible because of the low latitude of ancient Newfoundland.

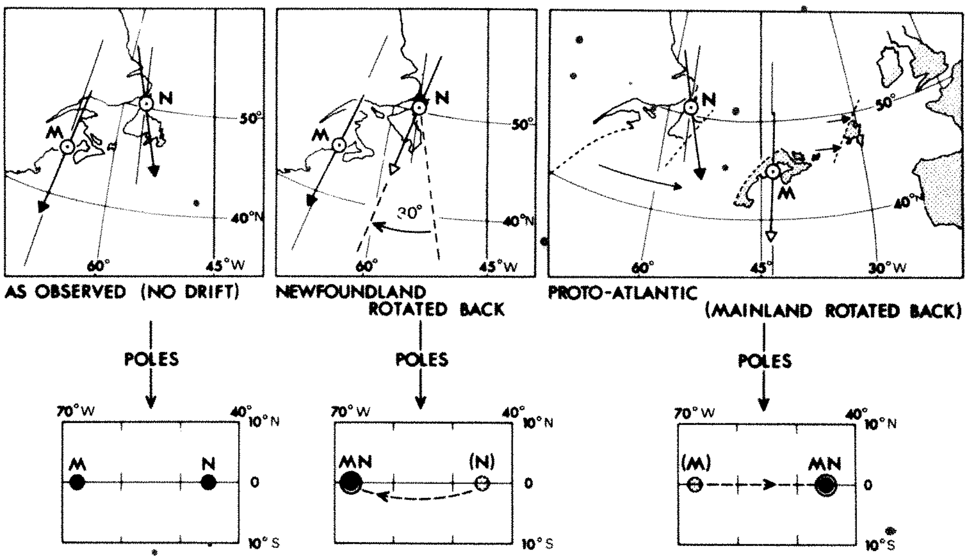
After an inconclusive application of this test[2,3], Black[4] compared Palaeozoic rocks of matching age in western Newfoundland and mainland eastern Canada, concluding that his data uphold a 30° anticlockwise rotation of at least western Newfoundland during the middle to late Devonian. Black argued that this would explain observed regional structures in the north-eastern Appalachians. Except for differences in latitude, his widely quoted Cambrian and Devonian comparisons conform strikingly to the positive test in Fig. 1. Regional and local tectonics[5,6] and seismic results from the Gulf of St Lawrence[7] have been cited as evidence against this rotation. Further, Black's data were found inconclusive[8], because (1) the Cambrian remanence directions inferred in Newfoundland and New Brunswick (Fig. 3, S, R) are not significantly different; (2) the respective "Devonian" directions may not be contemporaneous; (3) by demagnetising only in alternating fields (AF) to 300 Oe, he was unlikely to have distinguished different high-stability components. Also[9], since the mainland sites (Fig. 3, R) form part[10] of the Avalon tectono-stratigraphic zone, rocks on opposite sides of the Central Mobile Belt were being compared (R, S). Therefore data in Fig. 1 could equally be taken to support either a rotation of Newfoundland or a proto-Atlantic model[11].

New magnetic data

To meet these objections we undertook new magnetic studies of mid-Ordovician to latest Precambrian rocks in Newfoundland (Fig. 3, N1–N3, N5–N7), using standard equipment. The results, summarised below and in Table 1, will be reported in greater detail elsewhere. Comparisons are with published data from tectonically stable mainland regions (Table 2).

Useful palaeomagnetic results have been obtained from carbonate rocks[12–14]. We collected limestone of the Lower Ordovician[15,16] St George Formation at 10 sites (62 samples) in the Port-au-Port area (N1). The natural remanence (NRM), carried in different samples by magnetite, haematite or both (compare ref. 14), was weak and fewer than half of the samples could be demagnetised. Haematite samples were unaffected by AF treatment (800 Oe) while thermal treatment was inconclusive, but in the magnetite samples both methods produced comparable, better-grouped new remanence directions (Table 1). St George limestone from Cape Norman (N2) gave similar results. This magnetic

Fig. 1 Palaeomagnetic test of rotation (schematic). Declinations of hypothetical 'observed' remanence vectors (solid arrows) and corresponding pole positions are shown for Newfoundland (N) and the adjacent mainland (M). Hollow arrows depict the restored vectors when either Newfoundland is rotated back[1] or the mainland site is rotated to a presumed location before the closing of a proto-Atlantic ocean[11]. The pivots are at site N and 90°N, respectively. For convenience, poles have been located at the present equator. The two rotations here are indistinguishable[9]: an unambiguous test of the Newfoundland rotation requires comparison with a mainland site known not to have rotated. Stippled portions (right) correspond to the Atlantic faunal realm[11].



behaviour in Newfoundland limestones parallels that found earlier in the mid-Ordovician Trenton limestone[12] (M1), where it was shown that the stable component originated before the completion of diagenesis. This suggests a similar origin in the Port-au-Port limestone, but proof is difficult and it is uncertain whether one should correct for the gentle (12–15°) tilt which is associated[10] with the Taconic (pre-mid-Ordovician) or Acadian (Devonian) orogeny or both. The (uncorrected) mean directions for areas N1 and N2 after AF or thermal treatment are all similar (Table 1). Pole N1 (Table 2) is based on sample rather than site statistics, since too few samples per site remained measurable after AF treatment. The tilt-corrected pole is 22°N, 120°E. Pole N1 is not significantly different from Pole N4 (ref. 13) for the St George Formation, where no tilt correction was reported.

A result[17] from pillow basalt and sheeted dikes of the Moreton's Harbour Group (N3) is useful for comparison with the St George Formation, since different rock types of similar ages are being compared. Most or all of the 8-km thick Moreton's Harbour sequence has been attributed[18,19] to island arc volcanism in the Lower[19] to Middle[18] Ordovician. Although these rocks lie in the Central Mobile Belt (Fig. 3), it seemed reasonable to include them in a test based on western Newfoundland, since they probably originated as part of the North American margin (D. F. Strong, personal communication). A stable remanence in magnetite, isolated by AF demagnetisation, presumably was acquired not later than the generally low-grade greenschist metamorphism of these rocks. The tilt-corrected pole (Table 2) is not significantly different from poles N1 and N4 (Fig. 4).

Lower Cambrian[15] Bradore sandstones sampled by Black[4] at St John Bay (Fig. 3, S) were re-sampled more extensively[20] at Canada Bay (N5). The NRM, carried by haematite, had a mean direction as in Black's AF-treated samples (Table 1), but by thermal demagnetisation a stable component misaligned with both the NRM and Black's direction was isolated at 665 °C: this shows that the objection[8] to exclusive low-AF treatment is well-founded. This component probably pre-dates the gentle (15–25°) Taconic and/or Acadian tilt of the sediments, though a post-tilting origin of the entire NRM is not impossible[20]. The stable direction corresponds to a reverse pole at 23°N, 160°E

*Ages are discussed in the references (see also Table 1). Ref. 26: Radiometric ages in the range 601–427 Myr are cited. Ref. 29: The authors cite numerous K/Ar ages with 'best mean age' 650 Myr, but they adopt 675 Myr, to allow for argon loss. Ref. 31: Other Franklin igneous sites have K/Ar ages matching an isochron of 625 Myr. Refs 32–36: 'Grenville' ages in the range 0.9–1.0 × 10^9 yr are cited, based on radiometric data or on inferred time of magnetisation.

†*N*, see footnote to Table 1; Treatment: a, alternating-field; t, thermal; a+t, mean of poles based on a and t treatment; Polarity: N, normal; R, reverse; M, mixed.

‡Average values are quoted for 30° clockwise rotations about pivots A (51.5°N, 56.5°W) and B (48°N, 59.5°W) (Fig. 3).

§Recalculated from original data.

‖Error circles (α_{95}) instead of ovals are cited by authors.

(Table 2), or 29°N, 167°E after tilt correction. Bradore standstones from St John Bay (N6) gave comparable (virtual) poles.

The gently dipping Cloud Mountain plateau basalts (N7) were sampled at 10 sites. They have been correlated stratigraphically[21] and through magnetic similarities[22,23] with plateau basalts in south-east Labrador of presumed late Precambrian to early Cambrian age[21]. Strong and Williams[24] consider the Cloud Mountain basalts to be co-magmatic with and contemporaneous with the chemically similar Long Rang dikes, which have a ^{40}Ar/^{39}Ar dating of 605±10 Myr (ref. 25). Only three separate flows could be identified. AF treatment isolated a stable component carried by magnetite, resulting in greatly improved within- and between-flow vector groupings. Its mean direction after tilt correction corresponds to the pole shown in Table 2. We note that a residual secular variation component may be present in these few flows.

Rotation test

There is no unique pivot for the postulated rotation of western Newfoundland. Black[4] relocated his Newfoundland palaeomagnetic poles by rotating the island 30° clockwise separately about two extreme pivots A and B (Fig. 3) using the mean restored pole position to compare with poles on the mainland. A similar procedure is followed here (Table 2). The uncertainty in pole positions due to averaging about the two pivots is ⩽1°.

Out of the three identical Ordovician Newfoundland poles, N1 and N3 are in turn identical with, and pole N4 is close to, the Trenton limestone pole[12] (M1). Here 'identical' is defined non-rigorously by an overlap of the 95% confidence ovals (Fig. 4). Pole M2 from the Front Range Intrusives[26] of uncertain Cambrian to Ordovician age is shown without oval, being the average of two poles equally weighted in ref. 26, based on AF and thermal treatment, respectively; the former but not the latter pole is identical to poles N1, N3, N4 and M1. With Newfoundland rotated back, the 'N' and 'M' poles become discordant, except pole N3 for which the test is inconclusive. These results are

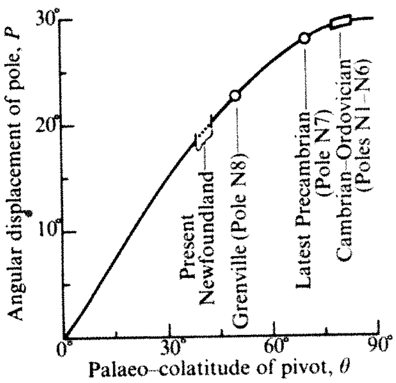

Fig. 2 Resolution (*P*) obtainable by palaeomagnetism for testing rotation (*R*) of a land mass, as a function of the angular distance (θ) between pivot and ancient pole, where[9]: $1-\cos P = \sin^2\theta\,(1-\cos R)$. *P* is the angular shift of the ancient pole on restoring the land mass to its pre-drift position. *P* cannot exceed *R*. Illustrated for the Newfoundland hypothesis ($R = 30°$) using actual results (Table 2). Note that, with minor error in θ, site locations N1–N8 may be substituted for the average pivot locations A and B (Fig. 3).

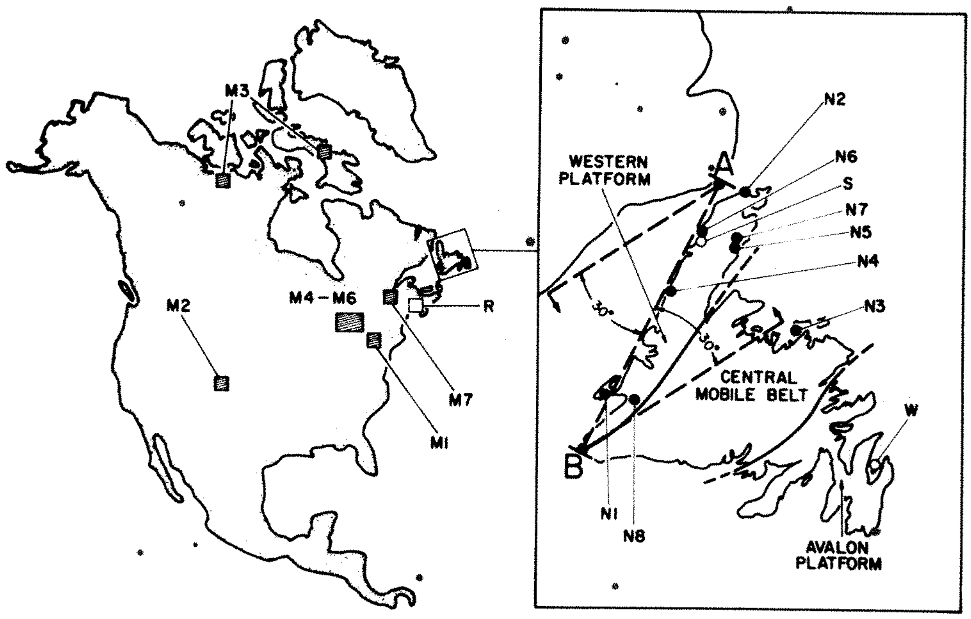

Fig. 3 Palaeomagnetic sites for testing rotation of Newfoundland (Tables 1, 2). R, Ratcliffe Brook, New Brunswick • (Lower Cambrian)[4]; M1–M7, other mainland sites. S, St John Bay[4]; W, Wabana[37]; N1–N7, other Newfoundland sites. A, B, alternative pivots[4] (Table 2).

incompatible with the proposed rotation, at least since mid-Ordovician time. A provisional Upper Ordovician pole (R. Van der Voo, personal communication) at 29°N, 118°E from thermally cleaned red sandstones of the Juniata Formation, Pennsylvania, is not significantly different from poles N1 (30°N, 119°E) N3, N4 and M1. This agreement may be due to insignificance of mid- to late-Ordovician polar motion relative to eastern North America, in which case the Juniata result is additional evidence against rotation of western Newfoundland.

Comparisons of the Bradore data[20] (N5) with those from Cambrian mainland localities that avoid the proto-Atlantic ambiguity are difficult, since the few reliable mainland poles (see ref. 27) have been cited as Upper rather than Lower Cambrian in age; also they are widely dispersed, suggesting rapid polar displacement. Hence a rotation test using the Bradore result seems premature. A Lower to Middle Cambrian pole at 13°N, 157°E for eastern Quebec was recently reported[28], however. Its fair agreement with the Bradore pole (23°N, 160°E) is destroyed when Newfoundland is rotated back. This may be taken as evidence against the proposed rotation.

On the mainland the youngest suitable Precambrian rocks are the Franklin intrusives[29–31]. Of numerous K–Ar datings, 675 Myr is the adopted age[30] cited for pole M3 (Table 2). but other Franklin diabases and lavas[31] give a pole close to M3 and are dated 625 Myr, compared with the 605-Myr age inferred for Cloud Mountain (N7). Figure 4 shows agreement between poles N7 and M3, but they strikingly diverge when Newfoundland is rotated back. Pending better knowledge of the Newfoundland–mainland age difference and of the time span averaged in the Cloud Mountain lavas, this result again is inconsistent with the rotation hypothesis.

The minimum radiometric age of 890–900 Myr of the Indian Head anorthosites[32] (N8) suggests that they may be contemporaneous with mainland rock formations dated at the time of the Grenville orogeny (1.0×10^9 yr). Pole N8 was compared with only mainland poles dated $0.9–1.0\times10^9$ yr, based on anorthosite (M4–M7)[33–36], to make it more probable that a synchronous Grenville event is being tested. Once again an initial agreement between 'N' and 'M' poles is lessened when Newfoundland is rotated back (Fig. 4). Unrotated, the oval of pole N8 overlaps all mainland ovals, whereas after rotation it misses two of these (M5, M6). The large size of oval N8, however, makes this test only marginally significant.

Significance of the test

Newfoundland data from the Ordovician, latest Precambrian, more marginally the Grenville and perhaps also the Cambrian, when compared with the mainland results, provide evidence against Wegener's[1] hypothesis. At the

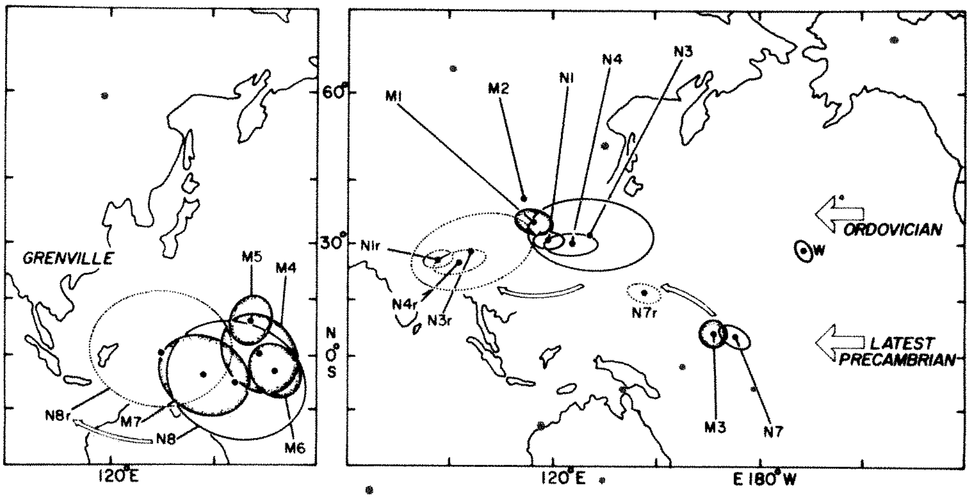

Fig. 4 Negative results of the rotation test for three age levels. Pole positions with 95% confidence ovals (Table 2) for the mainland (M) (shaded ovals), and Newfoundland (N) as observed (solid ovals) and after rotation (dotted ovals, site numbers followed by '*r*'). W, Wabana (Fig. 3 and text)[37]. Magnetic north or south poles are plotted to correspond to presumed north rotation poles.

same time we have verified that Black's[4] Cambrian results used by him in support of that hypothesis are inconclusive. Generally better data were available to us than to the earlier workers[2,4] in terms of statistics, magnetic control and comparative dating. Limitations are, however—(1) some large confidence ovals; (2) different populations (samples, sites, flows) being compared; (3) the small number of usable limestone samples (15) and of Cloud Mountain flows (three); (4) uncertainty regarding tilt corrections; (5) possible anachronisms between poles of any given age; and (6) the absence of a reliably Lower Cambrian mainland result to compare with pole N5.

Partly because of these limitations, we could not employ rigorous statistics. For example, an *F* test applied to negative evidence on rotation would ideally show, in each case with high probability, that the mainland and unrotated Newfoundland poles for a certain age are identical and that they become distinct when Newfoundland is rotated back. Comparing actual data, such as Ordovician poles N1, N4, M1, the latter condition is certainly met, but the former condition is only moderately probable. The difficulty is predictable from Fig. 4 and recurs in an *F* test of the Grenville poles. This restricts us to the use of confidence ovals for assessing significance.

We conclude that the evidence is inconsistent with western Newfoundland having rotated by 30° since the late Precambrian, and is consistent with the absence of any rotation, although a rotation by 5°–10° since the Ordovician is possible. To determine whether such lesser rotation actually took place calls for more refined palaeomagnetic data from Newfoundland and North America.

Finally, a Lower Ordovician pole from Wabana, eastern Newfoundland[37] (W, Figs 3, 4) is seen to be far displaced from poles N1 and N4 of similar age in western Newfoundland. This is compatible with the hypothesis[11] of a Lower Palaeozoic proto-Atlantic Ocean of undetermined width, in which the two portions of Newfoundland occupied opposite coasts. Poles W, N1 and N4 may be made to coincide by rotating Wabana towards Europe about some pivot in the central Atlantic.

We thank R. R. Pätzold, Dr P. S. Rao, H. G. Dawe, T. Vallis and P. Kirby for assistance. This research was supported by the National Research Council of Canada.

Current rifting episode in north Iceland

Axel Björnsson, Kristján Saemundsson,
National Energy Authority, Laugavegur 116, Reykjavik

Páll Einarsson, Eysteinn Tryggvason
Science Institute, University of Iceland, Reykjavik

Karl Grönvold
Nordic Volcanological Institute, University of Iceland, Reykjavik, Iceland

A major rifting episode is now occurring in north Iceland. This started on 20 December 1975, with a basaltic eruption, an exceptionally intense earthquake swarm and movement on an 80-km segment of the plate boundary. Inflation and deflation of the Krafla caldera indicate upwelling of magma and injection into the rift zone. Historical records show that similar episodic rifting occurs in this region every 100–150 yr.

THE plate boundary between the American and European plates runs through Iceland as a zone of active volcanism, seismicity and graben structures. The two plates are drifting away from the boundary at a velocity of about 1 cm yr^{-1} (ref. 1), but the mechanism of this drifting process at the boundary itself has not been clearly observed until now. A spectacular rifting episode started in northern Iceland on 20 December 1975, and is still not completed in December 1976. Intense earthquakes, widespread ground deformation and magmatism are affecting an 80-km long segment of the plate boundary. We describe here the geological setting of these events, the main observations to date and an attempted interpretation.

In north Iceland the Neovolcanic Zone has a north–south direction. Towards the south it connects with the Eastern Volcanic Zone of south Iceland, but towards the north it is offset to the west by about 100 km, by the Tjörnes Fracture Zone, to join the Kolbeinsey Ridge (Fig. 1). The structure of the Neovolcanic Zone in north Iceland is dominated by large swarms of faults and fissures, most of which pass through different central volcanoes where volcanic fissure eruptions, silicic rocks and high-temperature geothermal fields are concentrated[2]. Two central volcanoes in this region, Krafla and Askja, have developed calderas. The fault and fissure swarms are arranged *en echelon* subparallel to the north–south direction of the main zone. The northernmost parts of these fissure swarms are intersected in the area of Axafjördur by the Tjörnes Fracture Zone, which has an east–west direction.

The Tjörnes Fracture Zone is a zone of high seismic activity and large earthquakes, most of which seem to be associated with right-lateral strike-slip on WNW striking faults, one of which, the Húsavík fault, has been identified on land, and another, the Grímsey fault, inferred from earthquake location and a fault plane solution. These faults run parallel to each other and are about 40 km apart. The Tjörnes Fracture Zone cannot therefore be viewed as a simple transform fault[2–4]. The present events have been confined to the Krafla caldera, the associated fault swarm to the north and a segment of the Grímsey fault (Fig. 1).

Similar tectonic sequences have occurred before in the Neovolcanic Zone: the last eruption associated with major tectonic movements occurred in 1874–1875 in the Askja caldera and the fault swarm to the north. In 1724–1729 an eruption took place in the Krafla caldera and ground fissures moved in the associated fault swarm.

Attempts made since 1938 to measure ground deformation in this part of the volcanic zone, by measurement of horizontal movement have so far yielded ambiguous results[5,6]. Measurements of vertical movements here since 1966 have shown subsidence of about 10 mm yr^{-1} (ref. 7). Preliminary measurements show that horizontal and vertical ground movement during the present event is at least 2 m.

A geothermal power station (60 MW) is now under construction inside the Krafla caldera, a diatomite factory is located on the fault swarm to the south near Námafjall, and a small village is situated at Reykjahlíd (Fig. 2). A more intensive effort has therefore been made to investigate thoroughly all aspects of the present tectonic events.

Geology of the Krafla–Axarfjördur area

The present activity is taking place mainly within the Krafla caldera and in the Axarfjördur depression. The two areas lie on a fault swarm which is about 100 km long and has a maximum width of 10 km (Fig. 1).

Basaltic fissure volcanism is concentrated mainly within the Krafla caldera and near Námafjall (Fig. 2). In postglacial time about 20 eruptions have occurred in the Krafla caldera and its nearest surroundings, and about 15 in the Námafjall area. Most of the fissure eruptions are basaltic, but andesite and dacite flows have also been erupted in both areas. Voluminous silicic eruptions have not occurred in postglacial time but four subglacial silicic eruptions within and around the Krafla caldera have produced large domes or ridges during the last glacial period. The Krafla caldera contains explosion craters that have ejected small quantities of rhyolitic pumice. The most recent crater formed in 1724 at the beginning of the 1724–29 volcanic episode (Myvatn fires).

Tephrochronological studies[8] indicate that postglacial volcanism in the Námafjall and Krafla areas occurred in two main periods: in early postglacial time, and during the last 3,000 yr. The period of repose may have lasted more than 4,000 yr. The Krafla and Námafjall parts of the fissure swarm have erupted 6–7 times each during the latter period of activity. At least two of the eruptions are common to both areas. Volcanism near Krafla has been concentrated along the central part of the fissure swarm during this period; earlier, it was dispersed over the entire caldera. The largest volume of basaltic lava produced in a single eruption in the area came from the Threngslaborgir–Lúdentsborgir crater row on the Námafjall part of the swarm about 2,000 yr ago. Its total volume has been estimated as 2–3 km^3 and the areal extent is about 220 km^2 (refs 9–11). Few flows of the swarm, however, exceed 0.2 km^3.

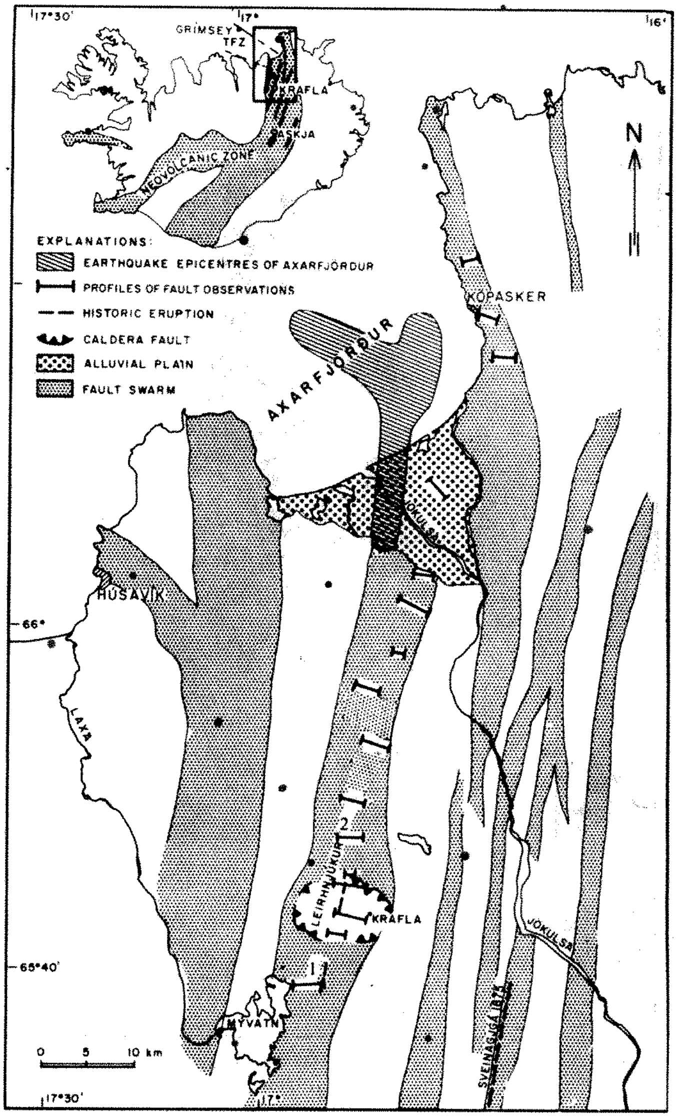

Fig. 1 Fissure swarms in the Neovolcanic Zone of north Iceland. The present rifting is taking place in the swarm through the Krafla caldera and extends from Myvatn to Axarfjördur. Inset map shows the location of the area in relation to the Neovolcanic Zone and the Tjörnes Fracture Zone (TFZ). Dates of activity: 1, 1727; 2, 1725–29, 1746, 1975.

The Krafla caldera measures about 10 km east–west and about 8 km north–south. It formed during the last interglacial period and has since been filled almost to the rim with volcanic material. The caldera's collapse almost certainly followed the eruption of a sheet of dacitic welded tuff which is exposed around the caldera (Fig. 2), and is an airfall tuff, blown mainly towards the north-east from a source near the centre of the caldera. A shield volcano with a diameter of at least 20 km existed before the caldera formation, and its remnants enclose the caldera on the east and west sides, exposing lavas and breccias dipping outward at low angles. Dykes and eruptive fissures trending parallel to the caldera ring fault are conspicuous around the caldera.

A high-temperature geothermal field lies within the caldera. Drilling has revealed temperatures >340 °C at

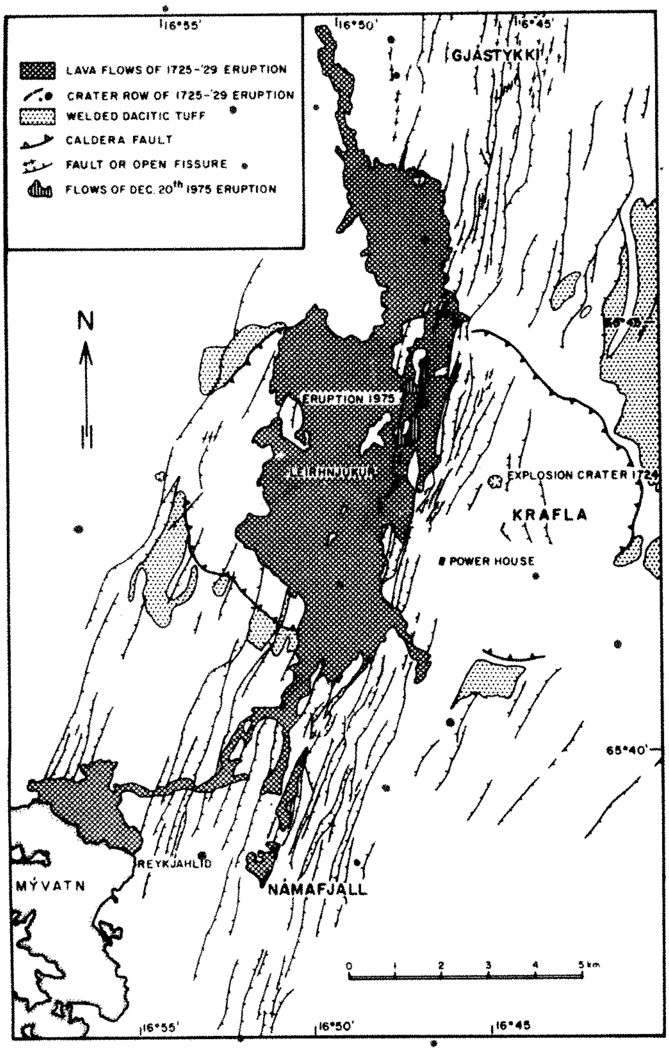

Fig. 2. Outline geological map of the Krafla caldera and the associated fault swarm.

2 km. Basaltic intrusions, with dolerite and granophyre, become increasingly abundant below 1.2 km. Corresponding coarse-grained rocks are conspicuous among xenoliths of the welded tuff and the ejecta of the 1724 explosive eruption. Another high-temperature geothermal field exists at Námafjall, and drilling to a depth of 1.8 km, revealed temperatures of over 290 °C.

Petrological studies in the Námafjall–Krafla area show compositions ranging from olivine tholeiites to rhyolites. Within postglacial time all these rock types have been erupted. The basalts of the fissure swarm through Námafjall and Krafla are quartz normative tholeiites which seem to be of almost identical composition throughout the region.

Axarfjördur is a down-faulted trough 25 km broad that has subsided at least 1,000 m relative to its uplifted western margin at Tjörnes during the Brunhes magnetic epoch[2]. Volcanism is unknown within the Axarfjördur depression but has occurred along its western and eastern margins. The fault swarm which passes through Námafjall and Krafla runs into the eastern part of the Axarfjördur depression.

Historic volcanic activity

Historical accounts mention only one eruption in the Krafla–Námafjall fissure swarm in 1724–1729. Contemporary descriptions of this eruption, the Myvatn fires, are available[12]. On 17 May 1724, a row of explosion craters formed. The eruption was mainly from one main crater, Víti, which ejected both silicic pumice and basaltic scoria, but mostly mud and rock debris from the near-surface rocks[13]. This eruption lasted only a day or two. In 1725, on 11 January, earthquakes occurred and ground fissures opened along the swarm from near Krafla southwards. Steam and mud craters formed in the Krafla and Námafjall geothermal fields, with little or no volcanic activity. Earthquakes were felt throughout 1725. No further significant activity was reported until August 1727, when a fissure eruption started in Leirhnjúkur near the centre of the caldera. A pulse in this eruption occurred in April 1728, when the eruptive fissure extended southwards to Námafjall. Another pulse occurred in December 1728. The lava continued to flow until September, 1729, when the eruption stopped. The lava flows cover about 35 km^2 and the total length of the discontinued volcanic fissure is 11 km (Fig. 2).

A minor volcanic eruption was reported on this fissure in 1746, accompanied by earthquakes and ground movements, but the eruption site or products have not been located.

A similar course of events was observed during the 1874–75 activity of the Askja caldera and the associated fault swarms[12,14]. In February 1874, increased steam emission was observed in the Askja caldera. Earthquakes and fissure movement were first observed during the autumn of 1874, 50 km north of the Askja caldera itself[14]. In January 1875, a small eruption occurred in the caldera, followed in February by a basaltic eruption within the fissure swarm, 50 km north of Askja, which continued intermittently for 8 months, accompanied by intense earthquake activity and considerable fault movement. Within the Askja caldera a maor silicic tephra eruption on 29 March produced approximately 0.5–0.7 km^3 of ash, calculated as solid rock[15], and a caldera of about 2 km^3 volume collapsed within the pre-existing caldera[15].

In 1618 earthquakes and faulting, lasting several months, in the fault swarm west of the Krafla–Axarfjördur swarm were recorded (Fig. 1) (ref. 16).

The initial seismic activity

Conspicuous seismic activity was noted in the Krafla caldera during early 1975. Towards the autumn, when earthquakes approaching magnitude 4 occurred there, it became apparent that this activity was unusually high. The number of seismograph stations was therefore increased, and in October 1975 seven stations were in operation within 60 km of Krafla. Furthermore, a local civil defense committee was set up and an emergency plan was designed in case of a volcanic eruption.

In the morning of 20 December 1975, the seismic activity increased markedly. Shortly after 10 a.m. continuous tremor was seen on the seismograph closest to Krafla, accompanied by an intense earthquake swarm that soon saturated the seismographs. When this increase in activity was noticed an eruption warning was issued to the Civil Defense Authorities shortly before 11 a.m. At 11 : 08 an eruption started near Leirhnjúkur in the centre of the Krafla caldera[17,18].

The vigour of the eruption decreased quickly and at the same time the seismic activity, that started near Leirhnjúkur, propagated northward along the fault swarm. Within 2 h at least 40 km of the fault swarm had been activiated.

The earthquake swarm that followed the eruption continued for several weeks but after the first few hours the activity was mainly confined to two separate areas: inside the Krafla caldera and in the Axarfjördur region (Fig. 1). In both areas the magnitude of the largest earthquqakes continued to increase until mid-January. In the Krafla caldera the largest earthquakes occurred on January 6 and 19 (magnitude 5.0), but in the Axarfjördur region the largest earthquake (magnitude 6.3) occurred on January 13, 1976, and caused considerable damage in the village

Kópasker and vicinity. From 20 December to mid-February, during the most intense earthquake swarm, 36 earthquakes of magnitude 4.5 or larger and six earthquakes of magnitude 5.0 and larger occurred.

The epicentres in the Krafla area during this time were distributed throughout most of the caldera. Most of these earthquakes seem to be related to some process within the caldera itself, rather than the fault swarm that crosses the caldera from south to north. Most of the hypocentres were between 0 and 4 km deep, and a few were as deep as 10 km.

In the Axarfjördur area, however, there was a clear relationship between the distribution of epicentres and known fault systems. Epicentres were distributed along the north–south trending fault swarm from 66°00'N to 66°14'N, where the epicentre belt took a north-westerly trend to follow the Grímsey fault of the Tjörnes Fracture Zone (Fig. 1). The large earthquake on 13 January took place near the junction between these two fault systems.

The eruption and the lava

At about 11 : 25 a.m., 20 December 1975, an eruption was reported in Leirhnjúkur from an overflying aeroplane. At 10 : 25 pilots of the same plane had seen no sign of an eruption in the area. Other observations from aeroplanes crossing the area revealed that the eruption probably started at about 11 : 08 a.m.[17,18]. The first reports and photographs taken at 11 : 25 a.m. show that most of the lava had already been erupted.

The eruptive fissure is about 2 km long but lava was erupted from the northern half only, where three small individual lavas were erupted with a total surface area of 0.36 km^2. The new craters formed on the same fissure as was active during the eighteenth century eruption.

The first visitors to the eruption site at noon saw only relatively minor movements at the lava margin. However, they witnessed fault movements and the opening of a mud crater on a fault which cuts through Leirhnjúkur. In the evening of 20 December, very minor volcanic explosions were observed in the craters; the explosions ceased altogether during the following night. After the lava emission stopped the craters continued to emit water and steam, at first, with considerable force, then rapidly decreasing. Only minor steam vents are still active along the fissure.

The lava is an extremely vesicular pahoehoe type lava, with average thickness of <1 m. No cones were formed and there was no ash production. This lava is homogenous in composition and identical to other basalt lavas that have been erupted from this fissure swarm in postglacial time. It is basalt (quartz normative tholeiite) with occasional glomerophyric plagioclase and rare microenphenocrysts of olivine.

Horizontal and vertical movement

Movement along pre-existing faults was noticed very soon after the earthquake activity began. Some idea of the horizontal and vertical movement could be gained by measuring newly formed cracks. The width of individual cracks was measured and the aggregate movement deduced from measurements on profiles across the fault swarm (Fig. 1). In the Krafla area, rifting and vertical fault movement were both about 70 cm. In the Axarfjördur area, the aggregate widening of the fault swarm was 1.0–1.5 m on 30–40 individual faults[17]. Subsidence within the fault swarm in Axarfjördur is estimated to be at least 1 m.

Field inspection of the fault swarm between Axarfjördur and Krafla at 5-km intervals showed that the major movements were confined to the Axarfjördur district and the Krafla caldera, with minor displacements between these areas. South of the Krafla caldera, fault displacements of 5–10 cm occurred between Námafjall and Lake Myvatn.

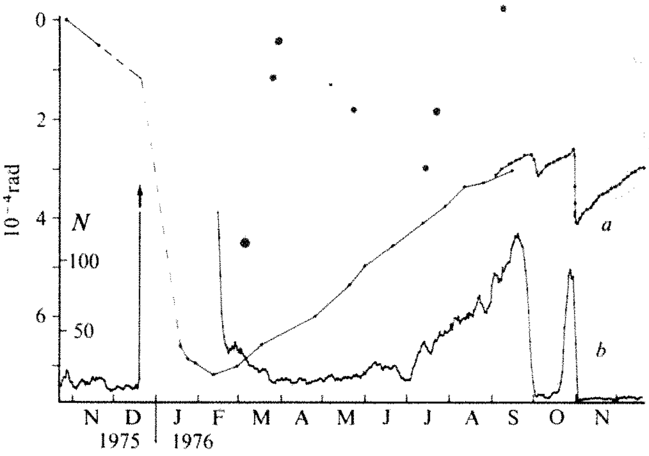

Fig. 3 Correlation between (*a*) the tilt of the Krafla power house and (*b*) the seismic activity within the caldera. The north–south component of tilt is shown, (increasing numbers mean tilt down towards north). The tilt corresponds well with the land elevation. *N* is the 5-d running average of the number of earthquakes per 24 h recorded at the seismic station near Reykjahlíd (Fig. 2) with amplitude above a certain threshold. From 20 December 1975, to 14 February 1976, *N* was >130 and most of that time >1000. The tilt measurements before 20 August were done by optical levelling by engineers of Thoroddsen and Partners, engineering firm.

The fault direction is 20°E. Most of the faults indicate a simple opening movement, but occasional faults have vertical displacements of up to 60 cm. Movements connected with the large Kópasker earthquake of 13 January affected faults east of Axarfjördur, although the epicentre of the earthquake was off the coast.

Levelling carried out in the southern part of the Krafla area in 1974, and in early March 1976, indicated that considerable subsidence had occurred. The maximum measured subsidence of 2.1 m relative to the north end of Lake Myvatn was found near the eruption site. Further, it was noted that a 70-m long building at the power station inside the southern part of the caldera (Figs. 2 and 3) had tilted about 700 μrad to the north relative to measurements made 2 months before the eruption.

Later events in the Krafla area

After the culmination in January 1976, seismic activity gradually decreased in both the Axarfjördur and the Krafla areas. In March 1976, the events in the Krafla area took an unexpected course and since then there has been a significant interplay between land elevation changes, fault movements, earthquakes and bursts of volcanic tremors within the Krafla caldera and the associated fault swarm.

Soon after the large earthquake swarm was over, the area started rising again (Fig. 3). The rate of uplift was relatively constant, 6–7 mm d^{-1}, at its maximum near the centre of the caldera, decreasing gradually outwards to <1 mm d^{-1} 10 km south of the centre. In May, a slow increase in the frequency of earthquakes was noticeable. Measurements showed that the land had regained 50% of the original subsidence by the end of September, and the earthquake frequency had increased by a factor of 10 as compared with the minimum in April. Then a sudden drop in the seismic activity was noticed and at the same time subsidence occurred at a relatively high rate, lasting 6 days and amounting to about 15 cm near Leirhnjúkur. During the period of highest subsidence rate, bursts of continuous tremor were seen on the seismographs and small earthquakes were recorded, originating in the fault swarm about 15 km north of the caldera, on the Gjástykki faults. On 4 October, the subsidence stopped, and the area started rising again at a similar rate as before.

The seismic activity remained very low until the land elevation approached the same level as before the last subsidence. Then the earthquake frequency increased sharply to almost the same level as before. The elevation had slightly passed the level of 30 October, when further subsidence started, lasting about 48 h, and the area around Leirhnjúkur subsided about 50 cm. The subsidence rate was much higher than in the previous event and was accompanied by continuous tremor on the seismographs. Simultaneously, fissures in the middle of the caldera showed significant contraction. About 5 h after the beginning of the subsidence a large earthquake swarm (not shown in Fig. 3) started again in Gjástykki north of the caldera. People travelling in Gjástykki felt earthquakes and continuous tremor and saw a cloud of steam emanating from a fissure. Later inspection revealed fresh fault movements and a new thermal area in Gjástykki. The earthquake swarm lasted 2 d, and as soon as the earthquakes stopped in the Gjástykki faults the land started rising in the Krafla caldera, this time at a similar rate to before. The earthquake frequency within the caldera is, in late December 1976, at a minimum, but is expected to increase sharply when the elevation approaches the level of 30 October.

Boreholes have recently been drilled down to 2 km in the Krafla area. One of these had been blowing for 4 months before the eruption. In April 1976, the CO_2 content of the aquifer water had increased from 200 to 20,000 p.p.m. The CO_2 content of the borehole has since lowered somewhat but is still 10–20 times higher than before the eruption. At the same time, the *p*H dropped from 8.6 to 1.9 in the discharge from another uncontrolled borehole, and has since returned to its previous value.

The composition of gas emitted from fumaroles has changed significantly towards increase in CO_2, relative to H_2S and H_2. The appearance of new fumaroles and increased activity of others indicates a significant increase in the thermal output of the area during the last few months.

Boreholes at Námafjall extend down to 1.8 km, and a considerable amount of data are available on these holes. Measurements since the events of 20 December 1975, have so far revealed no change in composition compared with earlier measurements.

Discussion

The main significance of the activity taking place now in northeastern Iceland is the light it throws on the mechanism of rifting and the associated magmatism. It demonstrates that the rifting long predicted for Iceland as a part of the oceanic rift system is episodic rather than continuous. The historical record shows that the interval between these episodes is of the order of 100–150 yr. Each rifting episode has a duration of several months to a few years, and extends over 50–100-km distance along the rift zone. The present episode started near the south end of the zone that was activated but propagated rapidly along the fault swarm. Seismic activity and faulting have since been primarily concentrated near the ends of the active rift; the central volcano Krafla in the south and the intersection of the North Iceland Rift Zone and the Tjörnes Fracture Zone in the north. Seismic energy release has been greater near the northern end of the zone than near its southern end, but the northern end now seems to be coming to a rest while the southern end is still active 12 months after the rifting started.

This rifting, like that in the eighteenth and nineteenth centuries, is closely connected with magmatism. The causal relationship between rifting and magmatism is, however, unclear.

The eruption of 20 December 1975, is only a minor manifestation of the total magma movement. The volume of the lava erupted (3×10^5 m^3) is much smaller than the volume of the initial subsidence bowl, which can be estimated at 10^8 m^3. The subsidence is interpreted as a result of the widening of the rift system and a movement of magma from the Krafla area along the fault swarm to the north, presumably along a horizontally fed dyke opened by the rifting process.

Later, in March 1976, the Krafla area started inflating, but the inflation has twice been interrupted by short subsidence events. At the end of September and the end of October (Fig. 3). These subsidence events are of a similar nature and it is probable that the difference between these and the large event that started on 20 December 1975, is only in degree.

The inflation is interpreted as being caused by magma transported from below accumulating at a shallow depth within the Krafla caldera. Simple model calculations indicate that the inflow of magma into the roots of the caldera since March is approximately 5 m^3 s^{-1}.

The deflation is caused by release of pressure in the magma chamber by widening of the rifts and flow of magma into the fault swarm north of the caldera. This flow is accompanied by volcanic tremors, earthquakes, faulting and thermal activity in the fault swarm. In this model the earthquakes in the caldera are caused by inelastic deformation of the crust above the magma chamber.

Further support of this model comes from work in progress on the distribution of earthquake hypocentres within the caldera and the attenuation of S waves, which strongly suggests the presence of a magma chamber below the depth of 3 km. The low *p*H value measured in the borehole fluid last April and the increase in CO_2 are interpreted as being a result of the influx of magmatic gases into the hydrothermal system.

Judged from previous historical events, years may pass before the area comes to rest. Therefore, and because of the economic importance, great emphasis is put on continued monitoring of the area, including telemetering of signals from three seismometers to an observatory where they are watched around the clock. The tilting of the Krafla power house is recorded twice a day and the ground movement is measured by optical levelling and gravimetry every 2–4 weeks. The movement of faults is monitored. The composition of borehole discharge is monitored regularly. The gases emitted from fumaroles are analysed every few weeks. Ground temperatures are measured and a close watch is kept on the thermal fields. Plans have been tested so the area can be evacuated at a very short notice in case of abnormal seismic activity.

From the data accumulated so far a better understanding of the rifting mechanism and the associated magmatism is rapidly emerging. It is obvious already that the data will reveal many of the detailed features associated with the formation of the Icelandic crust.

This paper is based on the work of many people who contributed data and took part in discussions. These include Sveinbjörn Björnsson, Gestur Gíslason, Egill Hauksson, Gunnar Johnsen, Hrefna Kristmannsdóttir, Níels Óskarsson, Gudmundur Pálmason, Oddur Sigurdsson, Gudmundur E. Sigvaldason, Ragnar Stefánsson, Valgardur Stefánsson, Sigurdur Thorarinsson, Gunnar Thorbergsson and Oskar Thordarson.

Note added in proof: On 20 January 1977, the floor of the Krafla caldera subsided again about 30 cm in 20 h. This was accompanied by seismic activity, fault movements and development of a new steam field within the fault swarm, Gjástykki. The centre of the caldera started to inflate immediately after this subsidence and another subsidence period is expected in early March 1977.

Saturated platelets are new intermediates in hydrocarbon pyrolysis and carbon formation

John Abrahamson

Department of Chemical Engineering, University of Canterbury, Christchurch, New Zealand

Formation of solid carbon during pyrolysis of gaseous hydrocarbons may involve 'saturated platelet' intermediates.

AN important problem in flames and in the industrial pyrolysis of hydrocarbons is the understanding of how solid carbon is formed, either in the gas phase (soot) or on surrounding surfaces. Various mechanisms have been discussed[1,2], but none takes full account of soot ball internal structure, electrical phenomena and the startling temperature range (1300–2300 K) of soot formation. This article proposes a single route to soot for all conditions, passing through sequential chemical and physical steps.

Small intermediate molecules

To explain soot formation from varied starting hydrocarbons, possible common intermediate molecules proposed are carbon vapour (C, C_2, C_3, and so on), benzene (and other aromatics), and acetylene[3,4]. Gaydon and Wolfhard[1] have convincingly criticised the carbon vapour route at lower temperatures. Certainly the band radiation of C_2 is not evident in pyrolysing hydrocarbons at lower soot-forming temperatures[5]. It has been suggested that benzene and other aromatics condense chemically to form the polyaromatic molecules found in flames[6], and hence soot. During pyrolysis of benzene, however, benzene absorption disappears well before soot-like luminosity is seen, without the appearance of polyaromatic bands[5]. Concentrations of polyaromatics in a premixed flame continue to rise slowly through the sooting region, indicating that polyaromatics are byproducts rather than intermediates of the sooting process[7].

Porter[3,4] states that acetylene is "the last stable hydrocarbon to be observed before carbon formation". It is formed in appreciable quantities in most pyrolyses above 1300 K, and is still relatively stable at the highest soot-forming temperatures (2300 K). Temperature measurements of the pyrolysis of methane show that an overall endothermic process is followed by an overall exothermic process[8]. This is consistent with strongly endothermic reactions to acetylene, followed by exothermic steps to soot. Porter has outlined processes which would begin with acetylene and end with soot. Obviously some polymerisation will occur ($C_2 \rightarrow C_{10^6}$) and some dehydrogenation (H/C from 1 to 0.1 atom ratio), but the sequence of these steps will be governed by the chemical kinetics. The high transition-state entropy decrease found with typical polymerisations, and the higher activation energies found with decompositions suggest that most decomposition reactions will be faster than polymerisations for temperatures higher than 1300 K (ref. 3). Porter concluded that little polymerisation could occur at sooting temperatures without some dehydrogenation, and that they were simultaneous processes and intimately connected.

Saturated platelets

If acetylene is the common small intermediate in soot formation, it is probable that there are larger intermediates formed before soot, for a study of soot formation in heated acetylene showed that the soot balls continued to grow in size even after all the acetylene had been removed[9]. Optical absorption evidence in an oxygen–acetylene flame showed that all the soot substance was present in some larger (absorbing) intermediate before much soot was detected[10], and cooled-probe tar collection in benzene pyrolyses[11] gave similar indications.

A continuum absorption has been seen in pyrolyses and diffusion flames of hydrocarbons[5]. This absorption was probably due to larger soot precursors or intermediates because it was seen in all pyrolyses and flames before sooting occurred, and it was not seen in the soot-free pyrolysis of methyl alcohol. These precursors of soot are probably generally formed from acetylene, for the continuum was found at lower temperatures in the pyrolysis of acetylene than with other hydrocarbons (including benzene). In a mass spectrometry study of transient species in low-pressure acetylene–oxygen flames[7], two types of species peaked in concentration before soot was found—polyacetylenes ($C_{2n}H_2$), and a group of much larger molecules in the mass range 300–500. These latter were found in very low concentrations (10^{-7} mole fraction) compared with the polyacetylenes, suggesting a route through polyacetylenes to soot, although the larger molecules could also contribute. Polymerisation of long rod-like polyacetylenes at higher temperatures seems unlikely, however, as configurational entropy and activation energy differences probably again favour decomposition reactions. Mass spectral data suggest that the larger molecules lost hydrogen continuously before or during sampling. By collecting 'young soot' on cooled tubes in the flame, the hydrogen–carbon ratio of the substance was found to be as high as 1.

These observations can be explained if one postulates that structures of the type shown in Fig. 1 are formed directly from acetylene. They retain the H–C ratio of acetylene at lower temperatures, and have a puckered layer of carbon atoms bonded by single bonds, except at the edges. Hence 'saturated platelets' is an appropriate term for them. They can retain radical sites, and acetylene can add on by a radical mechanism. Hydrogen atoms are held above and below the carbon layer on alternate carbon atoms, and can be lost as H_2 from the interior of the platelet by a radical mechanism. Hence graphite-like layers are formed from the inside, moving to the outside, and simultaneous addition of acetylene and dehydrogenation is possible in the same molecule at different sites in excellent agreement with Porter's prediction. If the dehydrogenation is more rapid than addition, only a perimeter of hydrogen atoms remains and one has the polycyclic aromatics observed in flames. Acetylene pyrolysis in conditions where no breakdown of the carbon skeleton of platelets is expected[12] (small hot wire immersed in cold acetylene) yielded an oily deposit on the walls, consisting of "a series of heavy polynuclear aromatics containing even numbers of carbon atoms". This is good evidence for the direct build-up of acetylene into these larger species.

Evidence supporting the existence of saturated platelets is the observation[13] of arrays of 0.154-nm (singly-bonded) C–C bonds by electron diffraction of 'young soot', in addition to the

0.141-nm graphite-like C–C spacings. Also, 'young' soot has 100 times the electron spin resonance strength of 'old' soot sampled further downstream in the flame[7], indicating many radical sites on the young soot. This is consistent with the presence of saturated bond areas on the adhering material which neutralise free radicals in the process of dehydrogenation to the more stable aromatic form.

The thermodynamics of platelets, calculated from group properties, can be summarised thus (see also note added in proof)

$$\begin{array}{llll}
\mathrm{C_2H_2} \xrightarrow{1} 2\,(\mathrm{CH})\ (\text{saturated platelet}) & & \xrightarrow{2} 2\mathrm{C}\ (\text{graphite}) + \mathrm{H_2} & \\
\Delta H_1^\circ = -240\ \mathrm{kJ\ mol^{-1}} & & \Delta H_2^\circ = 15\ \mathrm{kJ\ mol^{-1}} & \\
\Delta S_1^\circ = -360\ \mathrm{J\ mol^{-1}\ K^{-1}} & & \Delta S_2^\circ = 220\ \mathrm{J\ mol^{-1}\ K^{-1}} &
\end{array}$$

all at 300 K. ΔG_1° is negative for temperatures < 650 K, whereas ΔG_2° is negative for all temperatures > 70 K. Saturated platelets can then be expected to be short-lived at flame temperatures before dehydrogenation occurs. The kinetics of acetylene disappearance and the appearance of ethylene, benzene and so on, at the lower temperatures has been interpreted in detail in terms of radical platelets. This analysis will be published elsewhere, but it is sufficient to note here that the 'polymer' of composition $C_{n2}H_{n2}$ found by Silcocks[14] in particular corresponds well with the existence of saturated platelets.

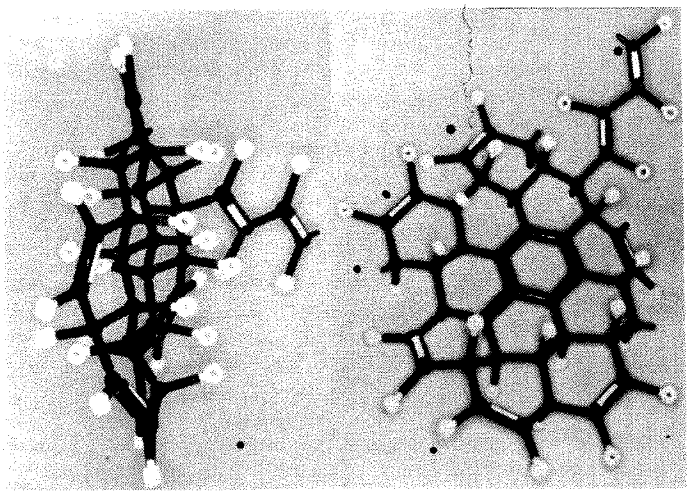

Fig. 1 *a*, Model of a $C_{27}H_{27}$ saturated platelet, with attached C_4H_4 radical chain, showing the puckered carbon skeleton and distorted general shape. The $C_{27}H_{27}$ heat of cumbustion $Q = 330$ kJ mol^{-1} C atoms, equal to that of a bituminous coal[14]. *b*, Model of a $C_{38}H_{38}$ platelet with attached C_4H_4 radical chain, showing a central aromatic region formed by dehydrogenation. The $C_{38}H_{38}$ $Q = 365$ kJ mol^{-1} C atoms, higher than that of a bituminous coal[14,15] but accounting for several C–O bonds restores Q to that of coal.

Control of platelet formation and growth

Formation of saturated platelets probably begins with the formation of benzene (or a derivative) and then naphthalene (or a derivative). Experiments with nitric oxide[14] indicate a radical mechanism for acetylene disappearance, so a phenyl radical and then larger radicals are likely intermediates on the route to a saturated platelet radical (Fig. 2). The disappearance of acetylene can, in fact, be explained only by the involvement of a large molecule. The kinetics of disappearance are second order over the extraordinary temperature range 650–2500 K (ref. 15). Bimolecular mechanisms which are currently favoured[15] utilise small radicals such as C_2H, especially at high temperatures. Reactions with five to seven atoms in the transition state, however, become energy-transfer-limited at temperatures in the vicinity of 1000 K (ref. 16). Hence a small radical–acetylene reaction which was second order at lower temperatures should become third order at temperatures not much higher than 1000 K. If the radical is attached to a large enough body (platelet), the decomposition should remain second order to very high temperatures, as observed.

Soot formation may be limited at the higher temperatures by the initial steps of producing phenyl (C_6H_5) radicals or similar aromatic radicals, as expected from entering an energy-transfer-limited regime. This would explain why, in premixed flames, naphthalene and benzene derivatives produce soot at lower fuel–air ratios than acetylene[1]. This 'sooting tendency' in competition with oxidation has been used to argue for the aromatic polymerisation route, and against the acetylene mechanism, but the survival of some aromatic radicals derived from benzene or naphthalene fed to the flame may bypass the otherwise limiting step of making benzene or naphthalene and allow a faster build-up of acetylene on these radicals to form saturated platelets.

In shock tube studies[17] of benzene, toluene, ethylbenzene and indene in the temperature range 1600–2300 K, soot particles were identified by the scattering of light of 488 nm wavelength, but there was also absorption of this light in the pyrolysing mixture before scattering occurred. There was absorption at 632.8 nm which increased later than that at 488 nm, entirely consistent with the absorption found by Parker and Wolfhard[5]—a continuum spreading from the ultraviolet into the visible spectrum. Measurements of the ratio of absorption at these two wavelengths[17] show that the ratio reached a steady value (when dehydrogenation had ceased) close to the time soot particles appeared. Again, these observations are consistent with the formation of saturated platelets which are dehydrogenated to the point where they are agglomerated to soot particles. The continuum spreading into the visible is likely to arise from increasingly conjugated double bonds, either in chains attached to the platelets or integral with its structure, on an edge.

The finding that this absorption reached a plateau which was lower (lower soot yields) with higher temperature in contrast with the higher rate of absorption increase with higher temperature, was interpreted[17] as indicating competition between a rapid direct soot formation from aromatics, and a slower indirect route to soot by fragmentation reactions (for example, through acetylene). An alternative explanation is that the absorption measured platelet concentration rather than soot during its inital increase, and that initiation of platelets, which occurred almost solely at the beginning of the shock period when hydrocarbon concentrations were high, has a negative temperature coefficient because of a rapid route through an aromatic (unstable) vying with a slower acetylene (stable) initiation. Thus, as the temperature was raised, fewer platelet initiations occurred, resulting in a lower conversion to absorbing platelets and soot. Growth of each platelet was more rapid with rising temperature, however, showing a more rapid rise of absorption.

Agglomeration of platelets

A mechanism proposed for agglomeration of larger intermediates is physical nucleation and condensation into liquid droplets. This was supported by Lahaye, Prado and Donnet[18]. If liquid condensation occurs at all, however, it must be limited to the very lowest of sooting temperatures. The large molecules found by Homann and Wagner[7] correspond to C_{25}—C_{40} polycyclics. The condensation points of these molecules can be estimated—the polycyclic perhydrochrysene ($C_{18}H_{30}$) has a boiling point (1 atm) of 630 K (ref. 19) and the condensation point of the C_{40} molecules is likely to be no greater than 1100 K (by extrapolation of Fig. 35 from ref. 20). Johnson and Anderson[9] collected 'polymer drops' from the pyrolysis of acetylene, but these only appeared when they sampled in regions with the temperature below about 570 K. They concluded that any drops observed after pyrolysis had been condensed on to small carbon particles and then only when the pyrolysis gas was cooled below 570 K. It is thus unlikely that a liquid droplet route can operate in the formation of soot balls.

A number of observations support an electrical mechanism of soot ball nucleation. An increase in soot particles deposited on electrodes from a diffusion flame was found after seeding with cesium chloride[21]. When soot formation was promoted and positive hydrocarbon ion concentrations were elevated by adding carbon tetrachloride in a diffusion flame[22], there was a local depletion of ions where soot was forming. The concentrations of large positive hydrocarbon ions in premixed flames have been shown to peak just upstream of soot formation[23], and many of the younger soot particles were positively charged[24].

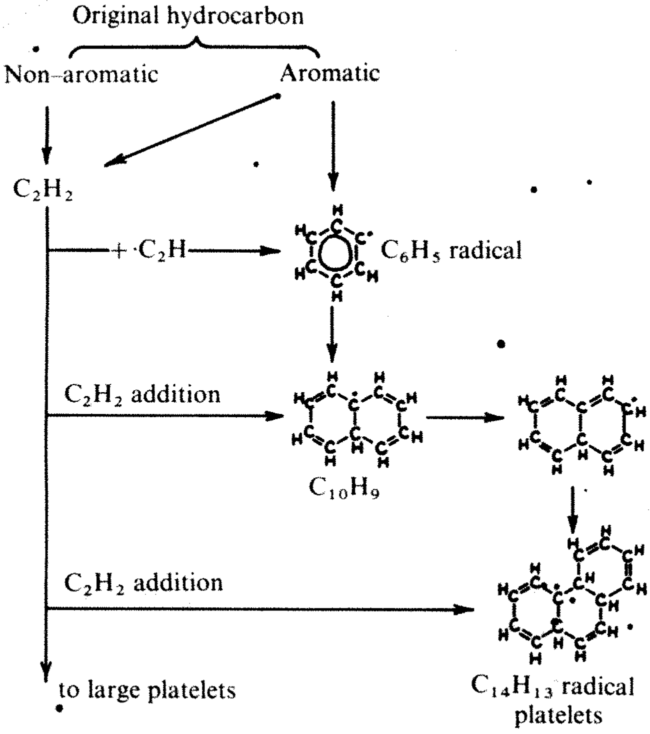

Fig. 2 Initial steps in the formation of a saturated platelet by radical addition of acetylene.

The necessity of electrical charges playing some part in soot formation has been challenged[1,25] with the observation that in the absence of a flame and its non-equilibrium ions produced by chemi-ionisation, ionisation should be negligible, and a pyrolysing hydrocarbon is not expected to soot by an electrical mechanism. There is electric probe evidence of charge carriers being generated in pyrolysing hydrocarbons in the absence of a flame in heated propane and methane[26]. Above 1330 K the probe current increased rapidly and carbon deposited only on the anode; during ethylene pyrolysis[27] at the lower temperature of 1100 K, with much higher electric fields, carbon deposited only on the cathode. Current transients from a probe immersed in shock heated ethylene indicated an ion recombination after the initial ionisation. These studies indicate that a flame is not necessary for the appearance of charge carriers related to soot formation, and suggest that the ions formed by the oxidation process itself are not necessary for some, at least, of the soot formation in flames.

At higher temperatures it seems that negative charge carriers were carrying more carbon than positive charge carriers[26], suggesting the existence of large negative hydrocarbon ions. Ion-pair processes $AB \rightarrow A^+ + B^-$, or ionisation $A \rightarrow A^+ + e$ followed by a rapid capture of the electron may well occur in hydrocarbons at these relatively low temperatures. Possible steps involve $C_3H_3^+$ ($I = 5.8$ eV, refs 28, 29) and C_2H^- (E.A. = 2.2 eV, see ref. 30), both of which have been found in flames[31,32]. Dehydrogenating platelets, however, have the possibility of creating aromatic edge sites with σ-electron affinities similar to those of C_6H_5, $C_{10}H_7$, $C_{14}H_9$ radicals (2.2 eV or 1.2–1.6 eV (refs 33 and 34)). Thus negative platelet ions are good candidates for the large ions mentioned above.

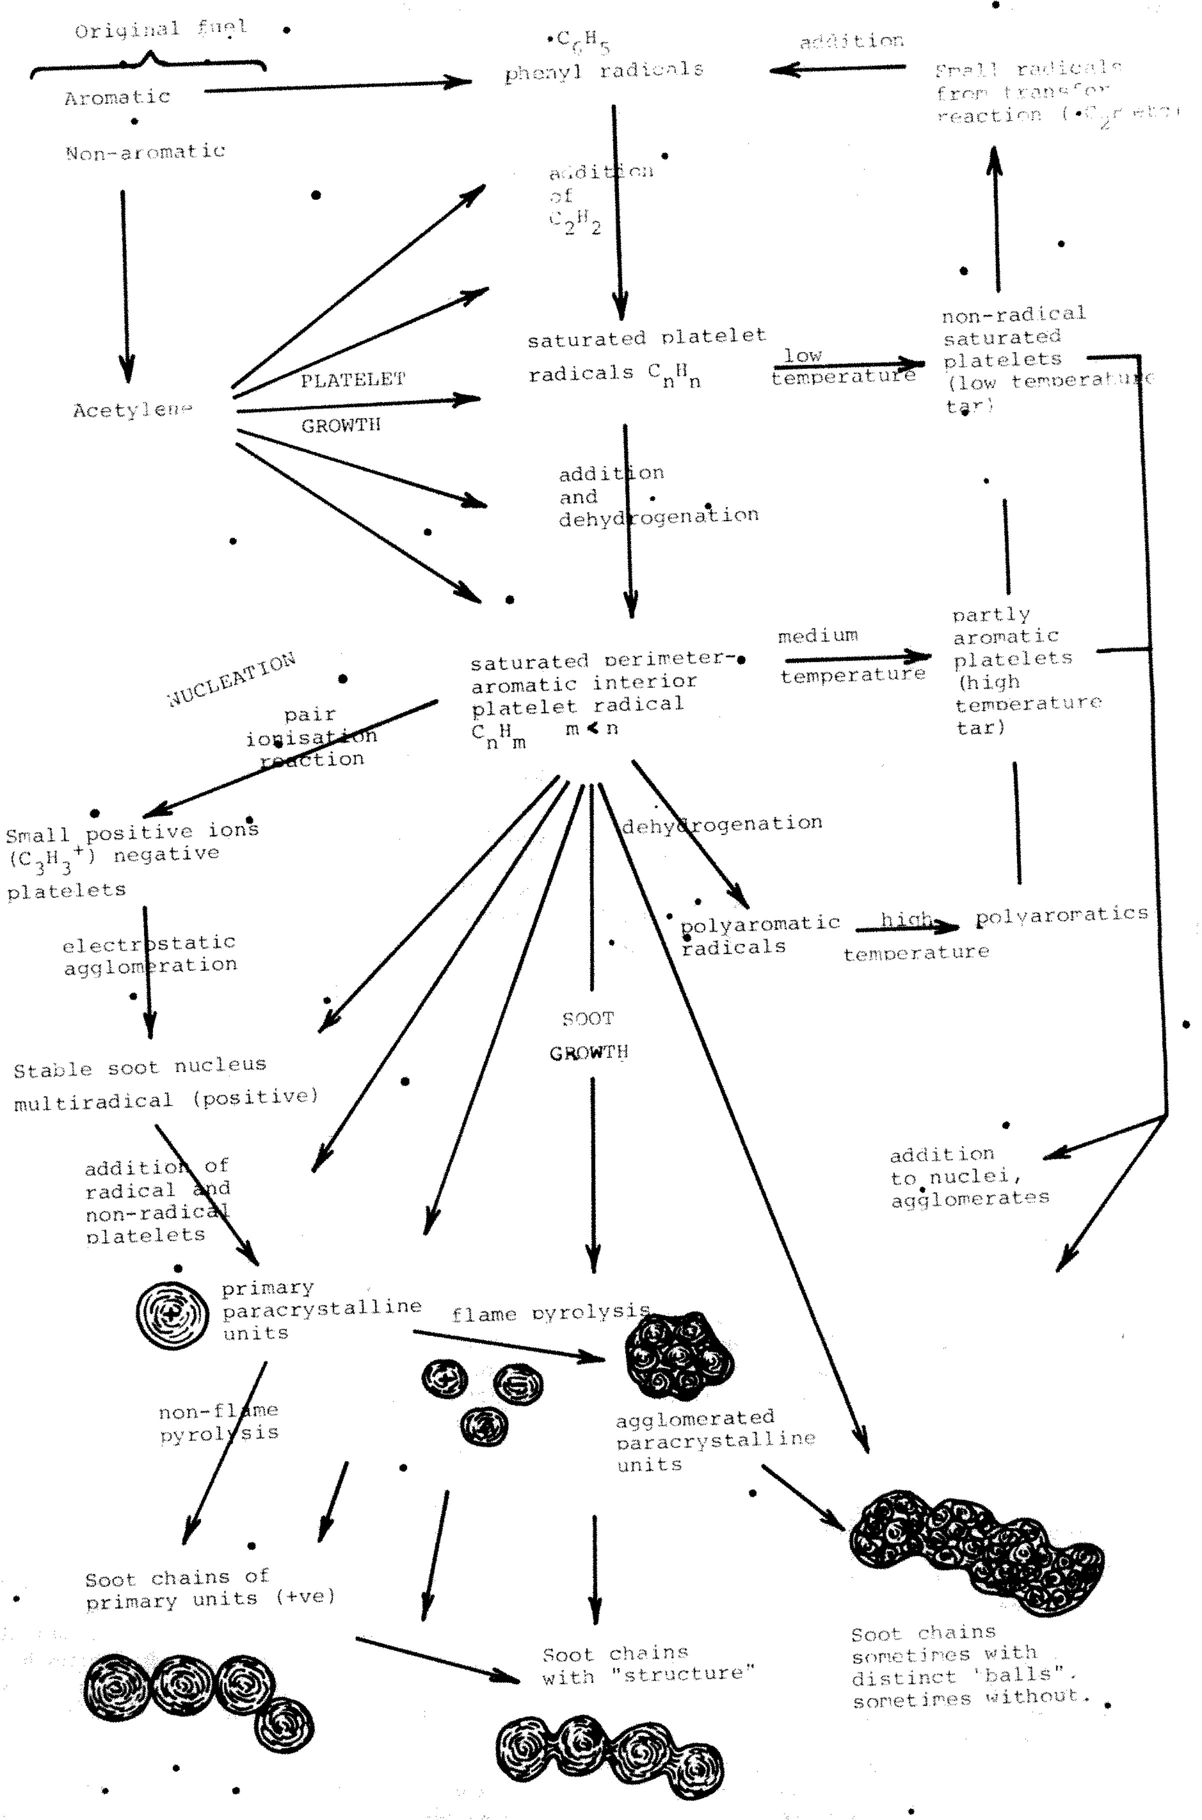
Evidence for generation of large negative hydrocarbon ions in pyrolysing hydrocarbons is indirect because studies have been done only in flames, for which an alternative interpretation is available—that electrons diffuse to the pyrolysis zone from the combustion zone, and attach to form negative ions. Large (up to the mass spectrometer limit, 130 mass number) negative ions have been found[35] on the fuel side of a diffusion flame. The validity of the electron diffusion interpretation is being checked by a similar study on pyrolysing hydrocarbons.

Thus, let us assume that a weak plasma exists in a pyrolysing hydrocarbon, consisting of small positive ions, large negative platelet ions and neutrals. Some of the neutrals will be platelets, and a certain fraction of all platelets and smaller molecules will be radicals. It is clear that this combination can lead to electrical-radical nucleation.

(1) Some radicals will attach ions, and on average will attach positive ions more frequently than negative ions (the positive ions are smaller and more frequently bombard other species because of their high velocities).
(2) The predominantly positive radical-ions attract and hold a negative platelet by an electrostatic force, resulting in a directional approach and instantaneous bonding.
(3) The resulting neutral radical will on average acquire another positive charge by process (1) (bombardment charging).
(4) A further electrostatic neutralisation as in (2) will occur.
This cycle will be repeated until sufficient radical sites will have been acquired so that neutral platelets begin to be attached (chemically) in appreciable numbers. The nucleation has then ended, and normal growth of the soot ball has begun, with the charge still predominantly positive, but having little influence on the growth. A factor which could also be important in maintaining the positive charge of nuclei relative to smaller gaseous positive ions is the polarisation energy of the packed platelets (that of aromatic crystals is about 1.5 eV (ref, 36)), which will reduce the energy of any ion-pair process originating from the nuclei.

Nuclei growth rate in the above ion-recombination process was calculated for the conditions of Prado's pyrolysis of benzene[11] at 1380 K; this gives a platelet collection rate of only 10^{-4} of the average rate required to build up the final 35-nm particles found by Prado. It seems that the growth accelerates after the nucleus is formed, and that the nucleus is very small, for the final particles contain material equivalent to 10^4 platelets. Notwithstanding the large uncertainties in ion concentrations, these conclusions should still hold. It is difficult to determine whether the growth is wholly irreversible. We have evidence from rapid quenching experiments (unpublished) that a gas phase equilibrium is obtained during soot formation which ignores the presence of solid carbon. This would support an irreversible growth, much slower than the prevailing gas kinetics. On the other hand, there must be competition between nuclei for platelets, and in the very early stages where the number of successful nuclei is determined and the process is unlikely to be irreversible, the electrical sphere of influence of each ion may be important. Thus the Debye shielding radius, or the much smaller ion-recombination radius, may determine the final number of soot balls. For Prado's condition[11], Debye radius calculations gave 2×10^{16} m^{-3}, compared with an experimental 10^{15} m^{-3}.

The physical form of soot is consistent with the platelet agglomeration ideas presented above. High resolution phase-contrast electronmicroscopy[37] has shown that the basal layers in soot particles are aligned parallel to the surface (onion-like), which is easily explained by the wrapping around of platelets deposited from the gas phase. Some layers show interlayer spacing well in excess of graphitic spacing, which is what would be expected from those remaining saturated platelet regions. 'Thermal' carbon blacks—made by the pyrolysis of hydrocarbo in the absence of air—show uniform spherical particles with



Original fuel
Aromatic
Non-aromatic
•C$_6$H$_5$ phenyl radicals
addition
Small radicals from transfer reaction (•C$_2$H etc)
addition of C$_2$H$_2$
Acetylene
PLATELET GROWTH
saturated platelet radicals C$_n$H$_n$
low temperature
non-radical saturated platelets (low temperature tar)
addition and dehydrogenation
saturated perimeter-aromatic interior platelet radical C$_n$H$_m$ m < n
medium temperature
partly aromatic platelets (high temperature tar)
NUCLEATION
pair ionisation reaction
Small positive ions (C$_3$H$_3$$^+$) negative platelets
dehydrogenation
polyaromatic radicals
high temperature
polyaromatics
electrostatic agglomeration
Stable soot nucleus multiradical (positive)
SOOT GROWTH
addition of radical and non-radical platelets
addition to nuclei, agglomerates
primary paracrystalline units

Soot chains sometimes with distinct 'balls", sometimes without.

ig. 3 Steps proposed here in the production of soot from a hydrocarbon fuel. At high temperatures (~ 2000 K) the initial steps are rate ontrolling, whereas at lower temperatures (~ 1300 K) the electrical stages are controlling. Production of methane and other light hydrocarbons on radical platelets is not shown.

single centre of growth. In contrast, furnace and channel blacks—made in the presence of air—show many more growth centres per unit mass, and these are firmly embedded together by more onion-like layers[37] around the outside. Wersborg *et al.*[23,24] observed this latter type in flames, and from the peak in particle numbers with distance it seemed that each growth centre had an independent existence in the gas phase before coming together. The different physical forms may be related to electrically aided or hindered agglomeration in that non-flame pyrolysis probably results in many soot nuclei maintaining a positive charge, hindering agglomeration, whereas in flames the soot nuclei may be positive, neutral or negative[24], encouraging earlier agglomeration.

The single-centred or multicentred units are finally found in many soots more or less tightly joined together in long chains. Howard[38] described well this final step of agglomeration, on the basis of the directional agglomeration of repelling like charges. All the steps proposed for soot formation are presented in Fig. 3.

Deposition of carbon on walls at high temperatures

The deposition of platelets on walls is likely to be important wherever the hydrocarbon gas phase has been heated sufficiently to generate acetylene. Examples are the conditioning and coking of thermal cracker walls[39], the deposition of laminated pyrolytic graphite on hot surfaces, and the extensive rearrangements of structure occurring within hydrogen bearing carbon materials on heating. In the heating of cokes, for example, acetylene formed from residual hydrogen can redeposit from the pore spaces as platelets, which will then constitute a graphitisable portion of the solid.

Many hydrocarbon pyrolysis experiments have revealed the importance of aged walls (platelet-covered walls) for reproducibility of rates. The generation of wall radical sites, radical transfer to gaseous species, and eventual termination perhaps back on the wall as radical platelets, can explain such behaviour, and the occurrence of induction periods. The importance of wall-derived radicals is relatively easily recognised, but electrical effects must also be considered. Abrahamson and Kennedy[26] found some electrical behaviour with their metal probe which was interpreted as being surface ionisation, at lower temperatures than that at which appreciable gas phase ionisation occurred. This wall behaviour is consistent with the crystal polarisation effect, whereby the energy of an ion-pair reaction involving a platelet is smaller if that platelet has its electron levels banded with other nearby platelets, as on a wall deposit. The electrical control of wall carbon deposition found by Abrahamson and Kennedy at slightly higher temperatures probably relates only to the initial stages of deposition, but it could well be useful in the commercial control of wall coking.

Deposition of carbon on walls at low temperatures

If wall surfaces can supply free radical sites, and chemisorb products of surface rearrangements, it is possible that saturated platelets may form on the wall surface itself, from small molecules other than acetylene. This route should be observable, if at all, at lower temperatures where acetylene and gas phase platelet formation are unlikely.

Lobo and Trimm[40] measured deposition rates in the range 650–770 K and found zero order kinetics with a common activation energy for deposition from acetylene, ethylene, propylene and butene. Again, a reproducible rate was obtained only after several[41] carbon layers had been deposited. Plummer[42] notes that the surface residue formed on nickel and tungsten has the same photoelectron spectra whether deposited from acetylene or ethylene. The residue formed from ethylene above 230 K. On heating to 500 K, hydrogen desorbed from the surface until a $(C_2H_2)_n$ complex remained, which was stable up to 1100 K. The formation of acetylene and hydrogen chemisorbed on to the surface—one interpretation of these experiments—is not likely to be energetically as attractive as the formation of saturated platelets $(C_2H_2)_n$ together with locally chemisorbed hydrogen. The electronmicroscope observation[43] that pregraphitic deposits formed on platinum catalyst from various hydrocarbons at 633 K covered only distinct tiny patches of the surface supports platelet formation.

These temperatures are similar to those expected for coal formation, and humus formation in soils. I will argue in a later publication that the saturated platelet is the archetypal molecule for both coals and humic substances, and that light hydrocarbons from rotting vegetable matter rearrange relatively rapidly on finely divided soil constituents to form humus, but slowly over extended periods on other platelets to form coal seams.

I thank the Nuffield Foundation for a Commonwealth Travelling Fellowship, and Professor J. F. Davidson and his staff in the Chemical Engineering Department, Cambridge, for their hospitality.

Note added in proof: A recent crystalline orbital calculation[46] of hydrogen atoms chemisorbed on to a single graphite layer (one side only) indicates that saturated platelets should be stable to temperatures of 300 or 400 K, rather than 70 K.

Sequence and structure of D-glyceraldehyde 3-phosphate dehydrogenase from *Bacillus stearothermophilus*

G. Biesecker*, J. Ieuan Harris, J. C. Thierry†, J. E. Walker & A. J. Wonacott

MRC Laboratory of Molecular Biology, Hills Road, Cambridge, UK

The glyceraldehyde 3-phosphate dehydogenase holoenzyme of Bacillus stearothermophilus *possesses precise 222 symmetry: in this respect it differs from the reported structure of the lobster muscle enzyme. Pairs of active sites are linked through a flexible polypeptide loop which probably mediates the structural changes giving rise to cooperative effects. Three additional salt bridges made by each subunit to others would make a major contribution to thermostability of the tetramer.*

MANY current ideas about the cooperative nature of protein transitions have derived from studies of D-glyceraldehyde 3-phosphate dehydrogenase (GPDH). The structure and mechanism of this enzyme have been investigated for several species (for a review see ref. 1). All known GPDH molecules are tetrameric with a molecular weight of 145,000 and bind four moles of the coenzyme, NAD. Although the four subunits are chemically identical[2] the affinity of NAD for the muscle enzyme decreases with each additional NAD bound. The first two moles of NAD are bound tightly and the second two loosely[3-5]. Yeast enzyme, however, displays a complicated mixture of positive and negative cooperativity[6,7].

The model which best describes the binding is controversial. The allosteric model[8] of cooperativity and the induced fit model[9-10] differ with regard to the preservation of symmetry at various states of ligation. Both models assume complete symmetry for the non-ligated and fully ligated states, but the induced fit model allows asymmetry for intermediate states. A model for GPDH has been proposed[11] in which the molecule is never fully symmetric, but consists of an asymmetric pair of symmetric dimers, and this view has received support from crystallographic studies of the lobster enzyme[12].

The enzyme from mesophiles becomes unstable once NAD is removed. Because of its greater stability, GPDH from the thermophile *Bacillus stearothermophilus* can be crystallised with a range of NAD stoichiometries from zero to four moles per tetramer[13]. The structure and properties of the bacterial enzyme are very similar to those of the muscle enzyme[14-16].

We report here the complete sequence of 333 amino acid residues in the subunit polypeptide together with the interpretation of an electron density map at 2.7-Å resolution of the holoenzyme with four moles of bound NAD. For the first time it is possible to compare the structure and sequence of a multisubunit protein from both a mesophile and a thermophile. Our structure differs in some important respects from the structure of the lobster muscle enzyme[12,17,18], especially with regard to molecular symmetry.

Experimental methods

B. stearothermophilus GPDH was purified for crystallography by a modification of the method of Suzuki and Harris[15], and for sequence work according to Hocking and Harris[19]. The sequence of the enzyme was determined largely (85%) by the automated Edman degradation technique with the aid of both spinning-cup and solid-phase sequencers (see legend to Fig. 1). The preparation, isolation and sequence determination of fragments of the enzyme are described elsewhere[20].

Holo-GPDH (with 4 mol NAD per tetramer) was crystallised by vapour diffusion against 2.4–2.7 M $(NH_4)_2SO_4$. The crystals contain a complete tetramer in each asymmetric unit. Rotation–oscillation data were collected on an Arndt-Wonacott camera[21]. An initial electron density map at high resolution was calculated by isomorphous replacement from two derivatives, and improved by use of the molecular symmetry[22,23].

Molecular structure

The complete amino acid sequence (Fig. 1) is highly homologous with that of the lobster enzyme[1,24]. Of the residues, 51% are identical in the thermophile and lobster enzymes, as compared with 70% identity between lobster and pig, and 68% between the lobster and yeast enzyme[1]. The essential cysteine 149 (ref. 25) is retained in a stretch of conserved residues. The number of arginines is increased from nine to 15 and the number of cysteines reduced from five to two. Lysine 183 which takes part in an acyl transfer reaction[26,27] in muscle apo-GPDH (NAD-free) is replaced by arginine in the thermophile enzyme.

A diagrammatic representation of the whole molecule is shown in Fig. 2. The overall structure of the subunit of the thermophile holo-GPDH is closely similar to that described for lobster GPDH, consisting of the two folding domains shown in Fig. 3. The first domain, residues 0–148, contains most of the residues involved in NAD binding. The secondary and tertiary structural features of the lobster enzyme are reproduced quite accurately. Similar folding domains have been found in other nucleotide binding proteins[28-31]. Side chains implicated in catalysis are contained in the second domain, the region comprising residues 149–333. In this domain the interaction of the β-sheet regions, β_5 with β_6, and β_7 with β_8, is different from that of the lobster enzyme and gives rise to a modified hydrogen-bonding pattern. This change results in the burying of aspartic acid 293 which has significance for thermostability (see below).

An important feature of this domain is an irregular S-shaped loop of polypeptide chain (residues 178–201) which is in contact with the NAD and with the S loop and the α_c helix of the subunit related by the dyad axis marked R (see Fig. 2). In addition, this S-loop interacts with several amino acids across the P axis.

The sequence of the S loop is highly conserved in the lobster, pig and yeast enzymes, whereas the homology between the thermophile and mesophile S-loop sequences is only average. This is surprising since the S loops form the core of the tetramer, and most of their residues are internal, and essential to the interaction across the R axis. Many hydrogen-bonding groups in the main chain of the S loop seem to be unsatisfied in both the lobster and thermophile enzymes. Conserved residues are similarly oriented in both structures. The conformation of the

Fig. 1 The primary structure of GPDH from *B. stearothermophilus* (upper) and lobster. The sequence of the thermophile enzyme was obtained by automated sequence analysis of fragments obtained from S(2 — ^{14}C)-carboxymethylated enzyme with cyanogen bromide, trypsin digestion of citraconylated protein and cleavage of succinylated protein with hydroxylamine[53] and with BNPS-skatole[54]. The remainder of the sequence was obtained by the dansyl-Edman degradation[55] of peptides from sub-digests of cyanogen bromide fragments with trypsin and staphylococcal protease[56]. The sequence of the lobster enzyme is from ref. 24. The residues of the enzymes are numbered to maximise homology between the sequences. Hence the N-terminal residue of the thermophile GPDH is numbered 0; deletions are introduced at residues 35 and 189 and insertions at 122 A and 138 A of the *B. stearothermophilus* protein.

S loop appears flexible, but is maintained by the packing of side chains and by interactions with neighbouring subunits made through the contacts across the P and R axes.

Those residues which form the extensive interface between subunits related by the P axis are highly conserved. The Q-axis interface involves few residues but these retain the same specific interactions as in the lobster enzyme[32].

Active site

The NAD binding region is shown in Fig. 4. The coenzyme is bound as in lobster GPDH, differences being confined to a few residues interacting with the adenosine portion of the coenzyme. All the residues implicated in substrate binding and catalysis are conserved except asparagine 181. We observe the same two strong electron-dense features which have been interpreted as bound anions and are probably the sites of the phosphate groups of the substrates during the catalytic reaction (Fig. 4).

According to Trentham's mechanism[33,34] (Fig. 5), glyceraldehyde 3-phosphate reacts with the enzyme to form a hemithioacetal (II), which is converted to an acyl-enzyme (III) with the transfer of a hydride ion to the nicotinamide C4. After NADH is replaced at the active site by NAD (IV) the acyl enzyme is phosphorylysed to give the product 1,3-diphosphoglycerate (V). In agreement with the results of Moras *et al*[12], a model of the hemithioacetal built into the active site with the substrate chain in an extended conformation points the hydride atom of C1 towards C4 of the nicotinamide and puts the 3-phosphate in the 'substrate' anion binding site (P_s in Fig. 4). The C1 oxygen is thought to be protonated by the N^6 of histidine 176, and the C2 hydroxyl of the D isomer can hydrogen bond to the hydroxyl of serine 148. The L isomer which is not a substrate, cannot bind in this orientation because its C2 hydroxyl would interfere with the imidazole ring of histidine 176. These conclusions agree broadly with those reached for the lobster enzyme.

Three amino acid side chains play an important part in the 'substrate' anion site (P_s). Two of these (threonine 179, asparagine 181) are in the S loop and the third (arginine 231) is surrounded by other side chains of the S loop. The S loop thus connects directly the NAD binding site of one subunit to the catalytic site of the R-axis related subunit.

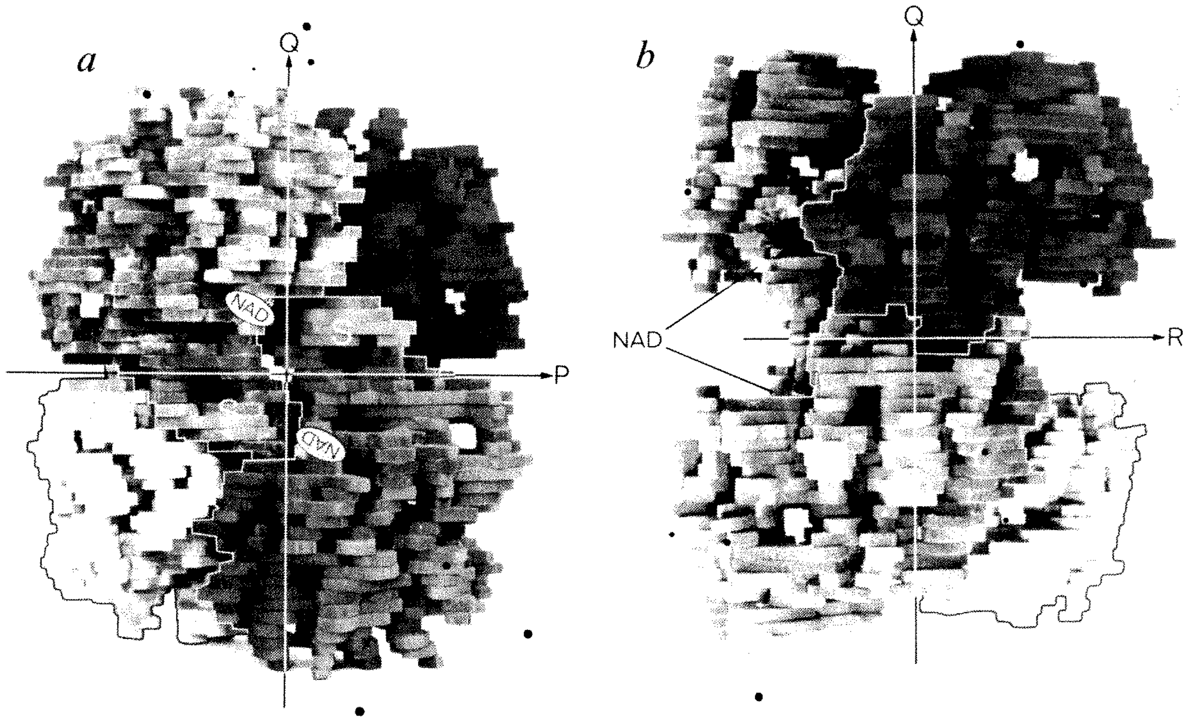

Fig. 2 The four subunits are related by three orthogonal twofold symmetry axes, designated the P, Q and R axes in accordance with the nomenclature adopted[31] for lactate dehydrogenase and lobster GPDH. The four NAD molecules bind to the enzyme close together near the centre of the molecule. *a*, The enzyme tetramer viewed down the R-axis; the S-loop regions are labelled 'S'. *b*, Viewed down the P axis.

NADH is replaced by NAD (IV, Fig. 5); this accelerates phosphorolysis and promotes specificity for phosphate instead of water as the acyl acceptor[35]. Model building shows that the attacking phosphate in the transition state (V) can be stabilised by hydrogen bonds with serine 148 and threonine 150, the amide nitrogens of cysteine 149 and threonine 150, and the C2 hydroxyl of the substrate. The C1 oxygen can be protonated by histidine 176. The 3-phosphate remains in the phosphate site P_s. The close proximity of the sulphur of cysteine 149 to the positively charged nicotinamide C4 would explain the acceleration of the reaction by NAD.

'Racker' band

The characteristic absorption band at λ_{max} 360 nm in holo-GPDH, the 'Racker' band[36], has been explained by the close association of the sulphydryl of cysteine 149 and the nicotinamide ring giving rise to a charge transfer complex[12].

We find that the addition of Hg^{2+} to holo-GPDH abolishes the Racker band, but unlike carboxymethylation, it does not weaken the binding of NAD to crystals. The crystal structure shows that mercury binds behind the active site between the SH groups of cysteines 149 and 153, rotating the side chain of cysteine 149 so as to remove the interaction between the SH and the nicotinamide, but it produces no other structural changes. It follows that this interaction can make only a small contribution to the NAD binding energy. The destruction of the Racker band by mercury without any other changes in the environment of the nicotinamide supports the assignment of the band to a charge transfer complex[37,38]. The distance of at least 3 Å between the SH of cysteine 149 and the nicotinamide ring rules out a covalent interaction[36].

Thermostability

B. stearothermophilus GPDH retains structural integrity and enzymatic activity at temperatures up to 60–70 °C (refs 39, 40), while the *Thermus aquaticus* enzyme[41] remains stable and active to 95 °C. The additional stabilisation energy needed to produce these dramatically increased thermostabilities amounts to only 5–10 kcal. Attempts to identify the source of increased thermostability by relating amino-acid sequences of the thermophile GPDHs to molecular models[41,42] were of limited success owing to the difficulty of distinguishing between sequence changes that are due to phylogeny from those involved in thermal stabilisation. Perutz and Raidt[43] compared the structures and sequence of ferredoxin from a mesophile with the sequences of the same enzyme from various thermophiles and found that their greater heat stability arises mainly from external salt bridges linking residues near the amino terminus to others near the carboxy terminus.

Now that the three-dimensional structures of a thermophilic enzyme and its mesophile counterpart have been independently determined it is possible to search for the stereochemical basis of the extra thermal stability. At the level of accuracy so far attained for the structures, the areas of hydrocarbon surface forming buried contacts within the individual subunits are not significantly different in the two enzymes. Changes in the internal hydrophobic residues between lobster and *B. stearothermophilus* are complementary and are accommodated without structural change. While the P-axis interfaces are essentially the same in both proteins, the hydrophobic interactions at the R-axis interfaces differ especially among residues 184–187. Several aromatic residues are in contact at the edge of this interface in lobster but not in *B. stearothermophilus*. Three tyrosines on the α_c-helix stack with a tryptophan in the S loop of the R-axis related subunit, giving rise to hydrophobic interactions between subunits, not present in the thermophile enzyme, which would indicate greater stability for this region of the lobster enzyme. Contrary to previous speculation, we find the core of the thermophilic enzyme to be no more hydrophobic than that of the mesophilic enzyme.

Although there is a close correspondence between the two structures, a comparative enumeration of hydrogen bonds cannot be made accurately, as their presence can only be inferred from the disposition of hydrogen-bonding groups which are very sensitive to detailed interpretation.

The *B. stearothermophilus* enzyme contains more arginines and two of these extra arginines form salt bridges across subunit interfaces. Arginine 194 forms a buried salt bridge with aspartic acid 293 from the P-axis related subunit. Due to the different conformation of the β-sheet in the catalytic domain this particular aspartate is buried in the thermophile while it is accessible to solvent in the lobster enzyme structure. This salt bridge would not have been predicted simply by relating the sequence of the thermophile enzyme to the molecular model of the lobster enzyme. In addition, arginine 281 of one subunit and arginine 281 from the Q-axis related subunit form a double salt-bridge with glutamic acid 201 from both the R- and P-axis related subunits. These interactions are shielded from solvent and bring the S loops from two subunits into contact with the other two subunits. These additional inter-subunit salt-bridges evidently stabilise the tetrameric structure of *B. stearothermophilus* GPDH, but we would expect that the overall stability of a thermophilic multisubunit enzyme also requires stabilisation of the tertiary structure of the monomer[41]. The detailed structural

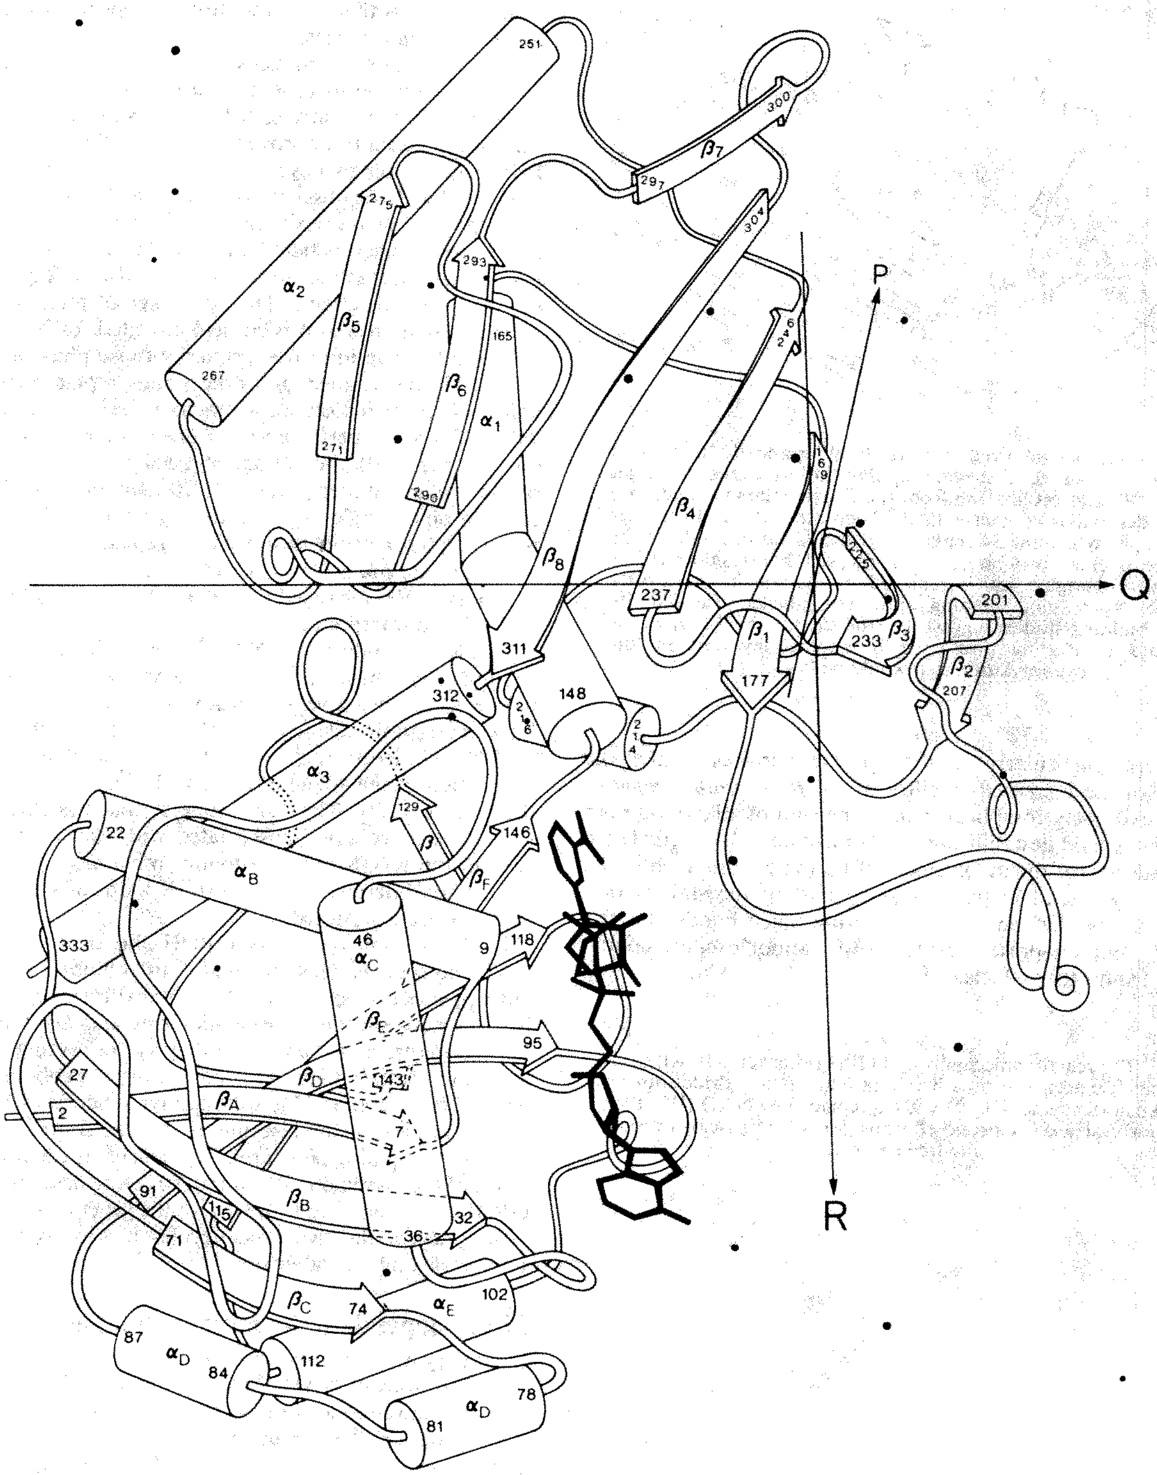

Fig. 3 A folding diagram of one subunit of *B. stearothermophilus* GPDH. The nomenclature for the sheets and helices of the first domain is that used for lactate dehydrogenase and lobster GPDH (ref. 31). The folding in the first domain (residues 0–149) is a β–α–β pattern with a central sheet covered on both sides by helices. In the second domain the extensive anti-parallel β-sheet region forms a subunit interface with the equivalent region of the P-axis related subunit. The S loop (residues 178-201) forms the intersubunit contact with the S loop and α_C helix of the subunit generated by the R axis. The carboxy-terminal helix, α_3, fits into a groove in the first domain. The secondary structure closely resembles that of lobster GPDH except where there are insertions or deletions in external loop regions between segments of secondary structure.

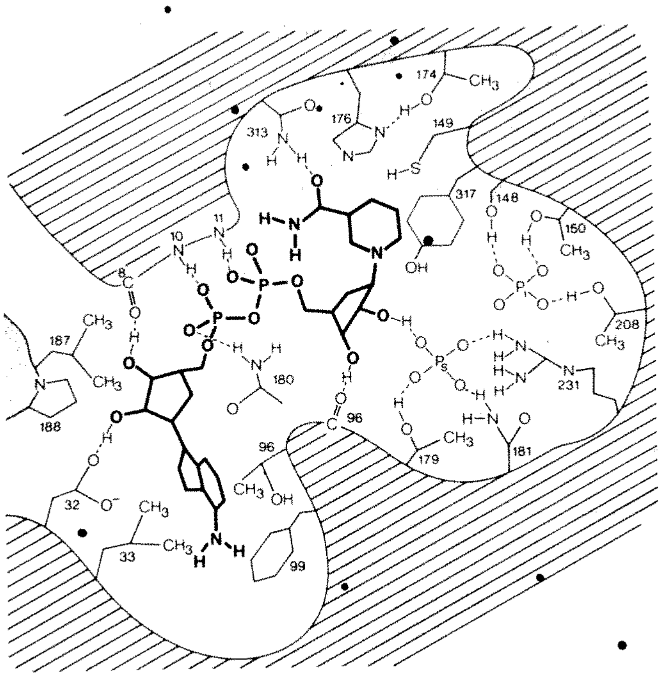

Fig. 4 Residues involved in NAD binding and the two anion binding sites in *B. stearothermophilus* holo-GPDH. Residues leucine 187 and proline 188 from the R-axis related subunit are in van der Waals contact with the adenosine ribose. In lobster GPDH phenylalanine 34 replaces leucine 33 on one side of the adenine pocket: proline 188 is conserved but residue 187 is glycine. Asparagine 180 is replaced by alanine in the lobster enzyme. The anion binding sites are labelled P_s and P_i. Model building studies suggest that the site for the 3-PO_4 of the substrate is P_s; the inorganic phosphate involved in the phosphorylation step would be P_i (ref. 12).

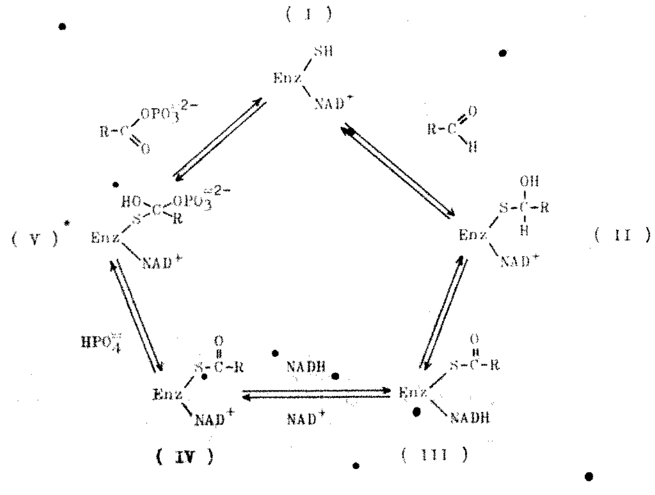
differences, particularly at the enzyme surfaces, make the analysis of the increased stability of the *B. stearothermophilus* enzyme extremely complicated since the sum of a large number of stabilising and destabilising effects must be considered. There is no evidence for the involvement of bound cations such as the calcium ions found in thermolysin[44]. Part of the stabilisation energy may be derived from surface hydrogen bonds and salt bridges[43], but on present evidence we cannot exclude contributions from other effects.

Fig. 5 The reaction mechanism of GPD (after ref. 33). After the enzyme (I) reacts to form a hemithiacetal (II) a hydride transfer gives an acylenzyme (III). NADH is replaced by NAD (IV), then phophorolysis via the proposed transition site (V) yields product and free enzyme.



Molecular symmetry

Folding of the main chain is very similar in the lobster and *B. stearothermophilus* enzymes but there are differences in the interpretation of the molecular structures. Although the subunits of the fully ligated form of GPDH from *B. stearothermophilus* are not related by crystal symmetry, they are nevertheless related by 222 symmetry. The positions and occupancies of five heavy atom sites show the 222 symmetry to be accurate. No structural differences between the four subunits had to be invoked to fit them to the four independently determined electron density images.

An averaged electron density map was not used for interpretation. Starting from a map based on isomorphous replacement with two derivatives, the non-crystallographic symmetry was incorporated to improve the phase angles by the method of Bricogne[23]. After two cycles of this procedure a final map was calculated with the observed structure amplitudes and the phases from the final phase recombination[45]. The map obtained by this procedure is much better than it would have been after averaging, which reduces the noise level but also smears out detail, especially of side chains. The advantage of phase combination over averaging has also been demonstrated for hexokinase[46].

This technique improves primarily those phase angles which are poorly determined by isomorphous replacement, but it is valid only if the molecular symmetry is accurate. For reflections with a figure of merit, $m > 0.7$ from isomorphous replacement (56% of the total), the average phase change after incorporation of molecular symmetry was only 20°. In contrast, the standard error in phase angle expected for $m = 0.8$ is 37°, which shows that the phases from isomorphous replacement are consistent with accurate molecular symmetry.

Moras *et al.*[12] averaged their map of lobster GPDH about the Q dyad and interpreted the map in terms of a non-symmetrical molecule, concluding that NAD is bound differently to different subunits. They have advanced this asymmetry as a partial explanation of the negative cooperativity of NAD binding. In their interpretation the adenine ring of NAD of one subunit is rotated by 180° relative to that of the R-axis related subunit, and the interaction of the adenine ribose with the protein is different in the two subunits. They also suggest that cysteine 149 in one subunit is more closely associated with the nicotinamide ring and, in the R-axis related subunit, more closely with histidine 176. Other differences between the S loops of symmetry related subunits are also noted.

In *B. stearothermophilus* GPDH the conformation of the NAD molecule is the same in all four subunits. The four NAD binding sites are equivalent. The sulphydryl of cysteine 149 lies halfway between the nicotinamide ring and histidine 176 in all four subunits, and there is no density connecting cysteine 149 and the nicotinamide. Histidine 176 is probably hydrogen bonded to threonine 174, although tyrosine 311 is close by, and the orientation of the histidine ring is the same in all subunits. The anion binding sites are also present in all four subunits. None of the asymmetry of subunit structure described for lobster GPDH has been found. In view of the functional and structural similarities of the two holoenzymes it is unlikely that one is symmetric and the other not.

NAD-dependent structural changes

Symmetry of the enzyme is maintained either in saturating concentrations of NAD, or in the absence of NAD. In crystals grown in lower concentrations of NAD, or soaked in NAD-free mother liquor, 0.5–1.5 moles of NAD are lost and structural changes in the protein appear in difference maps against holo-GPDH (ref. 48). The largest changes occur in the nucleotide binding domain of the subunit which has lost its NAD. The conformation of this domain changes towards that observed in a 6-Å map of apo-GPDH (ref. 47).

The large movement of the coenzyme-binding domain on loss of NAD to form apo-GPDH gives rise to an expansion of the molecule. An increase in molecular volume upon loss of NAD has also been detected by sedimentation equilibrium studies[48,50], and by small-angle X-ray scattering[51,52].

The negative cooperativity of NAD binding could be the result of a change in packing of parts of the protein chain, especially of the residues in the S-loop. In holo-GPDH this segment of 20 residues is devoid of secondary structure and most of its main chain is inaccessible to solvent. Expansion of the molecule in apo-GPDH opens this region and might make the S-loop more flexible. The following chemical evidence supports this. If muscle apo-GPDH is acylated, and then incubated at *p*H 8.5, the acyl group is transferred specifically from cysteine 149 to N^ε of lysine 183 (refs. 26, 27). (Residue 183 is arginine in the bacterial enzyme, but the position of the arginine side chain is the same as that of the lysine 183 in lobster GPDH.) In holo-GPDH this transfer does not happen because the N^ε is 10 Å from the sulphydryl of cysteine 149. The occurrence of the reaction in apo-GPDH only, is indicative of the greater flexibility of the S-loop.

The S-loop has many of the properties expected of a structure which transmits a structural change from one subunit to another in a cooperative system. It interacts with two adjacent subunits (including a direct coenzyme contact), it is shielded from solvent at least in holo-GPDH and lacks strong secondary and tertiary interactions. In addition, there is evidence that its structure in the apoenzyme is quite different from that in the holoenzyme.

We acknowledge the contribution made by Dr K. Suzuki in the early stages of this work, and thank Dr D. M. Blow for encouragement and Dr M. F. Perutz for helpful comments.

letters to nature

A better way of searching for black-hole explosions?

BLACK holes of $\lesssim 10^{15}$ g evaporate in $\sim 10^{10}$ yr, and eventually annihiliate into a burst of energetic photons and particles[1]. To test this theoretical prediction would be extraordinarily significant for quantum and gravitational physics. There could be $\sim 10^{23}$ 'miniholes' within our Galaxy[2–4]; on the other hand, there may not be any at all. But even if they exist in profusion, how best could we detect black-hole explosions? Attention has been focused on the problem of directly detecting the γ rays, but the prospects seem bleak[3]. The possibility that the particles ejected in the explosion may generate conspicuous effects has hitherto been overlooked. I argue here that collective interaction of electrons and positrons with an ambient interstellar magnetic field can (on some specific assumptions) generate radio bursts powerful enough to be detected from anywhere in our Galaxy, or even beyond. This opens up a more promising perspective on the search.

A conducting sphere, expanding into a uniform magnetic field, will develop surface currents which prevent the field from penetrating it. If the shell expands relativistically, with constant Lorentz factor $\gamma \gg 1$, out to a radius r_{max}, then the work done against the field is

$$\sim \gamma^2 \times (\text{energy of swept-up field}) \qquad (1)$$

(Note the factor γ^2, which occurs just as it would if the sphere were reflecting electromagnetic radiation.) A distant observer would see the part of the shell moving at angles $\lesssim \gamma^{-1}$ to the line of sight blue-shifted by $\sim \gamma$; he sees a surface current on this part of the shell increasing $\propto t^2$ for a time $\sim r_{\text{max}}/c\gamma^2$. The energy (1) therefore appears as an electromagnetic pulse with characteristic wavelength

$$\lambda \simeq r_{\text{max}}/\gamma^2 \qquad (2)$$

We now investigate how this classical electromagnetic phenomenon might apply to the type of 'fireball' resulting from an exploding black hole.

Suppose that, when the mass of an evaporating minihole has fallen to M_{crit} g, it vomits forth its remaining energy in an essentially instantaneous burst of $\sim 10^{31}\, M_{\mathrm{crit}}$ erg. In the Hagedorn theory, $M_{\mathrm{crit}} \simeq 10^{14}$ g; but on other theories of elementary particles it would be lower. Very near the hole, the energy would be distributed between a variety of exotic species; but we assume that these quickly decay, and that, by the time the ejecta have expanded to macroscopic radii, a substantial fraction (say $\sim 50\%$) of the energy is in a 'fireball' of electron–positron pairs[15]. From the theoretical relation between temperature and mass, we expect this fireball to expand with $\gamma_f = (M_{\mathrm{crit}}/2\times10^{16}\ \mathrm{g})^{-1}$.

For illustrative purposes, we consider fireballs with energy $\varepsilon_f \simeq 10^{37}\ \gamma_f^{-1}$ erg in electron–positron pairs. The number of pairs is then $N_f \simeq 10^{43}\ \gamma_f^{-2}$.

We must then address these questions:

(i) How large a radius can the fireball attain before the energy in the swept-up field decelerates it?

(ii) To what extent is it a good enough conductor to sweep up the field?

(iii) Would the fireball be braked by sweeping up external plasma as well as magnetic flux?

Suppose that the uniform external magnetic field is $B \simeq 5\times10^{-6}\ b$ G (where b would be ~ 1 for a typical interstellar field with energy density $\sim 10^{-12}$ erg cm^{-3}). If the fireball behaved as a perfect conductor, it would be significantly braked when it had swept up a magnetic field energy of $\sim \varepsilon_f/\gamma^2{}_f$. Thus we have, on energetic grounds, an upper limit to r of

$$r_{\mathrm{en}} \simeq (10^{16}/\gamma_f) b^{-2/3}\ \mathrm{cm} \qquad (3)$$

Quite apart from this limit, the fireball cannot behave like a perfect conductor and expel the magnetic field (without being decelerated) unless the charge density is sufficient to carry the currents. This requires a surface density $\sim 10^3 \gamma_f\, b$ charges per cm^2. The conductivity condition thus breaks down at a radius r_{cond} where $N_f/2\pi r^2$ falls to this value. One finds

$$r_{\mathrm{cond}} \simeq (4\times10^{19}/\gamma_f^{3/2}) b^{-1/2}\ \mathrm{cm} \qquad (4)$$

The appropriate value of $r_{\max}$ to use in (1) and (2) is the smaller of r_{en} and r_{cond}. For $\gamma_f < 10^7$, r_{cond} exceeds r_{en} (that is, the conductivity is good at all relevant times); so a fraction ~ 1 of the total fireball energy then emerges as electromagnetic waves of characteristic wavelength $\lambda \simeq r_{\mathrm{en}}/\gamma_f^2$. This means that, for $\gamma_f \simeq 10^5$, $\sim 10^{32}$ erg emerges at $\lambda \gtrsim 10\, b^{-\frac{2}{3}}$ cm; and for $\gamma_f \simeq 10^7$, $\sim 10^{30}$ erg emerges at $\sim 10^4\, b^{-\frac{2}{3}}$ Å.

Such a radio burst would be readily detectable anywhere in our Galaxy, or even beyond[6,7], and the optical flash from a $\gamma_f \simeq 10^7$ fireball could be detected $\gtrsim 1$ kpc away (J. V. Jelley *et al.*, to be published). We must, however, check the validity of our assumption (question (iii) above) that the fireball is not braked by external plasma before attaining a radius r_{en}. External particles can be swept up, yielding a relativistic blast wave, only if the gyroradius of a particle with Lorentz factor γ_f in a field γ_f B is $< r/\gamma_f$. This requires

$$r \gtrsim 4\times10^8\, b^{-1}\, \gamma_f \qquad (5)$$

In the cases $\gamma_f \simeq 10^5$ and 10^7 cited above, $r_{\max}$ ($= r_{\mathrm{en}}$) does not satisfy (5) for $b \lesssim 1$, so we are justified in assuming that the fireball transfers its momentum to the field rather than the ambient particles. (Arguments analogous to those used in deriving (4) and (5) show that the weak steady efflux preceding the final explosion cannot create a field-free heliosphere-type cavity around a minihole. This vindicates our assumption that the fireball impacts directly on to a typical ambient magnetic field).

In the 'extreme Hagedorn' case ($\gamma_f \simeq 300$), where the earlier argument would have yielded a strong ultra-low-frequency pulse that in any case would not propagate freely, (5) is fulfilled, so we would expect a relativistic blast wave with a swept-up shell. There is then no chance of getting efficient coherent radiation, the energy going instead into random relativistic particle motions. The field strength in the shell would be $\sim 5\times10^{-3}\ b$ G, and relativistic electrons with $\gamma_f \simeq 300$ would lose only 10^{-10} of their kinetic energy while the shell expanded. If a Hagedorn-type explosion occurred on a timescale Δt sudden enough to cause a coherent radio pulse, then most of the pairs would in any case have annihilated into photons. (The expansion timescale, in the comoving frame, when the fireball temperature falls to ~ 0.5 MeV is $\propto \gamma_f^{-2}(\Delta t)^{1/2}$, and our assumption that there is no time for annihilation to occur is self-consistent for $\gamma_f \gtrsim 10^5$.)

It is thus the case $\gamma_f \gg 10^3$ which—even though it entails a lower ε_f—offers the greatest promise of radio (or optical) detection. The pulse-production mechanism requires that the final outburst be 'instantaneous' in the sense that its timescale is $\lesssim \lambda/c$. This requirement is perhaps not met by quark theories, unless a lot of extra species occur above some energy $\gtrsim 100$ GeV. Because of this sensitivity to the uncertain particle physics, the absence of frequent strong radio pulses reaching the Earth cannot be used to improve the present upper limits on the number of miniholes in the Galaxy[2–4]. On the other hand, linearly polarised radio-frequency pulses (rather than γ-ray pulses) may well be much the most conspicuous manifestations of black-hole explosions, because radio techniques are exceedingly sensitive[6,7]. To dramatise the potential advantage, the γ rays from a fireball with $\gamma_f \simeq 10^5$ would only be registered by a detector of effective area 100 cm^2 if the event occurred within 10^{-2} pc; but even a crude non-directional antenna would detect the corresponding radio pulse at distances $\sim 10^4$ pc. And an Arecibo-type telescope could detect such pulses—each triggered by a single entity of subnuclear size—from as far away as the Andromeda galaxy!

I thank Bernard Carr, Stephen Hawking, John Jelley, Don Page and David Wilson for helpful comments.

Is Cas A illuminated by a binary system?

I REPORT here indications that the supernova remnant Cas A (and probably many others) contains a neutron star at its centre, in close orbit around a 'normal' star. The indications are of three types: of evolutionary, statistical and indirect character, arguing that the high observed magnetic field strengths and the steepening synchrotron spectrum cannot be explained by stochastic processes.

Supernova explosions are commonly believed to derive their energy from the collapse of the (degenerate) core of a formerly massive late star. The conversion of gravitational energy into the kinetic energy of radial motion could be achieved through a magnetic spring[1–3] rather than a combination of neutrino[4] and thermal pressures. The mass of the collapsing core is expected to be near the Chandrasekhar mass ($\approx 1.4 M_\odot$), because this is the minimum mass for gravitational instability according to stellar evolution theory, and because all the overlying material is ejected by the action of the magnetic spring. The core thus turns into a stable neutron star. Mass determinations[5] of neutron stars in binary systems confirm this picture, which might apply to supernovae of all types (I, II,...), their differences being due to the density of the surrounding medium which controls the mass in the envelope.

Most if not all of the massive progenitor stars of supernovae occur in binary (or multiple) associations. During the explosion, a binary system gets disrupted if the ejected mass is bigger than the remaining mass, which can happen in the first or, more likely, in the second event. If in the first event, we obtain (eventually) two pulsars; if in the second, mass flow from the normal star to the neutron star can give rise to a temporary X-ray source, and eventually to one or two pulsars (depending on the spin rate of the first neutron star). The measured peculiar velocities[6] of 12 pulsars suggest that several of them received two kicks in the past, and hence result from binary systems containing a neutron star.

We therefore expect a large number of supernova explosions to leave a binary neutron star at their centre. What will such a system look like? The young neutron star should act as a strong pulsar, with a relativistic wind of power $L \approx 10^{39}$ erg s^{-1} $\Omega_{2.5}^{4}$ (modelled after the Crab). A fraction of this power will heat the atmosphere of the companion star until enough plasma is evaporated for the formation of a common envelope. The time scale t for evaporating a small fraction α of the companion star's mass M is of the order (ignoring reradiation)

$$t = \alpha GM^2a^2/R^3L \approx 30y\alpha_{-3}a_{12}^2$$

where a is binary separation and R the stellar radius. For close binaries, a small evaporated mass fraction α should be sufficient to build up an atmospheric pressure which overcomes the pulsar wind pressure, first at mid-separation, and later at all distances outside a small cavity around the neutron star, so that a common envelope forms, and the pulsar is quenched. Instead of driving a relativistic wind, the rotating magnetised neutron star will henceforth accelerate the wind plasma of the companion star which impinges on its magnetosphere (through magnetospheric friction), and produce cosmic rays[7]. It will no longer act as a pulsar. Cyg X-3 could be a system in transition between the pulsar stage and the cosmic-ray stage; whereas Cas A is suggested to have reached the latter.

To obtain an independent estimate of the duration t of the pulsar stage, and to assure consistency of the whole model, we consider statistics. The present birth rate of supernovae in the Galaxy has been estimated[8] to lie between 10^{-1} and 10^{-2} yr^{-1}. Allowing for an enhanced activity throughout an early phase of the Galaxy, the total number of supernova explosions since formation should be 10^8 to $\gtrsim 10^9$. Unless neutron stars can be formed in a peaceful way[9,10]—which is not very likely even when magnetic fields are ignored—this number must not be smaller than the total number of neutron stars in the Galaxy. Neutron stars occur singly, as pulsars, and in binaries, visible during the X-ray stage. Extrapolation of the known data[11–13] on pulsars leads to a present total number between 10^4 and 7×10^5, depending on the distance scale, and upon the amount of beaming into a reduced spherical angle. Pulsar lifetimes peak near 3×10^6 yr so that there should be (at least) a total of 2×10^7 to 2×10^9 single neutron stars (= dead or alive pulsars) in the Galaxy. (Single neutron stars ejected as slow rotators from binary systems are not included.) This suggests a one-to-one correspondence between supernova explosions, and neutron star formations; Cas A may not form an exception.

Next, a single pulsar has not been seen in orbit around a normal star, although there should be[14,15] over 10^4 such systems in the Galaxy (inferred from the number of X-ray sources, or from the number of pulsars.) This implies that the pulsar stage t must be $\lesssim 10^{-4}$ times shorter than the lifetime of a massive star, that is, shorter than some 5×10^2 yr.

Cas A has an estimated age[16] of 3×10^2 yr, and a radius of 5 light yr. It does not contain a pulsar: even if the pulses were beamed away from us, we should see strong optical emission from the inner edge of the nebula, like the wisps in the Crab, or at least a strong compact X-ray source. Also, pulsar peculiar velocities[17] are rarely higher than 10^{-3} c so that a pulsar could not have escaped from the nebula. For these reasons, Cas A has been held to be a remnant without a central source, and has been treated[18] as a hot cloud expanding due to a powerful explosion in the past. Such a detonation wave becomes unstable, near its outer edge, towards convective motion and mixing with the interstellar plasma. From his numerical models, Gull[18] estimates a conversion of 2 or 3% of the total expansion energy into convection, which is held responsible for driving a dynamo that enlarges the interstellar magnetic field by a factor of $\approx 10^2$, to arrive at the inferred equipartition field strength of 5×10^{-4} G in the outer parts of the remnant. In most of the compact knots, the minimum magnetic field inferred from the radio synchrotron brightness is as high as 3×10^{-3} G. The radio intensity decreases with time, by roughly 1% per yr, but at a higher rate (1.3%) at 85 MHz than at 1.4 GHz (0.9%). Moreover, there is a soft X-ray luminosity of 3×10^{36} erg s^{-1}.

The difficulty faced by this model is the large observed magnetic field, which would require (many) more than seven turns to be performed by the interstellar material; even if there is enough energy available, a dynamo cannot do better than double the seed field during each turnover. With the observed convective velocities $\lesssim 10^{-2}$ c (ref. 18), such a dynamo cannot reach scales beyond 10^{-1} light yr. Similar difficulties arise for the radiating electrons whose synchrotron lifetimes are shorter, at energies above 10^2 GeV, than the lifetime of the remnant, and also much shorter than the replenishment timescale for Fermi acceleration[19].

These difficulties disappear if we assume the existence of a neutron star inside the remnant. This neutron star would have acted as a pulsar for an initial period of the order of some 10^2 yr, during which its extremely relativistic wind injects both electrons and magnetic flux into the supernova shell[20]. When overtaking trailing filaments (protostellar condensations), the frozen-in magnetic field gets hooked up, and forms the magnetic knots—which I interpret as filaments seen edge on. (Such knots do not occur in the Crab nebula, whose symmetry axis is nearly normal to the line-of-sight). For the same reason, the field line geometry between knots is near-radial.

The main reasons against an empty interior of Cas A are therefore, in decreasing order of cogency: (1) The finite scale, strong magnetic fields are difficult to explain, because a dynamo needs time; and relativistic particles are difficult to produce by the more or less ordered (radial) motion of a detonation wave. (2) If the majority of supernova explosions did not result in the birth of a neutron star, we might see more pulsars than have been (violently) born. (3) There is a trend both in late stellar evolution theory, and in astration theory[21] towards assigning an increasingly large probability to neutron star formation in supernova explosions.

I thank E. van den Heuvel for an illuminating correspondence, E. Krotscheck for discussions.

Dirac–Fock one-centre calculations show (114)H_4 to resemble PbH_4

RELATIVISTIC effects have a considerable influence on the chemical behaviour of the heavier elements. Our Dirac–Fock one-centre expansion calculations[1-3] indicate that the X–H bond lengths, R_e, suffer a relativistic contraction of about 5% for PbH_4 (ref. 1) or AuH (ref. 2) and 7% for TlH (ref. 3). If the relativistic effects are included, however, these R_e values mostly agree with experiment to within 2–3%. Relativistic effects also seem to be the main cause of the chemical difference between silver and gold[2] and, possibly, of the dominant monovalency of thallium[3]. A relativistic treatment becomes imperative to predict the chemical behaviour of the superheavy elements. Following evidence for primordial superheavy elements[4], we present here results for the tetrahydride of the element 114 or eka-lead. We believe that such a calculation gives a reasonable estimate for the covalent radius of this element. Although the dominant valency of 114 is expected to be 2, some tetravalent compounds are also expected to be stable[7]. As the latter valency is more convenient for calculations, having closed shells, we here consider (114)H_4.

Our approach here is as in ref. 1. No symmetry functions were used. A finite, homogeneously charged nucleus with $A = 298$ was assumed. The total energy, E_T, was calculated at five internuclear distances and the results were fitted into a third degree polynomial. The results are shown in Table 1, E_T variation in Fig. 1, and orbital energies in Fig. 2. The most striking aspect of the Fig. 2 is that the 6 $d_{5/2}$ shell is slightly above the 7 s. Therefore, a strong participation in chemical bonding is expected from the 6 $d_{5/2}$ and 6 $d_{3/2}$ shells. Similarly, a strong participation of the 5 d orbitals is suspected for AuH (ref. 2). The present values of R_e and k_2, 3.376 and 0.57 AU, respectively, are closely similar to those obtained[1] for PbH_4 using the same approximations, or 3.395 and 0.55 AU, respectively. The experimental k_2 for both $PbH(CH_3)_3$ and $PbH_2(CH_3)_2$ is 0.445 AU (ref. 9).

Table 1 Calculated results for (114)H_4

Bond length R_e	3.376 AU = 1.787 Å
Total energy $E_T(R_e)$	−49712.76 AU
Force constant k_2	0.57 AU
Orbital energies ε*	
7 $p_{3/2}$	−0.25712 AU
7 $p_{1/2}$	−0.43640
7 $s_{1/2}$	−0.80274
6 $d_{5/2}$	−0.77015
6 $d_{3/2}$	−0.93950

*At $R = 3.4$ AU

The covalent radii for elements C to Pb (ref. 6) are listed in the first column of Table 2. Combining them with the experimental R_e values in the second column, we find a covalent radius of 0.31 Å for hydrogen. Subtracting this value from the present theoretical R_e of 1.787 Å we find a covalent radius of 1.48 Å for quadrivalent (114). The difference of 0.04 Å between the R_{cov} for Pb and 114 includes the experimental error for PbH_4. The theoretical R_e differs by 0.01 Å.

As the effects of increasing atomic number, Z, on the bond length are quite different for Groups IB (Au), IIIA (Tl) and IVA (Pb), it is interesting to discuss these differences in terms of the electron configurations. Group IB has an s^1 valence configuration which is also the dominant component of the bonding molecular orbital in AuH. As this atomic orbital contracts strongly[5], due to relativistic effects, the experimental R_e for AuH is 0.09 Å shorter than that for AgH. For Group IIIA the valence configuration is p^1. According to the model in ref. 3, a transition from pσ bonding to $p_{1/2}$ bonding takes place when going from InH to TlH. Therefore the lost directional character makes the chemical bond of TlH weaker. Although the $p_{1/2}$ shell itself contracts, the sum of the two effects makes the R_e for TlH 0.02 Å larger than for InH. For the tetrahydrides of Group IVA, the $p_{3/2}$ and $p_{1/2}$ shells are filled. The average orbital energy $(2\varepsilon_{np_{3/2}} + \varepsilon_{np_{1/2}})/3$ depends only slightly on Z (Fig. 2). The theoretical R_e values increase by 0.03 Å from SnH_4 to PbH_4 and decrease by 0.01 Å from PbH_4 to (114)H_4. No evident interpretation can be given for these small changes.

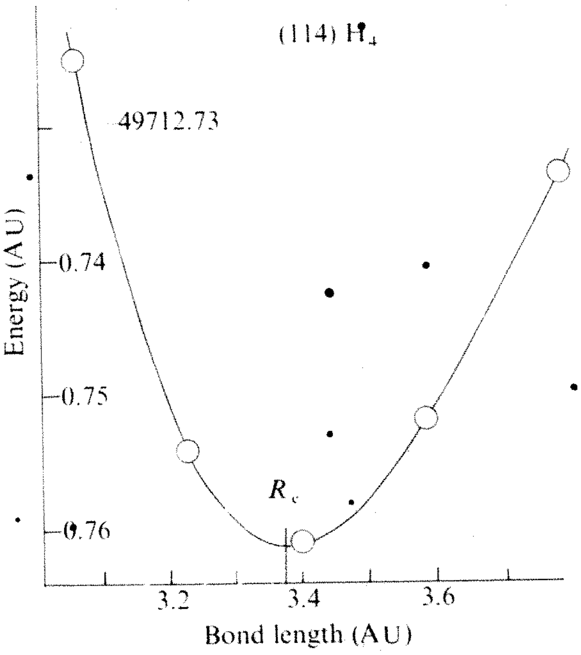

Fig. 1 Molecular total energy as a function of bond length. The curve is the fitted third degree polynomial.

We give here the first calculation of a bond length for a superheavy element. The result for the covalent radius of 114 is about 1.48 Å. Assuming also for metallic 114 the same crystal structure and lattice parameter as for Pb, the assumed atomic weight of 298 would lead to a density of 16.3 g cm^{-3} for the metal 114. The general chemical conclusion is that the covalent radii of 114 and its neighbours are expected to be comparable with,

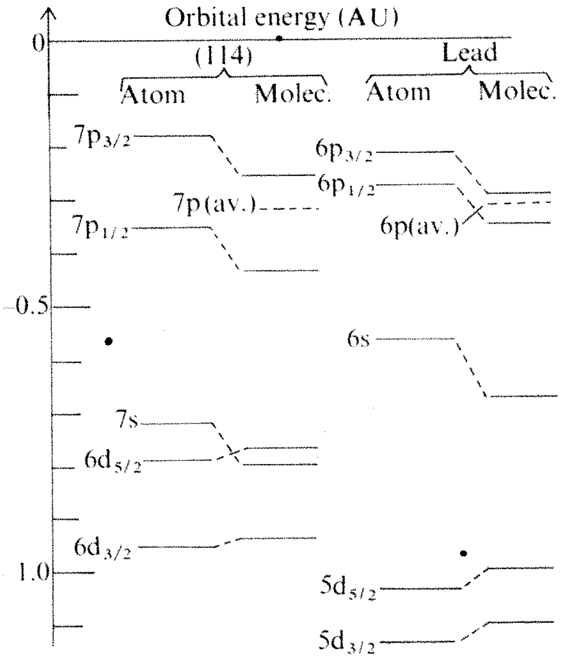

Fig. 2 Orbital energy diagrams for the free atoms of lead and the element 114 (from ref. 5) and for the molecules PbH_4 (from ref. 1, $R = 3.50$) and (114) H_4 (present work, $R = 3.40$).

Table 2 Covalent radii R_{cov} (Å) for the tetravalent elements C to (114), measured X–H distances, $R_{e,exp}$, for the compounds XH_4, and the corresponding distances, $R_{e,calc}$, calculated using R_{cov}.

A melting criterion based on the dilatation dependence of shear moduli

The elastic instability theory of melting, proposed by Max Born[1], held that melting in a crystalline material occurs when one of the elastic shear moduli vanishes, so that the material can no longer sustain an infinitesimal shear stress without flowing. This explains the fluidity of a melt, but fails to account for several other important characteristics of melting. Melting is a transition between two independent phases, while Born's theory is a single-phase theory which contains no distinct description of the melt, and thus fails to account for the discontinuous, first order character of melting. Because it is an essentially homogeneous theory, it does not explain the occurrence of superheating, the metastability of the melt, and the heterogeneous nucleation and growth features of the melting process. Also, subsequent observations of elastic moduli showed that none of the shear moduli is zero or near zero in the solid at the melting point. Because of these defects Born's instability theory currently enjoys little credibility. We believe, however, that correct application of Born's hypothesis leads to a simple modification of his initial criterion for melting which satisfies all the requirements of a physically realistic theory of melting. We show here that the hypothesis does predict a first-order transition between two phases and that the transition has a nucleation barrier, thus dismissing some of the physical objections to the hypothesis. Moreover, the hypothesis applies in the alkali halides, in that in each case one of the shear moduli falls continuously to zero through the melting expansion.

Suppose that one of the elastic shear moduli, μ, decreases monotonically with temperature increase, and that at some critical temperature the shear modulus vanishes or becomes sufficiently small that shear flow could occur by thermal activation. The consequent fluidity which allows each atom access to the entire fluid volume will cause an increase in entropy, due to the communal entropy, which in the case of the alkali halides equals $2R$. The onset of fluidity thus results in a decrease in free energy by $2RT$. In the virtual process of tracing back along the shear modulus curve, initially increasing the free energy by losing the communal entropy but progressively decreasing the elastic internal energy, a point can be located, at which the free energy of the solid equals the free energy of the virtual solid that has a vanishing shear modulus. (The elastic internal energy will be decreased by $> 2RT$, as the virtual process results in an additional decrease in vibrational entropy.) Thermodynamically, it is possible for the solid at the point thus located to transform isothermally to the vanishing shear modulus state. This is the melting point, and the transition will be discontinuous with an accompanying heat absorbtion. We therefore suggest that Born's melting criterion that melting occurs when the shear modulus of the solid vanishes, should be replaced by the following: melting occurs when a solid can transform isothermally to a state of zero shear modulus. The modified theory becomes a two-phase theory in that the solid at the melting point is described as solid at dilatation $\delta_m{}^s$ while the melt at the melting point is described as virtual solid with properties evaluated at $\delta = \delta_m{}^l$. Moreover, there is a nucleation barrier to melting equal to the communal entropy, and consequently the heterogeneous character of melting is also implicated by the hypothesis.

The behaviour of the alkali halides agrees with our proposal. Fig. 1 shows a plot of shear modulus, $\frac{1}{2}(c_{11} - c_{12})$ for the rock salt alkali halides, and c_{44} for CsBr and CsI as a function not of temperature, but of dilatation, that is, the relative increase in volume $\Delta V/V$ from room temperature to the temperature and phase of interest. Our data are obtained from refs 2–5. The last point in the close succession of points on the low dilatation side is the shear modulus at the dilatation, $\delta_m{}^s$ of the solid close to the melting point, while the isolated points for each curve are for $\mu = 0$ at the dilatation, $\delta_m{}^l$ of the liquid at the melting point. Although the shear modulus and the dilatation are both discontinuous with respect to temperature at the melting point, the points for the melt in Fig. 1 lie on the extrapolated curves for the solid, and consequently the shear modulus seems to be a continuous function of dilatation through the melting expansion and falls to zero at the dilatation of the melt. Born's melting hypothesis as modified above thus seems to apply for the alkali halides.

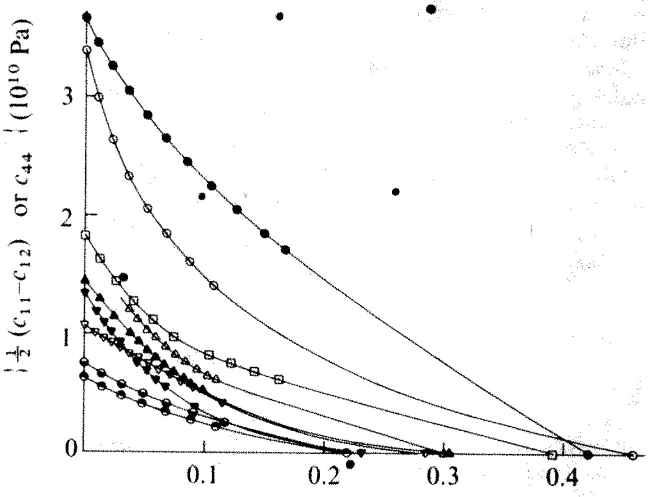

Fig. 1 The shear moduli $\frac{1}{2}(c_{11}-c_{12})$ for some rock salt alkali halides and c_{44} for CsBr and CsI as functions of dilatation, $\delta = \Delta V/V$. ○, LiF; ●, NaF; □, NaCl; △, KCl; ▲, KBr; ▽, KI; ▼, RbI; ◒, CsBr; ◒, CsI.

A fuller account of our work and evidence for the continuity of the bulk modulus with respect to dilatation through the melting expansion are presented elsewhere[6,7].

Non-radiative energy transfer in polymers

THE study of intra- and intermolecular transfer of energy by non-radiative processes is important in developing an understanding of such phenomena as photosynthesis and photo-stabilisation of polymers. Several theories have been proposed, notable among which is the dipole–dipole mechanism due to Förster[1] and Galanin[2]. Apart from the dependence on distance separating donor and acceptor, the probability of transfer is related to the angle between donor and acceptor moments. For this reason measurements of fluorescence depolarisation can be used to estimate the efficiency of transfer from donor to acceptor. Macromolecules provide interesting potential for studying intra- as well as intermolecular non-radiative transfer. Thus chromophore-bearing polymers such as polystyrene allow the possibility of excitation at one part of the molecule, transfer along the chain from one phenyl unit to another until an energy trap, an excimer site, is reached whereupon the energy is emitted as a photon. The principal emission observed from polystyrene at room temperature is that from excimer. We wish to make a preliminary report on some studies we have made on fluorescence depolarisation using a styrene–phenyl acetylene copolymer as donor, and perylene as acceptor.

The donor–acceptor pair were cast in poly(methyl methacrylate) films. This copolymer has polyene groups along the main chain as well as the pendant phenyl units. It has a much stronger emission spectrum than polystyrene and is thus more suitable for using in energy transfer studies. The results shown in Table 1 indicate that energy is being transferred from donor to acceptor, at the highest concentration of acceptor transfer is almost complete. At this level of concentration of acceptor the process of transfer is long range and the mechanism must be by dipole–dipole interaction. Applying Förster theory[1] to the data yields an R_0 value of 78 nm indicating coupling over relatively long donor–acceptor distances. Column 2 of Table 1 shows that as the efficiency of transfer increases, the extent of depolarisation of the emission from the acceptor also increases, in accord with the predictions of Förster's theory. It is also worth noting that intermolecular energy transfer is occurring involving perylene molecules only (column 4). However, the emission from the macromolecular donor shows no depolarisation which suggests that neither inter- or intramolecular non-radiative energy transfer is taking place.

We also measured the depolarisation of the excimer emission of several samples of pure polystyrene films cast from methylene dichloride solutions and obtained a value of 1.3 ($\lambda_{ex}=264$ nm, $\lambda_{em}=320$ nm). The instrument used to make the measurements was a Perkin Elmer MPF2, using the polarisation accessories provided by the makers. The value obtained for fluorescein was in agreement with the literature value.

Table 1 Depolarisation of styrene/phenyl acetylene copolymer (donor) and perylene (acceptor), suspended in poly(methyl methacrylate)

Acceptor concentration (M)	Efficiency of transfer from donor to acceptor	Depolarisation (1)	Depolarisation (2)	Depolarisation (3)
0	—	—	—	1.8
0.55×10^{-3}	0.40	6.8	3.2	1.7
1.46×10^{-3}	0.59	10.3	3.4	1.6
3.65×10^{-3}	0.73	16.0	4.7	1.5
7.30×10^{-3}	0.81	22.7	5.8	1.9
18.30×10^{-3}	0.99	25.0	10.5	1.9

The donor contained approximately 20% (by weight) of phenyl acetylene, and its concentration was constant at 10^{-3} M.

Depolarisation ($\bar{P}$) was measured using the equation[3] $\bar{P}=\dfrac{I_{VV}+GI_{VH}}{I_{VV}-GI_{VH}}$

Depolarisation (1) was obtained by exciting the donor and measuring the depolarisation of the acceptor emission: $\lambda_{ex}=285$ nm; $\lambda_{em}=442$ nm. Depolarisation (2) was obtained by exciting the acceptor and measuring the depolarisation of the acceptor emission: $\lambda_{ex}=410$ nm; $\lambda_{em}=472$ nm. Depolarisation (3) was obtained by exciting the donor and measuring the depolarisation of the donor emission: $\lambda_{ex}=285$ nm; $\lambda_{em}=380$ nm.

The results for the polymers have two possible interpretations: either (1) intramolecular energy transfer for these polymers does not occur to any significant extent by the dipole–dipole mechanism and therefore the currently held theory of energy migrating along the polymer chain into traps is incorrect, or (2) the probability of transfer does not decrease as $\cos^2$ (the angle between moments) but at some higher power. The data presented in Table 1 show that intermolecular transfer is occurring for perylene and consequently the $\cos^2$ relationship holds.

We conclude that energy transfer along polymer chains does not take place by the Förster-type non-radiative mechanism. Further experiments are being carried out to attempt to elucidate the mechanism of intramolecular transfer for polymers.

Large ground deformation on Mount Etna volcano

AN 11-km traverse of benchmarks for precise levelling across the summit of Mount Etna was established and levelled in July 1975. The traverse runs from a reference benchmark near the Piccolo Rifugio (about 2515 m a.s.l.) in the south, across the summit cone (highest station about 3210 m a.s.l.) and down to the rim of the Cratere Ellittico Caldera near Pizza Deneri (about 2780 m a.s.l.) (Fig. 1). The traverse is re-occupied about twice a year to monitor vertical ground movements associated with volcanic activity, the method being similar to that used on Kilauea Volcano, Hawaii[1–3]. A Zeiss Ni2 self-levelling level with micrometer and 3-m invar staff are used and precise levelling techniques adopted where possible. (Previous precise levelling on Etna[4] was restricted to dry tilt stations at three localities.) Closures on ½-km traverses are better than first order accuracy. Re-levelling has so far been carried out in May 1976 and

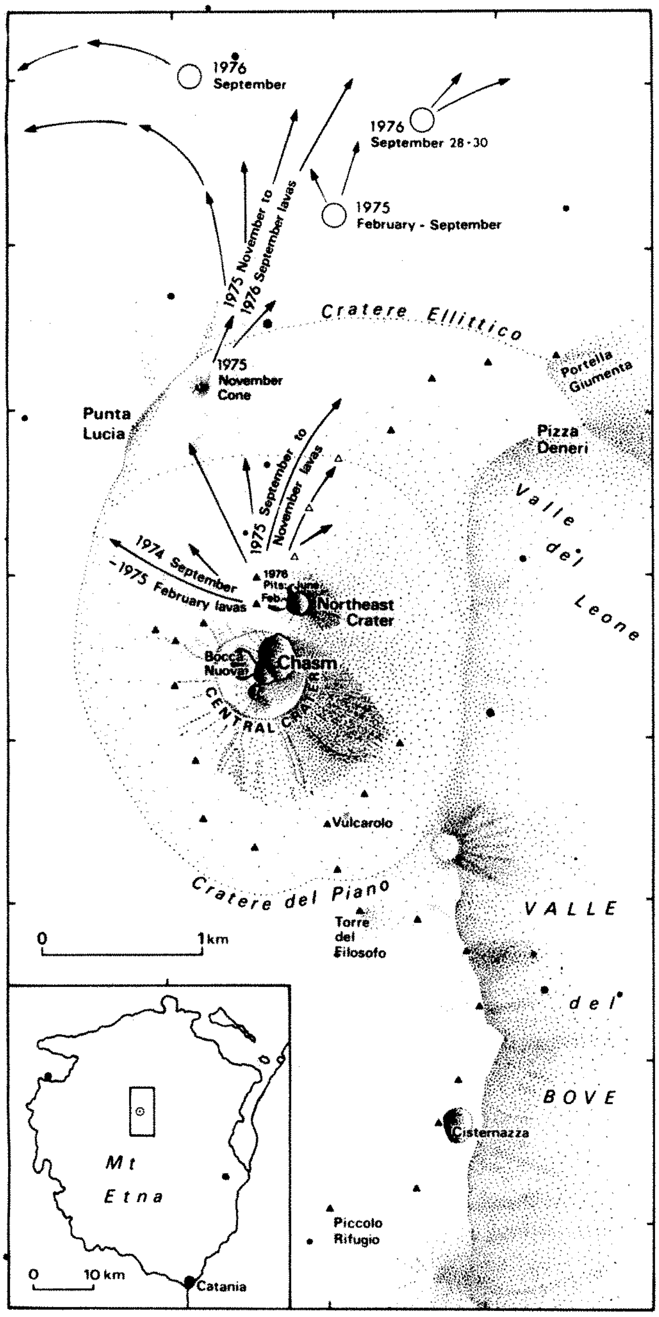

Fig. 1 Map of Mt Etna summit, showing the activity 1974–76, and the location of the levelling traverse. ▲, Principal benchmark; △, principal benchmark destroyed by lavas of September to November 1975; ○, approximate centre of quiet emission of lava; arrows show directions of lava flows.

September 1976, and takes about 6 d for the complete traverse. We report here the results of this repeated precise levelling, which show that an area at least 2 km across subsided >1 m between July 1975 and September 1976. This could indicate high-level removal of magma, or incipient caldera collapse.

After being dormant for 3½ yr following the 1971 eruption, the North-east Crater started activity again on 28 September 1974, with strombolian activity quickly followed by lava eruption. This activity ceased on 23–24 February 1975, when lava began erupting from new boccas 2 km to the north at about 2,500 m a.s.l. (Fig. 1). The rate of eruption was measured up to 1.5 $m^3 s^{-1}$ during this phase of eruption, which lasted until 12 September. During the first occupation of the traverse (30 July–5 August 1975) lava was still coming out intermittently at this site, occasionally ceasing for a few days, when minor strombolian activity and internal collapse occurred at the North-east Crater. This alternation between emission of lava on the north flank and activity at the North-east Crater continued until 12 September, when north flank effusion stopped, and lava accompanied by strombolian activity erupted from the North-east Crater and began new flows down the northern slopes. These buried >1 km of the northern jeep track, and destroyed 14 of our benchmarks. Rates of eruption of 0.9 $m^3 s^{-1}$ were measured. This activity stopped on 28 November 1975, and on 29 November a new fissure opened 450 m ENE of Punta Lucia (altitude ~2900 m a.s.l.), with eruption of lava and violent strombolian activity, which rapidly built up a cone about 40 m high. In early 1976, a collapse pit about 120×70 m formed on the west flank of the North-east Crater, accompanied by considerable emission of ash and the onset of intense sulphur-bearing fumarolic activity.

At the time of the second occupation of the traverse, 20–26 May 1976, activity near Punta Lucia continued with intermittent weak strombolian activity in the cone and emission of lava at a rate of 1–3 $m^3 s^{-1}$. Three weeks after the leveling on 17 June, a new summit vent opened on the north-west flank of the North-east Crater, and strombolian activity ensued, which, assisted by some collapse, produced a crater about 80 m wide. Strombolian activity continued until 20 August, interspersed with a 3-week period of high-pressure gas emission in late July. Quiet effusion of lava near the Punta Lucia vent followed, but by the time the traverse was levelled for the third time (16–21 September 1976) large flows were emerging at a fairly high rate (3–4 $m^3 s^{-1}$) much further down the northern side, >3 km north of the summit at an altitude of about 2,300–2,400 m.

In May 1976, unusually late snowdrifts prevented re-levelling of the northern half of the traverse, apart from the final 500 m. Vertical movements in this and the southern section proved small, but two isolated benchmarks 40 m apart protruding above the snow 300 m west of the North-east Crater were re-levelled, and gave 3.5 cm of relative downward movement towards the north-east.

In September 1976, new benchmarks were set up on the September–November 1975 lava, so that the whole traverse could be re-levelled. Changes in altitude since May 1976 were again small in the southern section, −1.3 cm being the largest movement; but in the northern section, inacces-

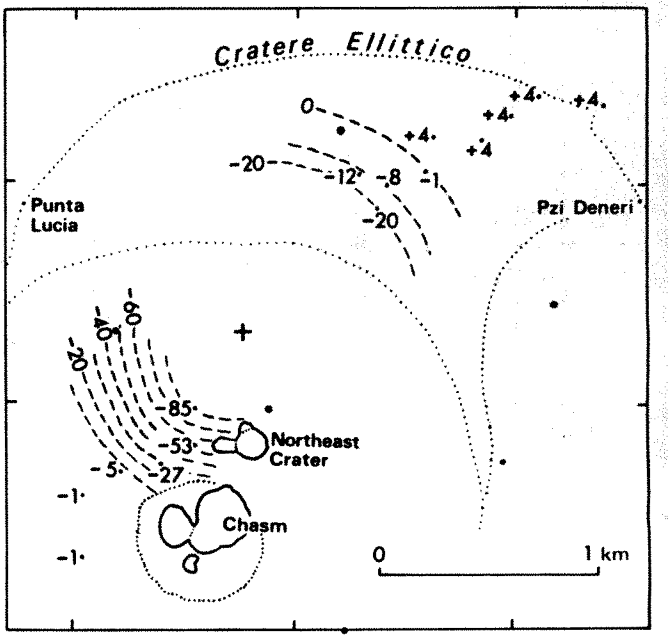

Fig. 2 Map showing relative changes in altitude (cm) of benchmarks between July 1975 and September 1976. – – – –, Inferred 10-cm contours of altitude change. +, The presumed centre of collapse.

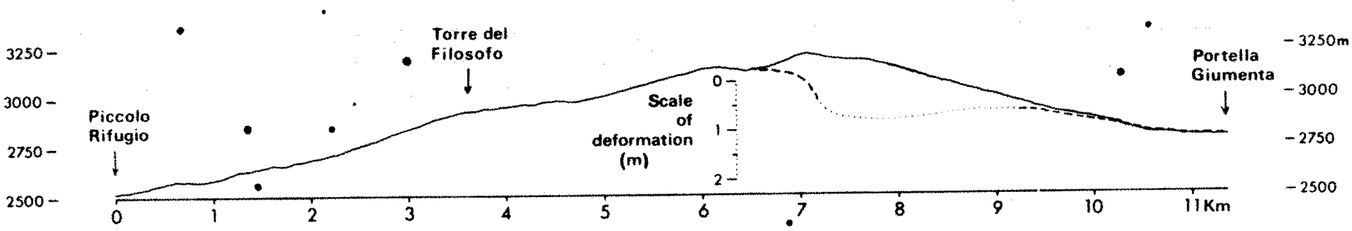

Fig. 3 ——, section of the levelling traverse (vertical exaggeration ×2); – – –, measured ground deformation between July 1975 and September 1976 with ×500 exaggeration, relative to the profile.

sible in May, the changes since July 1975 are very large. They indicate collapse of an area >2 km wide, from just north-east of the Central Crater in the south, to just south of the Cratere Ellittico in the north (Fig. 2). On the southern side of this area of deflation, the ground deformation increases northwards from −0.9 to −84.6 cm in only 700 m, and assuming a fairly smooth profile of deformation (Fig. 3) the amount of subsidence at the centre of collapse is likely to be >1 m. The maximum amount of collapse cannot be determined exactly since the centre of collapse lies in the unmonitored area where our benchmarks were destroyed. To the north of the unmonitored area, the amount of ground collapse decreases northwards from −19.5 to +4 cm, at which slightly inflated value it remains almost steady over the most northerly 800 m of the traverse.

About 1 m of vertical deformation in 1 yr is large, considering that no major eruption took place during this time. The most unusual feature of this subsidence is the small diameter (just over 2 km) of the area affected. This is unlike inflation and deflation on Hawaii, where the whole volcano is affected[1–3]. The actual tilt of the ground implied by these measurements is at least 1,200 μrad on the south side of the area of collapse.

The large amount of vertical deformation compared with the small horizontal extent of the area affected suggests that the cause of the deformation is at a shallow depth, and could result from several causes: one is that as the area of subsidence contains the North-east Crater flows of 1966–71 and 1974–75, we are observing cooling contraction and compaction of these flows. We think this unlikely especially as the 1971 flows on the south side of the summit cone show no such movement. Also, precise level tilt stations on older flows outside the area indicate deflation. Another more likely explanation is that the collapse could be directly related to the summit activity of 1975 September–November and 1976 June–August. One might expect the summit to be inflated in late July 1975, 6 weeks before summit activity, and deflated in September 1976, 1 month after summit activity. The levelling of the two isolated summit benchmarks in May 1976 shows that most of the collapse had already taken place at that time. This is likely to be the case since the summit activity in August was relatively minor. Finally, we could be witnessing incipient caldera formation, and that collapse could continue to take place in the area. Caldera formation has occurred on Etna at intervals of several hundred years, and the recent occurrence of other types of collapse at the summit, such as the collapse of the Bocca Nuova since 1970 and the collapse of the two new pits on the North-east Crater in early 1976 and June 1976 could support this view. The total void created by these three events is about 5×10^6 m³, added to an estimated 1×10^6 m³ created by the ground deformation. The volume of lava erupted during this time is at least an order of magnitude larger.

Whichever of the above possibilities proves to be correct, the interest of these results and the importance of continuing these observations is self-evident. They contribute to a greater understanding of the internal structure and workings of the volcano, which will hopefully lead to an increasing ability to predict activity, and point to areas of interest for other studies on the mountain.

Evidence for a low velocity layer at the base of the oceanic crust

As the quantity of seismic refraction data in the oceans increases it is becoming apparent[1–3] that there is a systematic increase in crustal thickness with age, at least out to about 60 Myr (refs 1, 2). To explain this phenomenon more precisely the detailed structure of the lower crust is required. We present seismic refraction data from the Northern Cocos plate which shows that thickening occurs by the formation of a low velocity zone (LVZ) at the base of the crust with a velocity

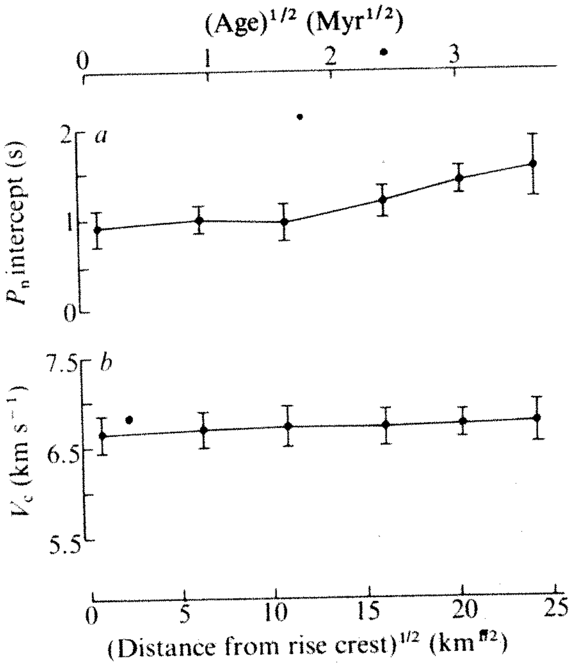

Fig. 1 *a*, Average mantle intercept times (P_n) and *b*, average crustal velocities V_c (ref. 2) against (age)$^{\frac{1}{2}}$ in (Myr)$^{\frac{1}{2}}$. The spreading rate is about 4.5 cm yr^{-1} and the error bars represent 1 s.d. The intercept times have had the travel time through the water column subtracted.

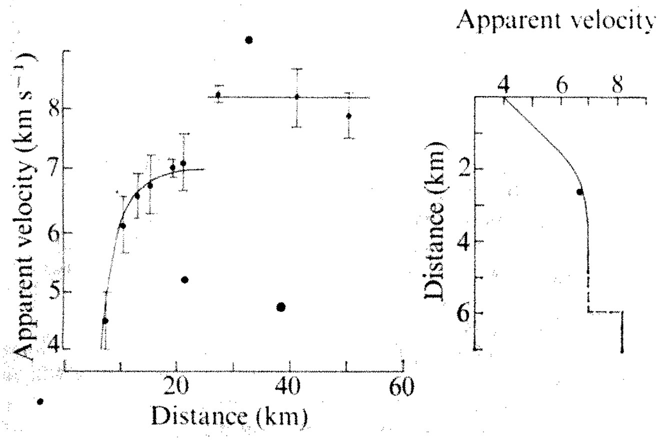

Fig. 2 Apparent velocities of first arrivals (with 1 s.d. error bars) measured across the array of receiving buoys (line 67).

< 6.8 km s^{-1}. One possible explanation of this in terms of these relatively low seismic velocities for the lower crust[4], is that upper mantle material becomes serpentinised by a hydration reaction as it cools. If so, this implies that the Moho boundary, except at very young ages, is a phase change (hydration) boundary. This supports the ideas of Hess[5].

Our data were taken over the Northern Cocos plate in an area bounded on the north and south by the Orozco and Clipperton fracture zones and on the east and west by the Middle American Trench and the East-Pacific rise (EPR). The spreading rate in this area is about 4.5 cm yr^{-1} (ref. 6). We have some 40 refraction lines each about 80 km long covering the area on an orthogonal grid. Most data were obtained from free-floating buoys and some from ocean bottom seismometers, using standard seismic refraction techniques. The upper mantle velocities obtained from these data, which show strong anisotropy, are discussed by Snydsman *et al.*[7].

Using only the first arrivals, the mantle intercept times and crustal velocities were measured and then averaged in age intervals after correcting for the water column travel time.

Fig. 4 Graph for line 8 showing trade-off between LVZ parameters and thickness of the overlying layer, found using the PmP critical point.

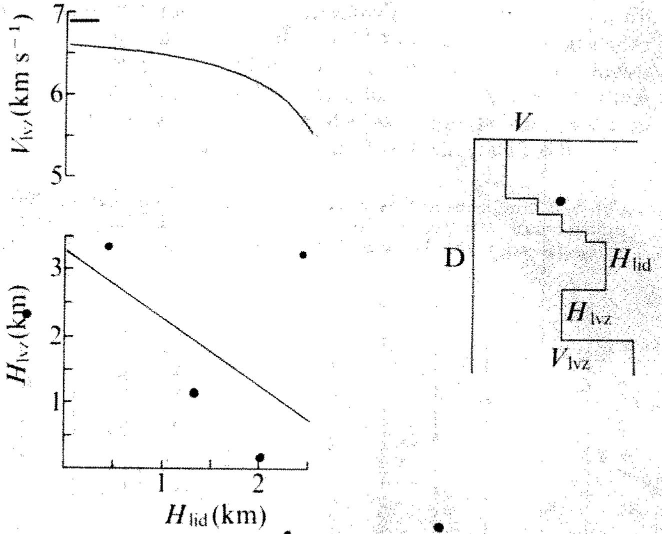

Fig. 3 Record sections from seismic refraction data taken at: *a*, 165; *b*, 275, and *c*, 600 km from the rise crest (lines 67, 47 and 8). The data are obtained by firing a sequence of explosive shots along a line from an array of telemetering buoys. The seismograms are then plotted on a reduced time scale, defined as $T_{\text{reduced}} = T_{\text{observed}} - \text{distance}/8.0$. On this scale horizontal lines correspond to 8.0 km s^{-1}. The travel time curves on each record section are interpretations based on correlating arrivals from one record to another. *d*, Base chart of area studied.

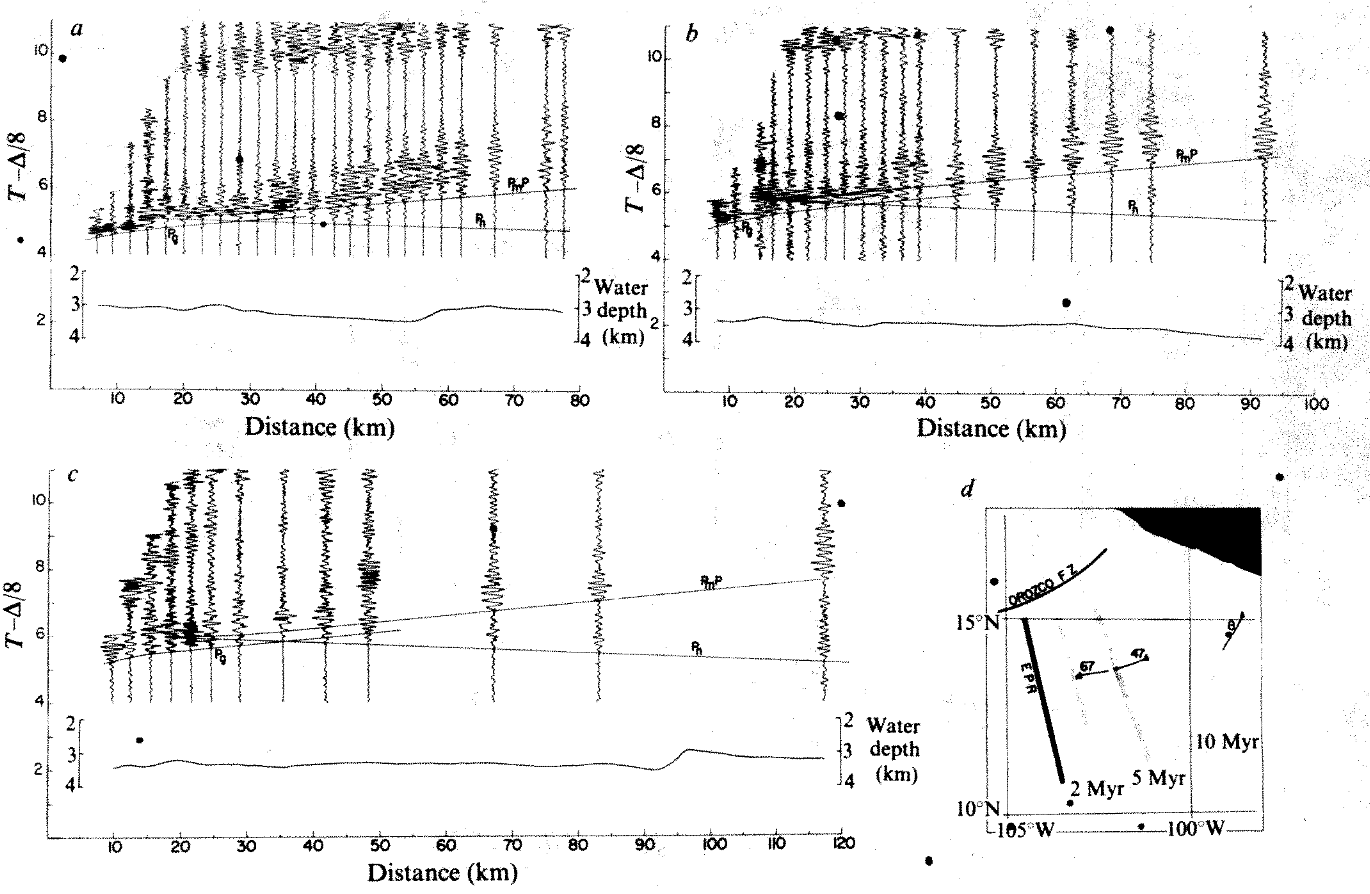

These averages were then plotted against $(\text{age})^{1/2}$ (Fig. 1). The $(\text{age})^{1/2}$ abscissa was chosen since the most rapid changes due to cooling can be expected in the early history of the crust[8]. From Fig. 1*a* it is clear that the averaged intercept time increases with age by about 0.5 s in 12 Myr. Of this increase only about 0.1 s could be associated with an increasing upper mantle velocity. We therefore conclude that the crust is thickening with age.

In obtaining the upper crustal structure we have used both the travel times and the apparent velocities measured across the 3.0-km long array of five receiving buoys. An example of the apparent velocities we obtained is provided by the data from line 67 (Fig. 2). This line was notable for the small drift of the buoys (< 1 km in 4 h) and the smooth topography. The travel times for this line are shown by the unfiltered record section in Fig. 3. In deriving a model for the lines, it was found that the simplest model which fits both the travel time and apparent velocity data within the observational error was a roughly linear velocity increase in the upper crust followed by a decrease in the gradient with depth. Theoretical apparent velocities from such a model are shown in Fig. 2 superimposed on the data. Although there is some smoothing of the apparent velocities introduced by the finite length of the array the existence of a discrete velocity jump associated with the layer 2–layer 3 boundary clearly is not supported, since this would appear as a discontinuity in the apparent velocity curve near 15 km. This conclusion is supported by all the lines for which we have good array velocity data and also by the results of Orcutt *et al.*[10]. The layered velocity model of the crust, usually assumed, seems to be a simplification and approximation but not a realistic physical model in this area.

To examine the crustal thickening with age, record sections were constructed of selected lines and velocity models which fit both first arrivals and later arrivals were constructed using ray tracing methods, synthetic seismograms and critical point locations. Three such lines (oriented perpendicular to the

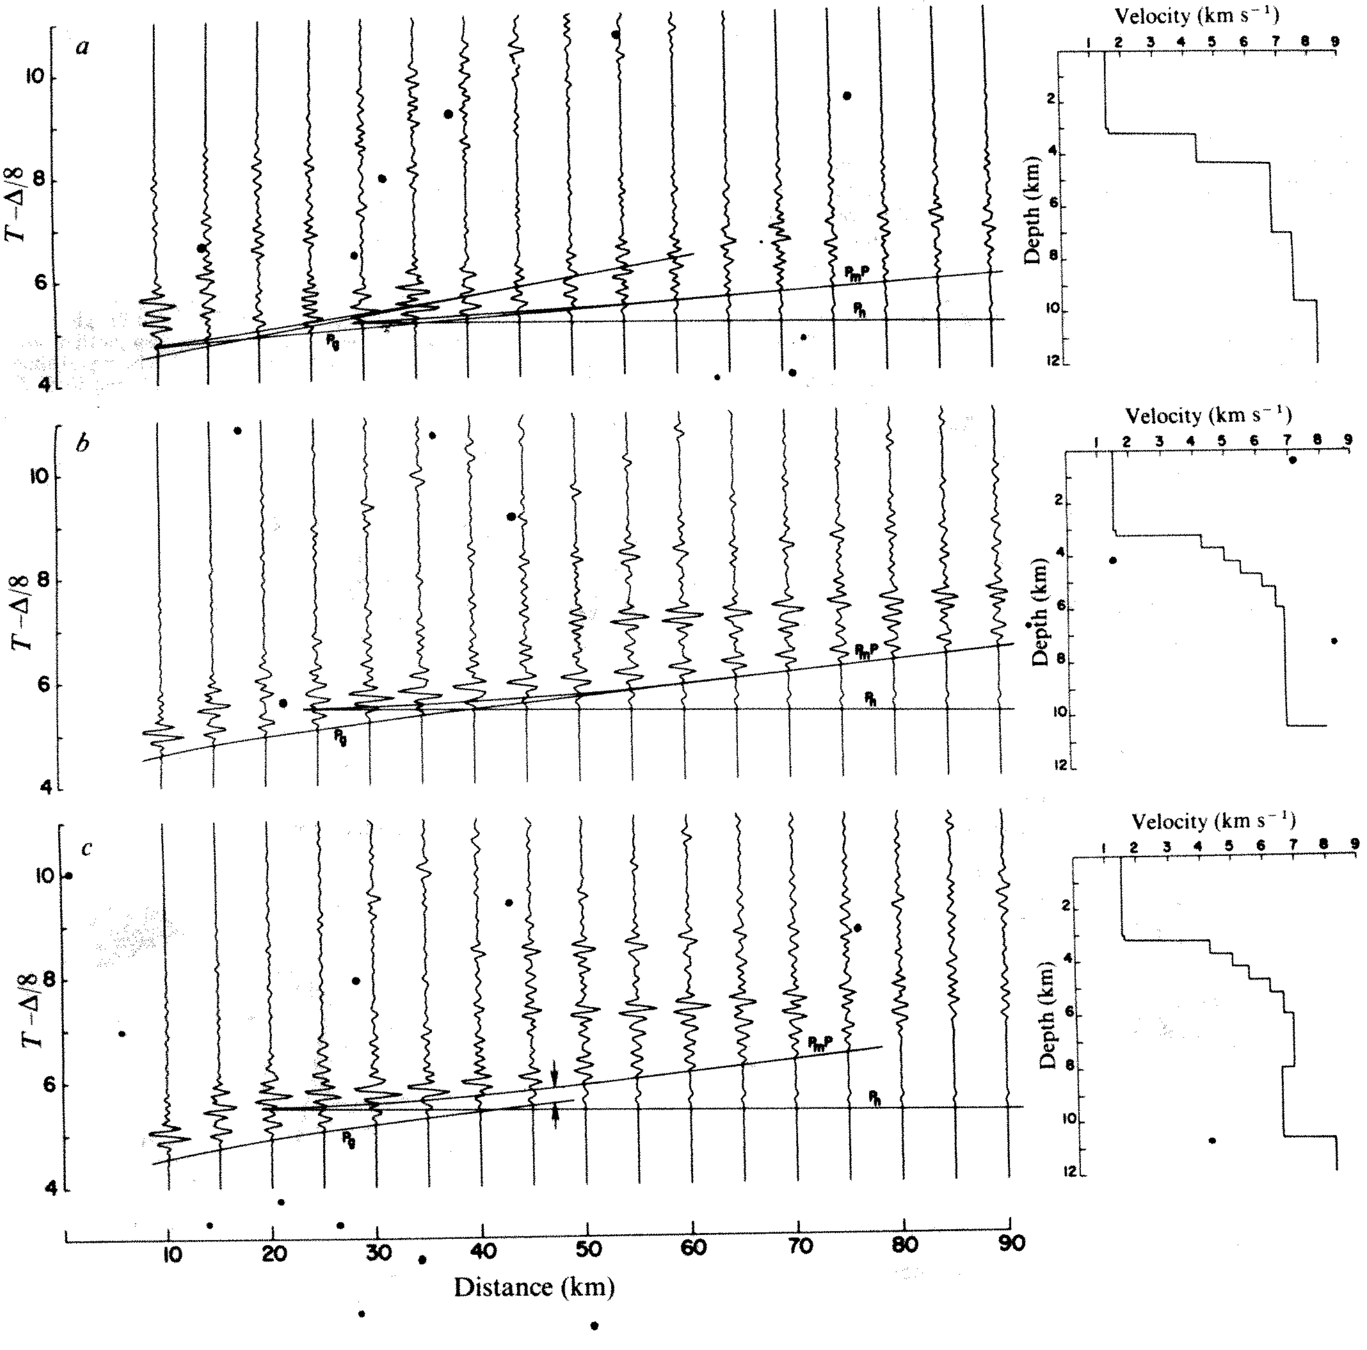

Fig. 5 A comparison of synthetic seismograms computed for three types of models. Model *a* has a basal high-speed layer. Model *b* has an upper crustal structure derived from our travel time and apparent velocity data and a constant velocity lower crust. Model *c* is similar to Model *b* except for the basal LVZ. Note the P_mP–P_g offset and the decrease in the P_mP–P_n critical point distance produced by the LVZ.

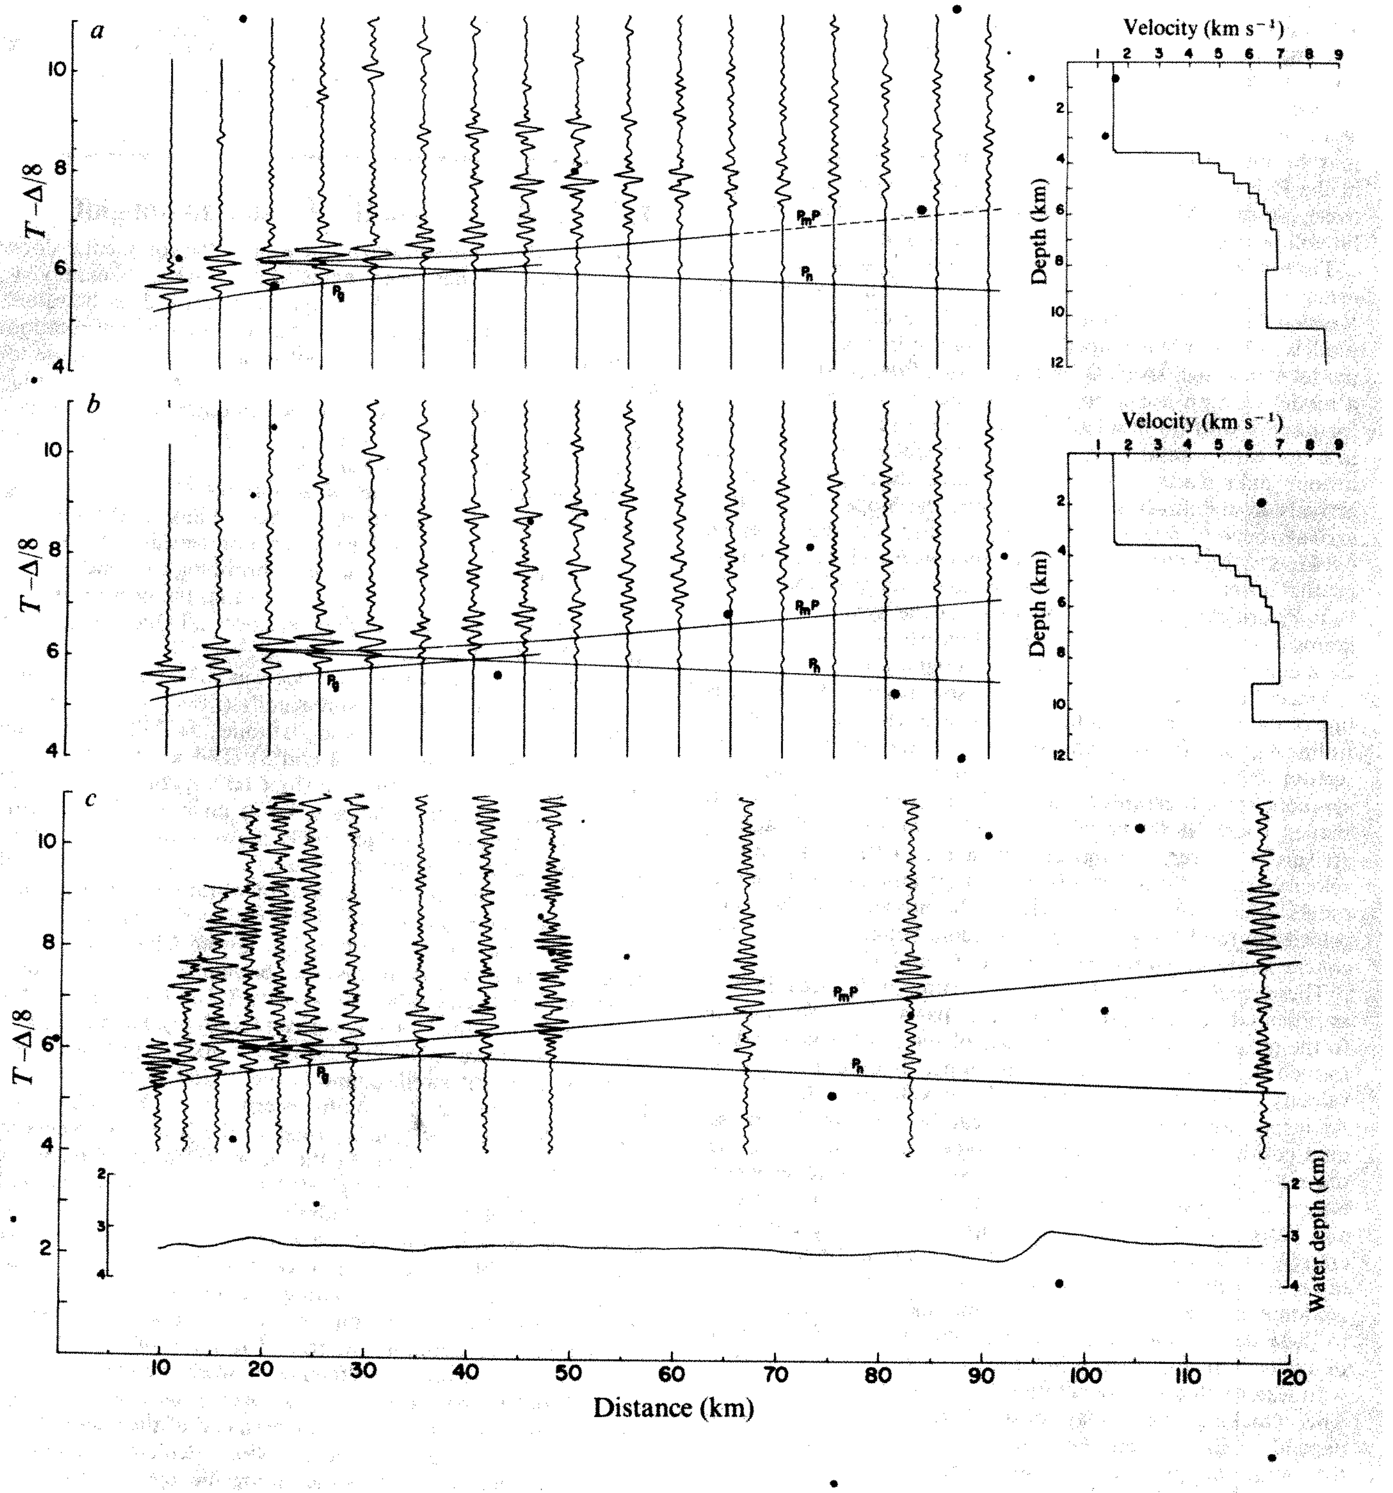

Fig. 6 A comparison of synthetic seismograms computed from the models shown (*a*, *b*) with line 8 (*c*). Model *b* with the thin LVZ fits the P_mP arrivals at large ranges better than *a* and is, therefore, the preferred model.

observed magnetic anomalies) are shown in Fig. 3, together with an interpreted travel time curve. Critical to our interpretation are the large amplitude late arrivals at distances greater than 50 km. These arrivals are wide-angle reflections (P_mP) off Moho[9] and at the largest ranges the apparent velocity, or inverse slope, of these arrivals must be asymptotic to the velocity at the base of the crust or, in the case of a LVZ at the base of the crust, they will be asymptotic to the velocity of the lid overlying the LVZ. One test for the existence of a LVZ is whether these arrivals are tangential to the crustal refracted arrivals or whether they are offset. For line 8 at 600 km from the rise axis there is a clear offset of about 0.35 s. The other two lines also have a well-marked offset of about 0.2 s. This effect is most easily seen by comparing these lines with lines close to the axis (not shown here) which show no offset. The wide-angle reflections also give the velocity of the lid, and in this case, we found velocities of 6.9, 6.8 and 6.9 km s^{-1} respectively.

A second independent test for the existence of a LVZ is the distance and time at which the P_mP critical point occurs on the travel time curves. This, coupled with a knowledge of the upper crustal structure and P_n velocity, can be used to determine if a LVZ exists at the base of the crust. For the lines shown in Fig. 3 the P_mP critical point is fairly clear and we can determine the maximum range at which the critical point may occur. Using the measured critical points, the derived upper crustal structure, and the asymptotic velocity of P_mP, we can determine if a LVZ is required at the base of the crust.

Using this method, we find that our three lines do require a LVZ at the base of the crust. There is, however, a trade-off between the thickness and velocity of the LVZ and the thickness of the lid, as shown in Fig. 4 for line 8. A further constraint may be placed on the LVZ by the distance to which energy in the P_mP path is propagated since the thickness of the layer overlying the LVZ strongly controls this feature (that is, a thick lid will propagate energy further than a thin lid).

To test our model, further, we synthesised seismograms, using the method of Fuchs and Muller[11] as modified by Kennett[12] for marine situations, for three different types of models. These models labelled *a*, *b*, and *c* in Fig. 5 include a model with a high-speed layer at the base of the crust (model *a*), a model with an upper crustal structure similar to that found for line 67 with no basal LVZ (model *b*), and a model similar to *b* but with a basal LVZ (model *c*). Model *a* clearly does not fit our data since it does not produce the high amplitude arrivals in the 15–20-km range; also, the slope of the P_mP arrivals beyond 50 km is 7.5 km s^{-1} and not the observed 6.8 km s^{-1}. The difference between models *b* and *c* is primarily in the offset between P_mP and P_g and the position of the P_mP–P_n critical point. A comparison of the synthetic seismograms in Fig. 5 and the data in Fig. 3 clearly supports the basal LVZ concept and the criteria for its recognition.

Since the models in Fig. 5 are not specifically related to any line of data, we next tried to compute synthetic seismograms to fit line 8 as accurately as possible. Fig. 6 shows the line 8 record section bandpass filtered from 0 to 8 Hz along with two synthetic record sections computed from models with differently shaped LVZs. Both models give a close fit to the P_g and P_n arrivals; however, the model with a thin LVZ and a higher velocity contrast fits the observed P_mP amplitudes better at ranges greater than 50 km. Hence the model with the lower velocity in the LVZ seems to fit the data better for line 8; this conclusion was also reached for lines 67 and 47.

These results suggest that the thickening of the oceanic crust as observed here and possibly in other parts of the world is due to the growth of a LVZ at the base of the crust which may be formed by a transformation of upper mantle material of velocity > 8.0 km s^{-1} into material with velocity $\lessdot$ 6.8 km s^{-1}. An inspection of the metamorphic reactions that might operate on a peridotite-type rock in a cooling environment to produce these low velocities suggests only one candidate, a serpentinisation or hydration of the peridotite. The data of Christensen and Salisbury[4] show that if the upper mantle were composed entirely of olivine then a 50% hydration would be required to lower the velocity from 8.43 to 6.5 km s^{-1}. If this serpentinisation hypothesis is correct, then a method of getting the water to these depths may be provided by the cracking front theory of Lister[13]. In this theory hot rock cooled rapidly by contact with water will crack, facilitating further cooling and cracking. This cracking front may proceed to considerable depths depending in part on the strength of the rock. Lister[13], in discussing this problem, had suggested such a mechanism for the formation of the Moho boundary.

J. Tuzo Wilson Knolls: Canadian hotspot

A YOUNG submarine volcano at the base of the continental slope west of Canada has been named after the Canadian geophysicist J. Tuzo Wilson. The volcano is capped by hawaiite, and has an angular separation from a proposed pole of rotation of the Pacific plate and the hotspot frame of reference close to separations for the Kodiak–Bowie seamount chain, suggesting that a hotspot which generated the seamount chain now lies beneath the young volcano. Radiogenic ages of some seamounts of the chain support this hypothesis.

The generation of a line of seamounts (Fig. 1), trending south-east from Kodiak to Bowie Seamounts in the Gulf of Alaska, has been ascribed to a hotspot beneath the Pacific Plate[1,2]. Bathymetric, geometric, chronological and petrological evidence presented here suggests that the hotspot is now located at the foot of the continental slope, off Queen Charlotte Sound, British Columbia.

In 1973, fresh glassy volcanic rock was raised in two dredge-hauls made on J. Tuzo Wilson Knolls (JTW) at latitude 51° 23′N, longitude 131°02′W and latitude 51°25′N, longitude 131°01′W, respectively (Figs 2 and 3). The knolls which rise from the base of the continental slope 60 km south of Cape St James, Queen Charlotte Islands, lie in an area of high sedimentation rate. The dredged rock shows little sign of manganese encrustation or alteration, and most likely was erupted recently, probably since the diminution of rate of sedimentation following the rise in sea level at the end of the last glaciation. The knolls lie at the southern end of Queen Charlotte fault, a transform fault which forms the boundary between North American and Pacific lithospheric plates[3–5] and lies north of the triple junction of the North American (NOAM), Pacific (PCFC) and Juan de Fuca (JDFA) lithospheric plates[5]. Oshawa Rise, a broad basement swell, connects the region of the knolls to Bowie Seamount, at the south-eastern end of Kodiak–Bowie Chain[1,4]. Minster *et al.*[6], in a global synthesis of movements of lithospheric plates relative to the hotspot frame of reference (HSPT), computed that PCFC–HSPT rotation during the past 10 Myr has been 0.83° Myr^{-1} about a pole at 67.3°N, 120.6°W. Colatitudes of seamounts of the Kodiak–Bowie Chain relative to this pole (Table 1) are in the range 36.9°–39.4°. The colatitude of JTW is 37.1°. After calculating the longitudinal difference between JTW and a seamount of the chain about the PCFC–HSPT pole, and assuming the rate of rotation of 0.83° Myr^{-1}, one may calculate the age difference between the seamount and JTW (Table 1, rows 4 and 5). Radiogenic ages of Giacomini and Kodiak seamounts, at the northern end of the chain (Table 1, rows 6 and 7) compare closely with calculated seamount–JTW age differences, as does the radiogenic age of basalt from nearby DSDP hole 178. Radiogenic ages of Bowie, Hodgkins and Dickens seamounts, near the southern end of the chain, are 5–6 Myr younger than the calculated age differences. Assuming that volcanism, once initiated at a seamount, has a duration of several Myr, such age discrepancies are not incompatible with the hypothesis that the active end of Kodiak–Bowie Seamount Chain lies at or near JTW, and that the rotation PCFC–HSPT has been constant for the past 22 Myr. Alternatively, the discrepancies may indicate variation in PCFC–HSPT motion through time.

Other possible locations for the active end of the Kodiak–Bowie chain on the Pacific plate are Dellwood Knolls and the south-eastern end of Dellwood Seamount Range (Figs 1 and 2), relevant colatitudes of which are 37.4° and 37.8°, respectively. The south-eastern end of Dellwood Seamount Range lies at the

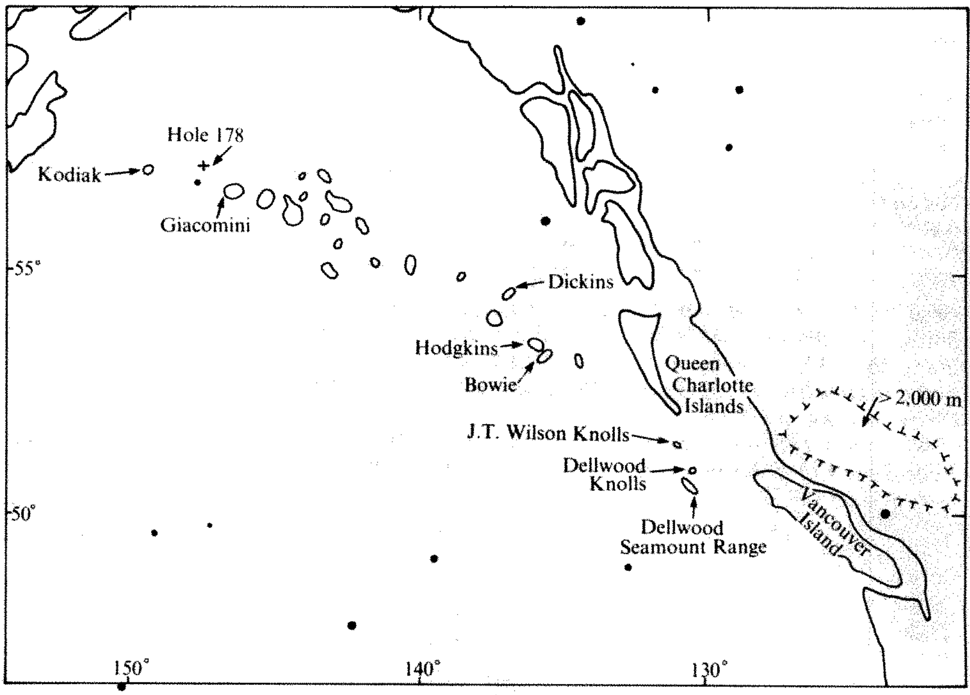

Fig. 1 Location of Kodiak-Bowie Seamount Chain in Gulf of Alaska. Ticked dashes enclose area of Coastal Mountains of southwestern British Columbia characterised by elevations > 2000 m.

northern end of Explorer Ridge. Dellwood Knolls lies to the east, on the eastern side of Revere–Dellwood fracture zone[5,7] (Fig. 2). Basalt without significant coating of manganese–iron oxides has been recovered at both of these sites. Analyses of major elements and norms of volcanic rock from JTW, Dellwood Knolls and Dellwood Seamount Range (Table 2) reveal that the latter two features are composed of low potassium tholeiite characteristic of spreading ridges, whereas JTW is composed of much more alkaline hawaiites, characteristic of the terminal phases of seamount volcanism. Thus petrology indicates that JTW is the most likely of the three features to be generated by a hotspot.

If initiation of volcanism at JTW occurred several Myr ago, the generating hotspot would now lie east of the plate margin under the North American plate. If this is true, geometry dictates that the hotspot lies on the same small circle about the PCFC–HSPT pole as the Kodiak–Bowie chain. A broad positive topographic anomaly and alkaline volcanicity should characterise such a hotspot[9]. In the coastal mountains of British Columbia, a topographic high does occur, centred at 51°N, 125°W (Fig. 1), but the colatitude (PCFC–HSPT) of this area is only 35°, and no young alkaline volcanicity is known from it.

Thus the tentative conclusion is that the Kodiak–Bowie Hotspot is at present located near J. T. Wilson Knolls.

The decision to name this topographic feature after the Canadian geophysicist J. Tuzo Wilson stems principally from its connection with an underlying hotspot. Professor Wilson was the originator of the hotspot hypothesis, and it is thus fitting that a hotspot be named after him, particularly one

close to Canada. He introduced the concept of transform faults and, with Frederick Vine, first delineated plate boundaries in the north-eastern Pacific. Thus it is fitting that his hotspot lie in the north-eastern Pacific, near the southern end of the Queen Charlotte transform fault.

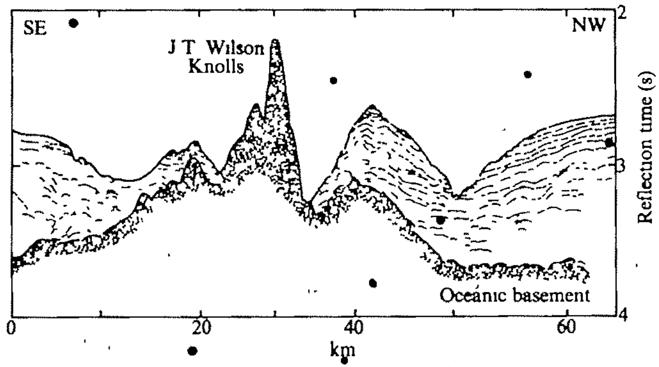

Fig. 3 Continuous seismic reflection profile across J. Tuzo Wilson Knoll. Sedimentary strata cut by canyons of the continental slope cover flanks of volcanic edifice rising from oceanic basement. Vertical exaggeration is 21:1.

We thank Captain Bowles, and officers and crew of the CFAV Endeavour, for cooperation in surveying and dredging, Professor R. T. Prider and Dr R. Binns, for providing analytical facilities at the University of Western Australia, Dr Stirling Shaw, Macquarie University, for X-ray diffraction analysis of rock samples, the Institute of Oceanographic Sciences (Wormley, UK) for office and library facilities, Mrs Angela Watters and Ms K. Hayne, for assistance in preparation of the manuscript. This work was supported by grants from the National Research Council of Canada and the Defense Research Board of Canada. The knoll was discovered during a joint cruise of the Institute of Oceanography, University of British Columbia and the Geological Survey of Canada (Dr D. L. Tiffin).

Cerium in chert as an indication of marine environment of its formation

THERE are few if any investigations of deep-sea cherts or siliceous sediments from the geochemical point of view, although several geological and mineralogical studies have been published[1–6]. We present here data on rare-earth elements (REE) in deep-sea cherts, and compare them with relevant data on seawaters as well as cherts exposed on land.

Behaviour of cerium differing from that of other REE in marine environments is already known[7–10] with particular reference to manganese geochemistry, but a similar distinction in predominantly siliceous sedimentary rocks has not been reported, to our knowledge.

REE in samples were determined with stable isotope dilution technique with relative uncertainties of <1.5%. Our investigations were performed on four deep-sea cherty rocks recovered during the Deep Sea Drilling Project, two microfossil separates, and three terrestrially exposed cherts, including an Archaean one from Gunflint, Canada. The microfossils were separated from radiolarian ooze by the sedimentation technique. The microfossils under consideration are siliceous and substantially free from calcareous ones[11]. Excepting 4-29C-1 (chert from the Caribbean Sea), the other deep-sea samples are from the central Pacific.

The results of REE determination are given in Table 1. Figure 1 shows the chondrite-normalised REE patterns for deep-sea samples; the REE abundances in the Leedey chondrite[12] are employed for the Masuda–Coryell plotting (plotting the logarithm of chondrite-normalised value against the order of atomic number of REE). It should be noted that all of the DSDP samples investigated show large negative Ce anomalies. The 'Ce anomaly' here is defined as the ratio of observed Ce abundance to that which would fall on the La–Nd join in the Masuda–Coryell plot. The Ce anomaly ranges approximately from 0.2 to 0.3, with the exception of the Caribbean chert (0.467).

The absolute concentration levels of REE in the four highly siliceous sediments show a large variation decreasing in the order 7-66-5, 16-163-14, 4-29C-1 and 17-167-85. Sample 7-66-5 is cristobalitic porcellanite, the next two samples are cristobalite cherts, and the last one, 17-167-85, is a quartz chert. Thus, the

absolute REE abundance levels in these cherty rocks seem to depend on the degree of diagenesis. With the present limited data, it is hard to discriminate on relative REE patterns between cherty rocks and microfossil separates. In general, La, Nd and Sm fall on a straight line, while Sm, Gd and Dy fall on another straight line; there is a small break at Sm.

Figure 2 shows the chondrite-normalised REE patterns of four terrestrially exposed cherts; one is a Transvaal chert analysed by Wildeman and Haskin[13] for REE. We have studied two cherts from Kamiasô, Gifu, central Japan, (Triassic–Jurassic) and a Gunflint chert (2.0–2.2, or 2.43×10^9 yr) (ref. 14), Canada. REE contents in the Gunflint chert are similar to but somewhat lower than in the Transvaal sample (about 2.0×10^9 yr) (ref. 13). A remarkable observation from Fig. 2 is that these cherts exposed on land either show a small positive Ce anomaly or seem to have no Ce anomaly at all, in contrast to deep-sea cherts. Kolodny and Epstein[15] have revealed a clear distinction in $\delta^{18}O$ between terrestrially exposed and deep-sea cherts. They conclude that the lower values of $\delta^{18}O$ of terrestrial cherts compared with DSDP cherts are attributable to the shallower water environment in which the terrestrial cherts were formed. This conclusion is consistent with that derived from the present study.

Goldberg *et al.*[7] found that Ce in a seawater sample was depleted by a factor of 0.23 relative to the adjacent rare-earth elements. The corresponding Ce anomaly for eight Atlantic Ocean samples from two stations (45°N, 16°W and 43°N, 28°W) is about 0.32 as a geometrical mean, on the basis of data presented by Høgdahl[16]. He also reported, however, that Ce is present in normal concentrations in seawaters of the Puerto Rico Trench, the West Deep Cariaco Trench and Barents Sea[16]. It should be noted that these areas are all relatively close to continents and/or the dimensions of the seas in question are small compared with oceans. The water of the Black Sea[17] also does not show a substantial Ce anomaly.

It is evident that the presence or absence of Ce anomaly and its extent and direction of deviation can be a good indicator of aqueous (perhaps marine) environment of formation for cherty rocks. A Caribbean chert indicates a smaller depletion of Ce compared with the Pacific ones. This could be due to the Caribbean Sea being encircled by a chain of islands. The REE patterns of terrestrial cherts can be interpreted as suggesting that they were formed in coastal areas, marginal seas or land-enclosed seas.

Our results suggest that, in shallow-sea areas, Ce perhaps mostly involved in suspended solid particles behaved apparently in the same fashion as other REE, while in deep-sea areas Ce was subjected to selective removal relative to other REE. Difference in residence time of lithogenous suspended particles is one of the major factors responsible for this areal difference. Comparatively long residence time of suspended particles would promote disintegration into finer particles and their further alteration, which would be in turn favourable with chemical

reactions, including oxidation of Ce into the tetravalent form, and separation of Ce from other common REE; without particle disintegration, the size of particles in deep-sea areas can be finer as a result of sorting. This does not necessarily mean that the oxidation into Ce^{4+} starts in deep-sea areas. Høgdahl[18] found no Ce depletion in unfiltered water samples from the River Gironde and its mouth to the sea, while a slight Ce depletion was detected for filtered waters.

Almost all of samples studied display rather small negative Eu anomaly, which is considered to reflect that of a probably continental source material.

Two major theories, biogenic and volcanic, have been advocated to explain the genesis of cherty rocks. If volcanic activity is directly responsible for chert formation, the rocks so formed should not show a negative Ce anomaly. This preliminary investigation suggests that high-accuracy REE determinations can lead to useful results if applied to researches in siliceous sedimentary rocks and related subjects.

We thank the Deep Sea Drilling Project for supplying the samples and Dr M. Adachi for helpful discussions. The Gunflint chert was kindly offered by Drs S. Matsuo and K. Kanehira.

Factors controlling grain weight in wheat

THE physiological factors controlling differences in grain weight between cultivars of wheat are not fully resolved. The experiments described here indicate that final grain weight in two cultivars of wheat is mainly dependent on the rate of accumulation of dry matter, which in turn is governed by the number of endosperm cells formed. Cell number in the endosperm seems to be regulated by the supply of assimilates available to the grain during the first 2 weeks after anthesis.

Two cultivars of wheat (*Triticum aestivum* L.), Maris Huntsman and Val, were grown in pots in the open from November 1975 to July 1976, and tillers were removed to maintain a constant density of 320 shoots per m^2. The plants reached anthesis on 7 and 8 June, Val being the earlier, and attained a mean grain number per inflorescence of 48.8 (Maris Huntsman) and 48.5 (Val). In the first experiment inflorescences were collected at intervals from anthesis to maturity. Grains were removed from the lower two florets of the 10 central spikelets of the inflorescence, and the weight per grain determined after drying to constant weight. The stage of development of the endosperm was determined from median transverse sections of grain fixed in gluteraldehyde, embedded in epon, and examined from 2-μm sections using phase contrast optics.

At maturity, Maris Huntsman contained 21% more dry matter in the grain than Val (Fig. 1), and the rates of increase in dry weight for the period 14–30 d after anthesis, calculated by regression analysis, were $1.63\pm0.09\ \mathrm{mg\ d^{-1}}$ (Maris Huntsman) and $1.12\pm0.07\ \mathrm{mg\ d^{-1}}$ (Val). The higher rate in Maris Huntsman could have been due to a greater supply of assimilate, or to its grain being a more efficient sink, or to a combination of the two factors.

It has been suggested[1] that the rate of increase in dry weight of the grain may be closely related to sink size as determined by the number of endosperm cells formed, and our data provide evidence for this. Examination of the developing endosperm showed that by 14 d after anthesis, the outer layer of endosperm cells had ceased to be meristematic in both cultivars, and had differentiated into recognisable aleurone cells, indicating that the number of endosperm cells had been fixed[2]. The effect of cell number in the endosperm on the rate of increase in dry weight and on final grain weight was tested in a second experiment, in which floret number per inflorescence was reduced to four on two dates by removing all florets except the basal floret of the four central spikelets. Florets were removed at

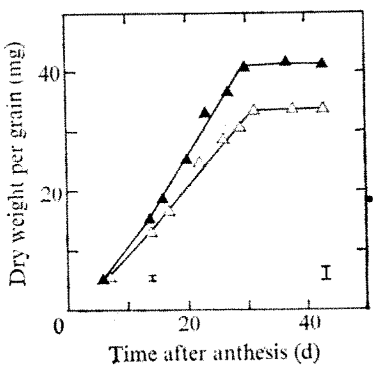

Fig. 1 Dry matter accumulation of the lower two grains of the 10 central spikelets of the inflorescence. Each point is the mean of 64 inflorescences. Vertical bars indicate the least significant differences ($P < 0.05$) at 15 d after anthesis and at maturity. ▲, Maris Huntsman; △, Val.

anthesis to provide an excess of assimilate available to the remaining grains during the period of cell division in the endosperm, and 15 d after anthesis, to give an excess of assimilate during the time when development was due entirely to cell expansion in the endosperm. Inflorescences were collected on three dates between 15 d and maturity, and the weight per grain was determined after drying to constant weight. The number of endosperm cells was determined in grains fixed in 1 : 3 acetic acid–absolute ethanol and macerated with fungal cellulase[3]. Grains from the basal floret of the four central spikelets in intact inflorescences were controls.

Reducing floret number at anthesis increased the dry weight per grain at 15 d and the number of endosperm cells in both cultivars, although the effect was larger in Val (Fig. 2, Table 1). Also, the rate of dry matter accumulation was stimulated, resulting in an increase in total dry weight at maturity of 13% in Maris Huntsman and 47% in Val. The reduction of floret number at 15 d produced only a small increase in the final dry weight of the grain.

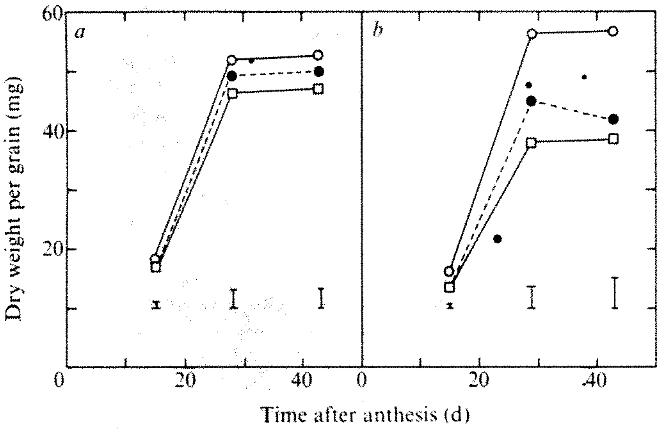

Fig. 2 Dry matter accumulation of the basal grain of the four central spikelets of the inflorescence. *a*, Maris Huntsman; *b*, Val. Each point is the mean of 20 inflorescences. Vertical bars indicate the least significant difference ($P \leq 0.05$) between the control and either treatment. □, Control; ○, florets removed at anthesis; ●, florets removed 15 d after anthesis.

Grain formed in intact inflorescences of Maris Huntsman contained 19% more endosperm cells and accumulated 21% more dry matter at maturity than those of Val. The difference in grain weight between the cultivars was closely correlated with the difference in the number of endosperm cells, suggesting that cell number in the endosperm is a major factor controlling the rate of increase in dry matter and final dry weight. The operation of this control is demonstrated by the small effect of increasing the supply of assimilate to the grain at 15 d, when the number of endosperm cells was fixed and further development was due to cell expansion only.

Grain weight in intact inflorescences seems to be determined mainly by differences in the supply of assimilate to the developing grains, which in turn regulates the size of the grain sink to match the amount of assimilate available.

The implications for plant breeding are twofold. First, the potential sink size in some wheat cultivars is a function of the number of cells in the endosperm and the level of assimilate supply during the meristematic phase of endosperm development. Second, the number of endosperm cells formed seems to be a reliable indicator for use in selection for the yield component, final grain weight.

Table 1 Effect of reducing floret number at anthesis on the number of endosperm cells formed per grain. Each value is the mean of 10 grains, 15 d after anthesis

	No. of cells	
	Control	Florets removed
Maris Huntsman	145,000	157,000
Val	122,000	158,000
s.e.m.	2,200

Pattern of lean and fat deposition in adults

THE fact that obesity becomes more common when societies change from a subsistence/labour intensive to an affluent/sedentary way of life might be taken simply as a demonstration that easy living encourages slothfulness and gluttony. Fat people, however, do not in general seem to eat more than thin ones, and there is increasing evidence of an inherited component of obesity. It seems more likely therefore that, throughout much of past history, individuals who had a genetic constitution predisposing them to store energy preferentially as fat have had some kind of advantage for survival. We have used a computer simulation model of energy balance to compare the effects of different seasonal patterns of work output and food availability on individuals with inherent tendencies towards either leanness or fatness, and to illustrate the circumstances and the manner in which the latter type has a relative advantage over the former.

In subsistence agricultural societies, most adults are smaller and take less food than those in affluent communities. The pattern of eating is often feast-and-fast; the heavy manual work of cultivating the next year's crops frequently coincides with reduced availability of food. In these conditions, the ability to store excess energy efficiently and to release it when needed for physical work has survival value. In affluent societies however, a regular, adequate food supply is guaranteed and activity is fairly constant throughout the year. There is not the same need for the body to store and release energy. Rather, people tend to overeat and longevity may be improved by the ability to 'burn-off' excess energy and so avoid obesity with its health penalties. A possible method of meeting these different requirements for optimal survival would be to vary the relative proportions of lean and fat tissue used in storing excess food energy. The efficiency of converting food to fat is about 70% (refs 1, 2); fat tissue has high energy density and low tissue maintenance requirements. Food energy is converted to protein with an efficiency of only 40% (refs 1–3); lean tissue has a low energy density and relatively high maintenance metabolic needs. Both fat and lean tissues are very efficiently mobilised for energy.

We have defined the ratio P as

$$P = \frac{\text{energy stored as (or mobilised from) protein}}{\text{total energy stored (or mobilised)}}$$

Values of P for non-obese subjects can be calculated from the classical starvation studies of Keys *et al.*[4], and Fig. 1 shows the distribution obtained.

The modal value of P is between 0.05 and 0.10, but a tail extends to much higher values. By contrast, in obese subjects the P values calculated from Passmore's starvation studies[5] were all very low and ranged from 0.02 to 0.04. In Keys's data there is a significant negative correlation between the value of P and the percentage of the body which was fat, but no correlation between the value of P and the total body weight. The P value is therefore associated with a body type but not a body

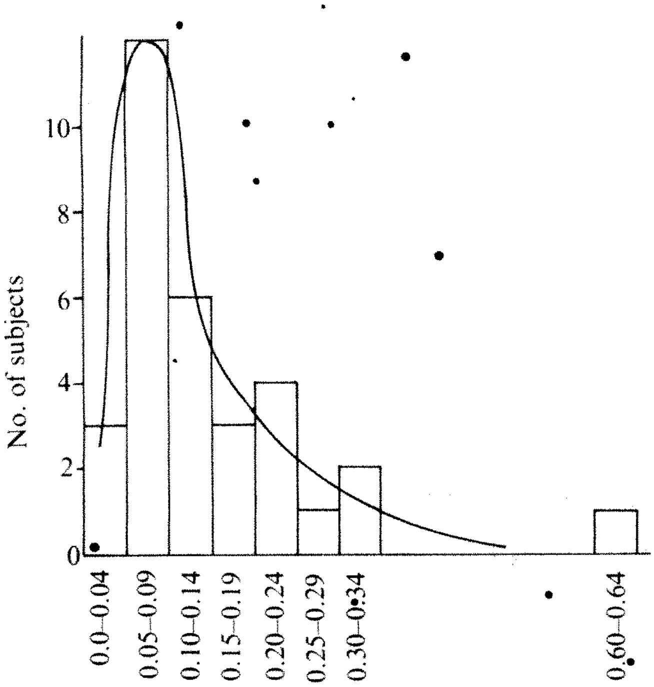

Fig. 1 A histogram showing distribution of values of the ratio of energy mobilised from protein to total energy mobilised. Taken from ref. 4.

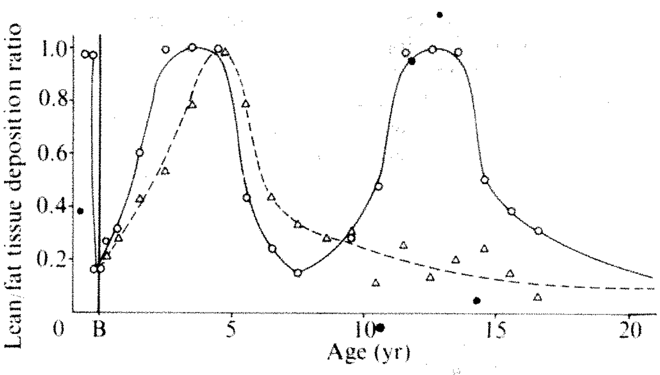

Fig. 2 Variations in children of the ratio calories deposited as protein to total energy deposited. ○, Boys; △, girls. Sources as given in ref. 6.

size. As the subjects in Keys's experiment were fasted, they lost most of their body fat but there was little change in P value. It seems likely that the value of P is set in an adult and remains fairly constant regardless of present body weight. In children, however, P varies widely with age and there are significant differences between boys and girls during adolescence[6] (Fig. 2).

The computer model[10] has enabled us to quantitate the effect of different P values among adults in subsistence and affluent societies. For both societies, we have modelled men with constant values of P set at $P = 0.03$ ('fat man') and at $P = 0.30$ ('lean man'). These are near the tenth and ninetieth percentiles of the range of P.

As an example of men in a subsistence community, we have used data from Gambian farmers with food intakes and activities at different times of the year as described by Fox[7]. The model has reproduced the observed weight changes (Table 1).

The total weight changes given by the model were similar in both 'fat' and 'lean' men. The 'fat man' used mainly fat to balance his energy budget, but the 'lean man' drew upon his lean tissue, which is largely muscle, to meet his energy deficits. The 'lean man' therefore depleted his muscles just when they were needed for heavy work. Although no field studies are available to us, it seems reasonable to suppose that the ability of an individual to perform sustained muscular work would be impaired by the loss of muscle tissue. In acute experiments[4] loss of handgrip power is correlated with loss of body lean tissue. The utilisation of fat as a storage medium therefore has two advantages; it is not only more efficient but also spares muscle tissue which is needed for manual work.

In affluent societies, body weight is slightly higher and maintenance energy needs are also slightly higher in consequence. In contrast to the Gambians, there are only minor seasonal variations in food intake and activity, and there is a tendency for intake to rise above maintenance needs. We have modelled the effects in the 'fat man' and the 'lean man' of 5% and 10% increases of intake above the requirement for weight stability. The mean food intake was kept constant at this new level and there was a 20% random variability about the mean intake to simulate daily variability[8] (Fig. 3).

The model predicts that body weight would rise and take 3–6 yr to reach new equilibrium levels. Table 2 shows that with a constant 10% excess of energy, the 'fat man' gained 18.1 kg in body weight, but the 'lean man' only 8 kg. More significant are the changes in body composition. In the 'fat man' the per cent body fat rose from 12% to 23%; the 'lean man' rose from 12% to 13%. Since the ill effects of obesity are probably related both to excess weight and excess fat, the 'fat man' may well suffer a double penalty for overeating the equivalent of one small chocolate bar a day.

In contrast to adults, the P values in children change during growth (Fig. 2). Using a modification of our computer model,

Table 1 Seasonal patterns of weight change and body composition for subsistence farmers, derived from computer model

'Fat man'	Total body weight, W (kg)	ΔW	Body fat, F (kg)	ΔF	Body lean L (kg)	ΔL	% Fat
Starting weight (59)	59.0		11.3		47.7		14
5 months cultivation		−4.0		−3.4		−0.6	
food ↑ work ↑ (55)	55.0		7.9		47.1		10
4 months harvest		+5.7		+4.8		+0.9	
food ↑ work ↓ (60)	60.7		12.7		48.0		15
3 months rest		−0.9		−0.8		−0.1	
food ↓ work ↓ (59)	59.8		11.9		47.9		14
'Lean man'							
Starting weight	59.0		11.3		47.2		14
5 months cultivation		−3.1		−0.9		−2.2	
food ↓ work ↑	55.9		10.4		45.5		13
4 months harvest		+4.8		+1.5		+3.3	
food ↑ work ↑	60.7		11.9		48.8		14
3 months rest		−1.3		−0.5		−0.8	
food ↓ work ↓	59.4		11.4		48.0		14

Observed weights[7] in parentheses.

we have shown[6] that a sustained shift up or down in the pattern of P values throughout childhood would produce substantial changes in body composition, equivalent to ectomorphy and endomorphy, even though food intakes were unchanged.

In adults it seems that the P value has implications for body composition, and in some circumstances, for body weight also. In subsistence communities it seems advantageous to use fat as the main energy store, and thus to spare muscle in conditions of stress. The low P value associated with this pattern of adaptation seldom produces obesity in these conditions because of the limited availability of food. As communities become more affluent, however, the survival advantages of a low P value no longer apply, as obesity and its complications become an increasing problem for the men with the low P values. The shape of the curve in Fig. 1 is compatible with a genetic basis for the distribution of P values. These data are derived from North American men, but have a low modal value, that is a 'fat man' value, consistent with adaptation to subsistence conditions. The presence of some individuals with a high P value might indicate genetic drift. Such a genetic mechanism could explain the inherited pattern of obesity commonly found in affluent countries. In affluent conditions, a genetic drift of the P value to higher levels would have no survival disadvantages and might even have positive advantages although these would occur mainly after reproductive age. If the affluent society persists, there may thus eventually be a higher proportion of 'lean' individuals.

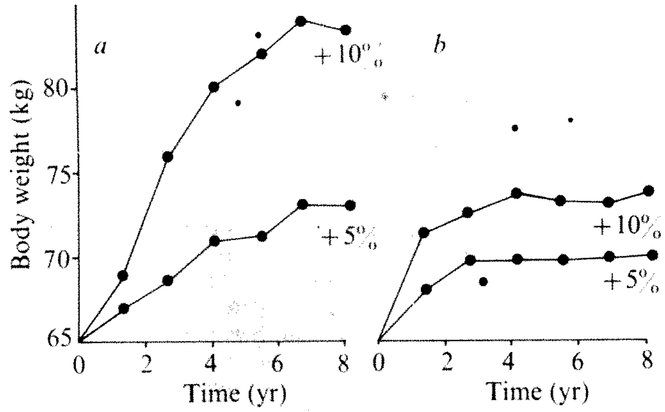

Fig. 3 Changes in body weight associated 5% and 10% above maintenance food intake. *a*, $P = 0.03$; *b*, $P = 0.30$.

James and Trayhurn[9] have speculated on the enzyme pathways which might be responsible for the utilisation of fat and protein to meet energy needs and we are developing a more sophisticated computer model to try to localise the critical pathways. The apparent importance of the P value in determining human body composition suggests that treatment of obesity could be effected by chemotherapy to raise the value of P as an alternative to present methods which stimulate the basal metabolic rate or depress appetite. If the P value could be raised from 0.03 to 0.30, then our model suggests that an obese man would slowly lose weight and fat without altering his energy intake.

Table 2 Computer model predictions of changes in body weight and composition with overfeeding of 'fat' and 'lean' men

	Total weight, W (kg)	ΔW	Fat tissue, F (kg) %	ΔF	Lean tissue, L (kg)	ΔL	
Starting values	65		11		54		12
Final levels with food intake 5% above maintenance requirements							
'Fat man'	73	+8.0	17.7	+6.7	55.3	+1.3	17
'Lean man'	68.9	+3.9	12.0	+1.0	56.9	+2.9	12.5
Final levels with food intake 10% above maintenance requirements							
'Fat man'	83.1	+18.1	26.2	+15.2	56.9	+2.9	23
'Lean man'	73.0	+8.0	13.1	+2.1	59.9	+5.9	13

Dominance and reproductive success among female gelada baboons

THE relationship between dominance and reproductive success has been of considerable theoretical interest, with an extensive literature reporting its existence among males in many species[1]. Although female dominance hierarchies are known to exist in various species, the possibility of a similar relationship for females has not been investigated in detail. Indeed it is often assumed that Bateman's principle[2] implies that intrasexual selection (and hence the effectiveness of dominance as a reproductive strategy) will be very much reduced among females. Only one study of mammals presents unequivocal evidence of a relationship between dominance and reproductive success for females[3], although there is indirect evidence that it may occur in several other species[4-7]. We report here evidence for such a relationship in the case of female gelada baboons (*Theropithecus gelada*) in the wild.

Gelada baboons live in reproductive units that typically consist of a single adult male and up to 10 mature females with their offspring[8]. During a field study of this species in Ethiopia in 1974–5, dominance ranks among the females in each of 11 reproductive units were determined by analysing the frequencies of approach–withdrawal type agonistic interactions within each unit. In all cases, the hierarchies were found to be strictly linear.

The number of immature animals less than 3.5 yr old at the start of the study was known for each unit, together with the number of infants born into each unit during the subsequent 9 months of intensive study. From detailed studies of the social structure of these units, it was possible to determine probable mother–offspring relationships with some confidence. Survivorship for immature animals up to the age of 3.5 yr was estimated to be 80% (unpublished data). Thus, on average, the data for each unit will deviate from either the true number of births or the number of offspring surviving to the age of 3.5 yr by only about 10%. In view of this, no attempt was made to correct the raw data in any way.

Figure 1 shows the mean number of offspring per female for females of the various dominance ranks. There is a significant correlation between these two variables ($r_s = 0.667$, $n = 8$, $P < 0.05$), and a linear function has been fitted to the data by the method of least squares. In practice, a linear function is *a priori* unlikely, because, no matter how low a female's dominance rank may be, she will have some finite (albeit small) probability of reproducing. But, fitted exponential and hyperbolic functions give only marginal increases in goodness of fit.

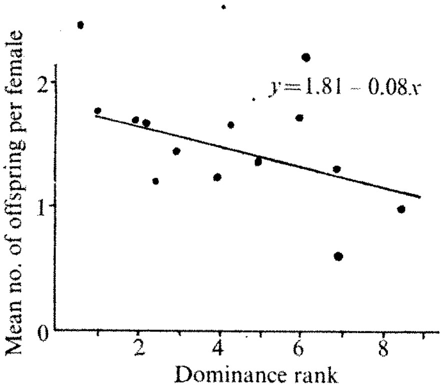

Fig. 1 Relationship between the mean number of offspring per female and rank in the female dominance hierarchy (see text for details).

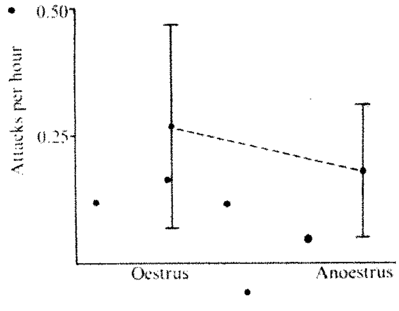
Since the linear function does not yield a zero value for reproductive output until the equivalent of rank 23 (a value well beyond the normal range of unit size for this species[8]), a linear approximation is quite adequate for most purposes.

Two alternative explanations for these results might lie in a confounding of variables. First, it could be argued that, as the number of females in a unit increases, mutual interference among them might result in a lowering of each of their individual reproductive rates by the same amount. The fact that the samples for low ranks are based on large units, whereas those for high ranks are based on both small and large units, will tend to bias the results in favour of the latter. Consequently, the average output would seem to be higher for dominant females than for subordinates, although there was no underlying relationship between dominance and reproductive success. That this is not so in the present case can be shown by comparing the reproductive outputs of the top three ranking females in small units (four or five females) with those of the top three females in large units (six to nine females). The former averaged 1.889 offspring per female, compared with 1.778 for the latter: the difference is not significant (randomisation test: $t=0.509$, d.f.$=16$, $P > 0.0$). Second, it could be argued that, because the number of offspring a female can expect to have will be in part a function of her age, the results obtained could be due to a relationship between age and dominance rank. It can be shown, however, that there is no significant relationship between these two variables; furthermore, it can also be shown that, while there is a relationship between age and number of offspring, this is independent of the relationship between dominance and number of offspring (unpublished data).

The available evidence suggests that dominant females achieve this reproductive differential by harassing subordinate females, thereby causing them to undergo more oestrous cycles before conception than do dominants. This can be seen from two relevant sets of data.

First, Fig. 2 compares the frequencies with which a sample of nine females were harassed by females in their units who were more dominant to them when they were in oestrus and when they were out of oestrus. For these purposes, oestrus is defined as the part of the menstrual cycle during which the areas of sexual skin are surrounded by fluid-filled vesicles, sexual activity being most common during this period[9,10]. The difference between the two conditions is significant (randomisation test for matched pairs: $P=0.023$, $n=9$), attacks being about 50% more common during oestrus than during anoestrus.

Fig. 2 Mean frequency of attacks received from the more dominant females of their units by females who were in the oestrous and anoestrous parts of the menstrual cycle (vertical bar gives 1 s.d. either side of the mean).



Second, an examination of (1) the order in which sets of females which were synchronised in their menstrual cycles stopped cycling and (2) the order in which sets of females who gave birth within a period of 2 months of each other did so indicates that the order of (probable) conception corresponds closely to the order of dominance ranks. To maintain statistical independence, the data were analysed by considering only successive dyads in each set: in other words, triads, for example, were treated as two sets of successive dyads, *A*-with-*B* and *B*-with-*C*. On this basis, there were nine dyads in each of the two data groups, of which only two dyads in each case were in reverse order of dominance (binomial tests: $P=0.09$ in each case, $n=9$). Combining probabilities by the method due to Fisher[11] gives $\chi^2=9.632$, which, with $2k=4$ degrees of freedom, is significant ($P < 0.05$), indicating that order of conception tends to follow order of dominance ranks.

The precise *modus operandi* of this process is uncertain, but suspicion rests strongly on the likelihood that harassment during oestrus results in a disruption of the female's ovulatory cycle, either by causing it to be anovulatory or by precipitating spontaneous abortion of the ovum before or soon after fertilisation. Two lines of evidence support this interpretation. First, no differences could be found between dominant and subordinate females in either the rates of mounting or the frequencies of ejaculation received from their males. Furthermore, no female was ever observed to actively interfere with the solicitations or copulations of other females. Second, there is circumstantial evidence from captive studies of both *Theropithecus* and *Papio* that intense aggression and/or stress can result in the sudden, premature termination of oestrous cycles[10,12].

This research was financed by the SRC. We thank the Ethiopian Wildlife Conservation Organisation and the Institute of Ethiopian Studies of the National University, Addis Ababa, for support and sponsorship.

Assessment of egg load by *Pieris brassicae* (Lepidoptera: Pieridae)

IF offered a choice of cabbage or *Reseda* the large white butterfly (*Pieris brassicae*) first lays a certain number of eggs on the former food-plant and then oviposits on ***Reseda***. We have found that several cues enable the butterfly to 'assess' the egg load present on a plant or leaf, and at the appropriate moment switch to the previously less acceptable species. Overloading is thus avoided. Feeding larvae and damaged foliage are also deterrents to oviposition.

Egg-laying females (of the Cambridge and Oxford strain of *P. brassicae*[1]), confined in net-covered cages, were offered a choice of two cabbage leaves from the same plant, matched for age, position on the stem, size, shape and texture. Damaged leaves and those bearing signs of mildew, aphid or slug infestation were discarded. One whole plant (with a control) was offered on which *P. rapae* had oviposited. The types of leaves used, with their treatment, are shown in Table 1. To avoid position effects, leaves were transposed periodically.

We found that *P. brassicae* lay a reduced number of eggs on leaves bearing their own eggs; model plastic eggs; crushed egg fluid; body fluids pressed from the tips of female abdomens; feeding caterpillars; and leaves from which egg batches had been removed. They were not inhibited by larvae placed on a leaf surface, by model caterpillars or by an airstream with larval odour. The most powerful deterrents were feeding larvae and certain plant extracts[2] (Tables 1 and 2).

The butterfly's response to yellow plastic eggs or yellow patches painted on the leaves (a single trial) indicated that visual cues contribute to the selection of suitable leaves. Similarly the repellant effect of the eggs was reduced if they were dyed green. Vision may also play a part in the rejection of leaves on which larvae are feeding or which display old damage, holes and emarginations[3].

The reduction in number of aerial visits (without leaf contacts) to plants and leaves bearing hidden eggs, crushed egg fluid or body fluids, or from which eggs had been removed, indicates that airborne cues associated with the presence of eggs are appreciated from a distance.

Similar results were obtained with recently damaged leaves and crushed leaf extract painted on the surface. The reduction in the number of settlings after contact with experimental leaves carrying a heavy egg-load, or smeared with egg fluid (Table 2), indicates that chemoreception through the tarsi[4] also occurs.

The relative increase in the number of small egg batches (1–10) and the associated paucity of large batches (60 upwards) and a lack of orderly linear arrangement of eggs on experimental leaves, suggests that the female experiences disturbing or discouraging elements while in the act of laying, some of which may be perceived through the tip of the abdomen. This was also intimated by the behaviour of females attempting to lay on paper leaves (Table 2).

The colour and shape of eggs, if visible to the approaching butterfly (Table 1) represent one aspect of the deterrent, but our experiments indicate that an airborne pheromone-like emanation associated with the egg is the most important factor discouraging the fluttering female. After the removal of egg batches, leaves could still inhibit oviposition (Table 1), suggesting that the female, while laying, adds a deterrent marker to the eggs, either incorporated in the cement (which is difficult to remove from the leaf surface) or consisting of a discrete secretion of the accessory glands associated with the reproductive organs or genitalia, or the ovaries themselves.

Experiments using the small white (*Pieris rapae*) and

Table 1 *P. brassicae* ovipositing in experimental situations on cabbage leaves

Condition of leaf	No. of trials	No. of eggs trials	Remarks
Egg laden	45	1,129	13 leaves without eggs; none with > 150 eggs
Clean		6,913	No leaves without eggs; 16 with > 150 eggs
Smeared with *P. brassicae* egg fluid	6	317 (7 batches)	3 leaves without eggs
Smeared with distilled water		1,410 (34 batches)	No leaves without eggs
P. brassicae eggs brushed off surface	11	858 (25 batches)	1 leaf with under 10 eggs; none with 150 eggs
Surface brushed only		3,199 (93 batches)	All leaves with over 10 eggs; 1 leaf with > 150 eggs
With yellow model eggs attached	9	70 (4 batches)	The ♀ sometimes investigates model egg batches by extending the proboscis and drawing it back and forth over the surface like a bow across a violin
Clean		750 (68 batches)	
With first instar larvae feeding	4	140 (14 batches)	
Clean (treated with crushed cabbage extract in 2 trials)		750 (68 batches)	Contrast would have been greater on a clean leaf without extract
Damaged by feeding larvae	8	628 (18 batches)	
Undamaged		2,663 (74 batches)	
Smeared with tip of ♀ abdomen	8	234 (15 batches)	The leaf may have also been contaminated with egg fluid, haemolymph, mecomium and fluid from the gut
Smeared with distilled water		2,880 (67 batches)	
Red cabbage (red drumhead cultivar)	2	40 (3 batches)	
Green cabbage (greyhound cultivar)		2,008 (58 batches)	
White (heart) leaf from same plant as control	2	313 (13 batches)	Larvae only very rarely metamorphose when reared on cabbage 'hearts'
Green leaf (flower of spring cultivar)		2,658 (84 batches)	
Old (growing)	3	874 (19 batches)	This also applies if whole young plants are matched against older plants
Young (growing)		1,008 (42 batches)	

the monarch (*Danaus plexippus*) both of which lay eggs singly, suggest that a similar mechanism in these butterflies limits overloading of the host plant (Table 3). Whereas the large white chiefly depends on tarsal contact for testing the suitability of the leaf, the small white uses the tip of the abdomen, while the ovipositing monarch generally taps the leaf surface with the antennae after settling, although vision seems to have a role where larval infestation is concerned. W. W. Brandt (personal communication) has seen birdwings (Ornithoptera) in New Guinea apparently searching *Aristolochia* vines visually (starting from the bottom and working upwards) and flying off should they discover the presence of an egg on a leaf. If such an egg is removed, the next female searcher will lay on the plant.

Table 2 Behaviour of ovipositing *P. brassicae* and evidence of airborne and contact cues

Cabbage leaf treated with plant extracts or egg material	No. and duration (h) of trial	Aerial visit without contact	Visits with leaf contacts*	Settling on leaf (wings folded but no oviposition)	No. of eggs
Repellent plant extract (5 species tested)	7 trials	125	27	15	136

NC, not counted.

*The leaf was touched with the feet or wings but fluttering continued until the butterfly flew away.

†These females went through all the motions of laying egg batches but only in one case actually extruded eggs. The small white butterfly (*P. rapae*) regularly tests the leaf with the tip of the abdomen and then decides whether or not to lay, but this is unusual for *P. brassicae*.

Similar undetected deterrents associated with eggs and feeding larvae may be widespread among the Lepidoptera. This could explain the development by some plants, such as *Passiflora*, of faked eggs[3] and larva-like stipules[5]. Such a response to heavy butterfly predation assumes visual assessment by the laying female. It would be interesting to investigate the scent of these plant-part mimics, especially the faked eggs.

Repellent markers have not been recorded in the Lepidoptera before, but have been described in entomophagous parasites as a means by which the female prevents overparasitisation of the host[6]. A chemical associated with the eggs of the noctuid moth *Heliothis virescens*, present on, in and around the eggs after oviposition and in ovarial tissue (but not in accessory gland extract) is said to elicit host area searching in an egg–larval parasitoid[7]. In the case of the cherry fruit fly (*Rhagoletis cerasi*) and related species[8,9], marking of the host plant is affected by active spreading of the repellant across the fruit surface by the ovipositor. In *P. brassicae* it seems that the pheromone-like repellent is excreted on to the leaves or, as in *Heliothis*, is present in the tissue or covering of the egg itself.

It was not surprising that *P. brassicae* responded more positively to feeding larvae than to its own eggs, since such a threat to the food source is immediate and certain. It was also to be expected that deterrents found in lethal food plants (for example, *Cheiranthus cheiri* (wallflower) and *Erysimum* (treacle mustards) (refs 2 and 10 and unpublished results)) which also contain the usual cruciferous oviposition and feeding stimulants, would be both powerful and decisive in their action. Moreover, the quality of the deterrent is marvellously suited to the large white butterfly's lifestyle, for it neither inhibits nor reduces egg laying too drastically. By urging the female, fluttering among the cabbages, to 'try her luck' just a little further on, it ensures the dissemination of her progeny on suitable foliage.

We thank Howard Hinton for help with the literature, Brian Gardiner and Claude Rivers for replenishing our stocks of butterflies and for useful advice, and Bob Ford and J. Meerman for technical assistance.

Table 3 Experiments with ovipositing *P. rapae* and *D. plexippus*

Alternatives offered to *P. rapae*	Duration of experiment	No. of eggs	Remarks
Leaf of green cabbage (greyhound)	4 trials 1 h	105	—
Leaf of red cabbage (red drumhead)		12	
Cabbage plant in pot	12 h*	254	
Tropaeolum plant in pot		196	Eggs also laid on flowers
11-leaved clean cabbage plant	12 h*	245	—
13-leaved egg-laden cabbage plant		129	—
Single clean cabbage leaf	(*a*) 4 trials 30 min	(*a*) (*b*) 60 187	
Single egg-laden cabbage leaf	(*b*) 1 trial 3 h	(*a*) (*b*) 14 116	
Clean cabbage leaf	2 h	86	52 contact visits
Cabbage leaf with 80 eggs crushed on underside		21	25 contact visits
Clean cabbage leaf	1 h	46	—
Leaf with batches of *P. brassicae* eggs crushed on surface		20	—
Clean cabbage leaf (underside brushed)	1 trial 15 min	66	♀♀ very keen to lay and clean leaf became overcrowded
Cabbage leaf with 12 ♂♂ abdomens lightly brushed on underside		45	
Small clean cabbage leaf (lightly brushed on underside)	3 trials 40 min	133	
Small leaf from which 90 eggs were lightly brushed off underside		53	
Alternatives offered to *D. plexippus*			
A. curassavica clean plant	3 trials 30 h	281	♀♀ near end of egg laying
A. curassavica egg-laden		243	
A. curassavica clean plant	3 trials 12 h	112	♀♀ near end of egg laying
A. curassavica with feeding larvae		40	

In the absence of leaves, *P. rapae* will oviposit on objects in the cage whereas *P. brassicae* dies without laying eggs.

*When the favoured leaf becomes egg laden the contrast declines.

Tumours and viruses in mice injected with plutonium

THE α-particle emitting plutonium is, at present, the bone-seeking element of greatest public concern. For man, however, the best evidence of damage from α-particle emitters in bone concerns radium, for which the pattern of deposition differs from that of plutonium. We report here an experiment designed to compare the effects of plutonium in mice with those of radium, previously reported[1,2].

The specific questions we considered were (*a*) Do plutonium-induced tumours contain viruses? (*b*) Does sex affect the viral status or incidence of tumours? (*c*) Are the tumours similar to those induced by radium? (*d*) Are they variable with dose and time, or different irradiation chimaeras[3].

The solution injected intraperitoneally was minimally polymerised plutonium (predominantly ^{239}Pu) citrate[4] passed through a 25-nm Millipore filter.

The design of the experiment and distribution of tumours in each of eight separate groups of animals are shown in Fig. 1. No controls are included in Fig. 1, but for 15 CBA/H female controls carefully examined earlier, and hundreds of normal CBA/H mice maintained until death but less rigorously examined, no osteosarcomas were observed. The median lifespans of untreated male and female mice are about 24–28 months beyond the age of 3 months, when treated mice were injected. These figures differ little from those of CA/H mice injected with 10 nCi ^{239}Pu (22 and 26½ months, respectively; Fig. 1).

In chimaeras CBA *T6T6*/A, 9/20 males and 14/20 females developed osteosarcoma after 100 nCi ^{239}Pu. Genetic tests by passage[3] of these tumours and one skeletal haemangiosarcoma confirmed that they originated from host tissue.

In natural mice given 100 nCi, leukaemias were observed in the same number of animals as osteosarcomas, 2/10 males and 5/10 females. After 30 nCi, osteosarcoma occurred in 4/10 male and 8/10 female mice. After 10 nCi, no osteosarcomas were observed in male mice but 9/10 died of other tumours including four carcinomas, two fibrosarcomas, two reticulum-cell sarcomas and one possible haemangiosarcoma: in females, however, osteosarcoma was the commonest tumour (6/10), accompanied by carcinoma in three, and two mice died early with reticulum-cell sarcoma.

Osteosarcoma is more readily induced in female than male mice, owing to the response of murine bone to oestrogens[5] (though in man the natural incidence of osteosarcoma is higher in males than females[6,7]).

The high incidence of tumours other than osteosarcoma, though unexpected, could agree with observations for rats inhaling soluble ^{238}Pu (ref. 8) and rats injected with various bone-seeking radionuclides[9]. Regarding leukaemia, though a small incidence of myeloid leukaemia[10] and "leukoses of the reticulosis type"[9] occurred in rats given plutonium, it has not been reported in mice. In CBA with a natural incidence of about 1% (refs 11, 12), seven cases out of 20 at risk of generalised lymphomatosis (excluding thymus) with lymphoblasts in peripheral blood was striking. Leukaemias occurred earlier than osteosarcomas. Also, there is a suggestion of an increase of early reticulum-cell sarcoma in animals given 10 nCi (the incidence in normal CBA mice is 5–10% (refs 2, 13) and of miscellaneous malignancies after 10 and 30 nCi, many at times later than the mean time for appearance of osteosarcoma (and so reminiscent of the late onset of specific carcinomas of cranial air sinuses in human radium cases, notably those with lower burdens of radium[14]). The late onset may be related to the long retention of radioactivity and immunological imbalance.

None of the chimaeras, which have perhaps an even lower

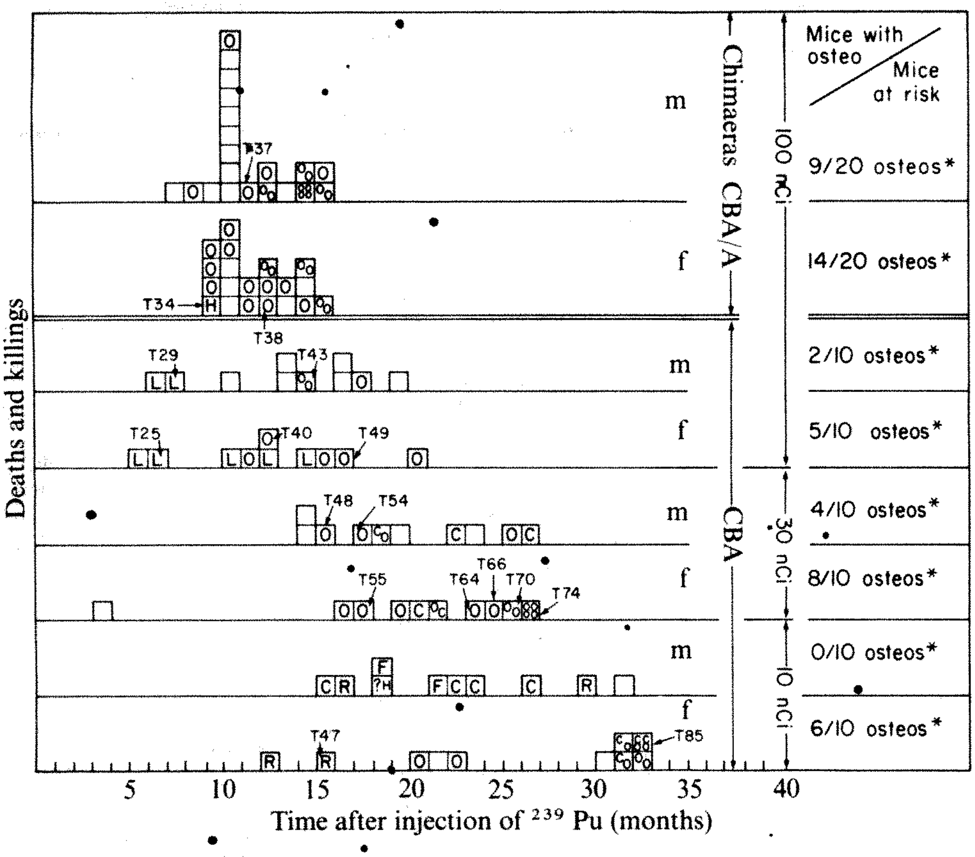

Fig. 1. Design and results of the experiment involving i.p. injection of CBA/H mice and CBA *T6T6*/A radiation chimaeras with ^{239}Pu citrate. Each mouse is represented by an individual box. This is plotted with time after injection of varying doses of ^{239}Pu citrate when the mouse either died or was killed. The types of tumours are indicated. O, osteosarcoma; H, haemangiosarcoma; L, leukaemia; C, carcinoma; F, fibrosarcoma; R, reticulum-cell sarcoma. Multiple entries indicate multiple tumours. Samples examined by electron microscopy are designated by the letter T followed by a number, for instance, T37. *osteo, Osteosarcoma; m, male; f, female.

incidence of all forms of lymphoma[15] than natural mice, developed leukaemia after 100 nCi. This may be due to a somewhat lower uptake of plutonium by bone marrow in chimaeras[16]. Such chimaeras, however, have a low incidence (1/69) of generalised lymphoma induced by β rays of ^{90}Sr–^{90}Y on donated haematopoietic tissue[17]. One might expect the 1,000 rad of whole-body irradiation given to the chimaeras to alter the normal cellular and humoral environment, but not to impair the expression of virus, rather the reverse[18].

The median lifespans of animals treated with 10 nCi (24 months) 30 nCi (20 months) and 100 nCi (13 months for CBA/H mice and 11 months for chimaeras) were shorter than for untreated controls (26 months). Malignant disease, varying in type between groups, was a major cause.

Table 1 lists the viral status of tumours examined electron micrographically. In osteosarcomas taken from chimaeras injected with 100 nCi ^{239}Pu, more virus particles were seen than in the other tumours. In 16 out of 19 tumours examined, virus was seen, and 'virus-like' particles were seen in one other tumour. No virus was observed in either of two tumours examined from animal T85. Figure 2 is an electron micrograph demonstrating the typical type-C particles. Viruses were commonly found either lying within cytoplasmic vesicles or budding from endoplasmic reticulum associated with degenerate cells. No difference could be seen in morphology of viruses in samples taken from different tumour types.

In the series no tissue taken from normal ribs of three CBA/H tumour-bearing animals showed any evidence of virus even after extensive search, though occasional viruses were seen in control animals of an earlier study[1].

Table 1 Viral status of ^{239}Pu-induced tumours

Dose per mouse (nCi)	Strain	Sex	ANL no.	Tumour type	Site of tumour	Time of appearance (months)	Virus present or absent
100	Chimaeras CBA *T6.T6*/A	Male	T37	Osteosarcoma	Sacrum	11	+
		Female	T34	Haemangiosarcoma	Sacrum	9	+
			T38	Osteosarcoma	Sacrum	12	+
	CBA	Male	T29	Lymphoma	Lymph node	7	+
			T43	Osteosarcoma	Right ilium	14	+
				Osteosarcoma	Thoracic vertebra 12		+
		Female	T25	Lymphoma	Lymph node	6	– ?
			T40	Osteosarcoma	Ischio pubis	12	+

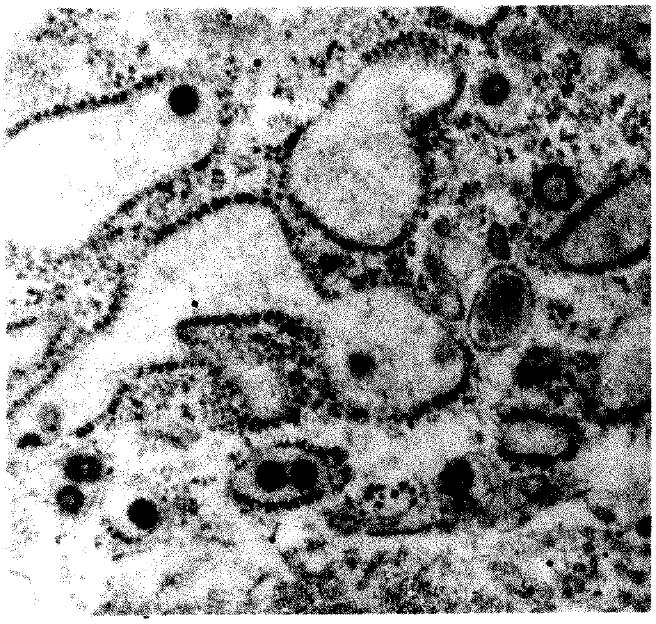

Fig. 2 Electron micrograph of a portion of tissue taken from an osteosarcoma (T54) showing viruses lying within cytoplasmic vesicles or budding from the endoplasmic reticulum (×47,600).

The particles appear identical with those observed in osteosarcomas from CBA/H animals injected with ^{226}Ra (ref. 1). This does not allow us, however, to implicate virus as the aetiological agent. Tumour tissue may merely provide a favourable environment in which virus can replicate sufficiently to be above the threshold of detection by electron microscopy. Three lines of evidence from current work in progress indicate that viral action need not be involved in radiation-related tumorigenesis. First, animals subjected to a procedure of immunisation with homogenates of tumour tissue and subsequently injected with ^{226}Ra develop osteosarcoma to about the same extent and in the same time as unimmunised controls[19]. Second, a single α particle directly hitting the nucleus may be insufficient to kill the cell[20], contrary to what some have previously supposed. Hence, survival of some cells with alteration of DNA is probable after a direct hit on the nucleus, and may lead to malignancy without the intervention of virus. Third, cells irradiated in culture with α particles have been transformed[21], in a manner similar to that shown by other workers using γ rays[22] and chemical agents[23], where transformation was shown to be independent of virus expression.

Our results need confirmation with larger groups of animals and smaller doses of plutonium (the lowest dose used led to a concentration about a thousandfold greater than that occupationally permissible to man).

We thank Faustina Mackevicius and G. T. Chubb for technical assistance in the electron microscope studies. This work was performed under the auspices of the MRC and USERDA.

RD-114 and feline leukaemia virus genome expression in natural lymphomas of domestic cats

THE widespread distribution of endogenous type C viral genetic sequences in many different vertebrate species[1,2] is now well established. The biologic implications of the presence of such endogenous type C viral genomes, especially with respect to normal and neoplastic growth, are at present of considerable interest[3]. The domestic cat (*Felis catus*) offers a unique model system for approaching this question, because of its ready availability, outbred nature and relatively short lifespan. Moreover, the genetic information of its endogenous xenotropic virus (RD-114) is distinct[4] from that of feline leukaemia virus (FeLV), a horizontally transmitted, infectious type-C virus of this species. RD-114 virus[5] is generally non-infectious for cat cells[6] and its pathogenicity is undetermined, whereas FeLV is known to be leukaemogenic under natural[7] and experimental[8] circumstances. The genetic information of RD-114 has been demonstrated in the DNA of domestic cats[9–11] and their close relatives, but not in more distantly related species of the genus *Felis*[12]. Both transcriptional[13] and translational[14] products of the endogenous RD-114 viral genome are also found in certain instances in the absence of complete virus in normal cat tissues. FeLV and RD-114 gene expression at the transcriptional and translational levels in domestic cats has been examined here in relation to naturally occurring lymphoma. Results indicate a significantly higher level of RD-114 transcription and translation in most lymphoma tissues compared with normal tissues. Although FeLV expression is also pronounced in lymphomas, this generally reflects the presence of infectious FeLV. In general, however, only the lymphomas from the younger cats show significant levels of FeLV gene expression, whereas RD-114 expression is high in lymphomas of both young and old cats. Although the relationship of this enhanced expression of the RD-114 genes to the neoplastic process is unknown, these findings indicate that certain functions of the endogenous RD-114 viral genome are closely associated with the development of lymphoid tumours in the cat.

Nucleic acid and antigenic differences between RD-114 and FeLV made possible the measurement of the expression of viral information for both viruses in the same tissues at the RNA and structural protein levels. The transcription of virus-specific RNA in the tissues was determined by molecular hybridisation using ^{3}H-labelled single-stranded DNA products (^{3}H-cDNA) complementary to viral nucleotide sequences and the S_1 nuclease method of assay. The levels of the 30,000 molecular weight major structural protein (p30) of both viruses were determined on the same tissues by competition radioimmunoassays. Sixty histologically normal tissues from 47 cats free from cancer and 55 lymphoma tissues from 31 lymphomatous cats were assayed for the RNA and p30 of RD-114 and FeLV. The normal tissues examined included spleen, liver, and

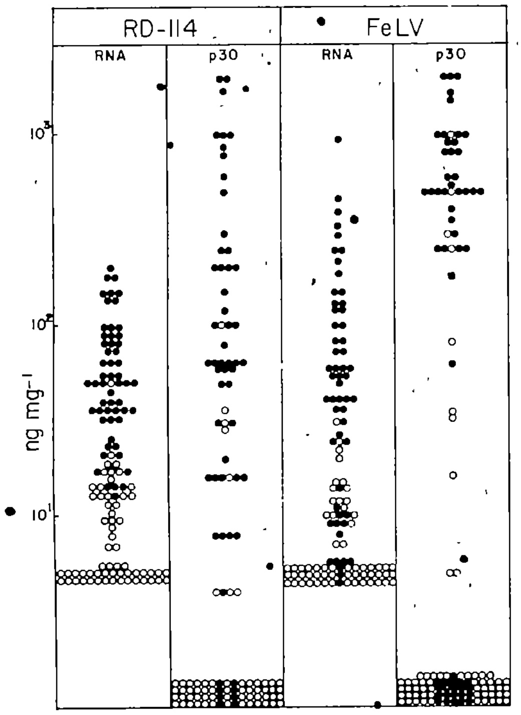

Fig. 1 Measurement of RD-114- and FeLV-specific RNA and p30 in normal and lymphoma tissues of cat. Viral RNA concentrations were determined by molecular hybridisation of tissue RNA with viral ^{3}H-cDNA using the S_1 nuclease assay. Total tissue RNA was prepared following a modification of a published procedure[20]. ^{3}H-cDNA was synthesised using a modified procedure of Benveniste and Scolnick[21]. Briefly, purified[22] RD-114 virus or FeLV (Gardner–Arnstein strain) grown in the human rhabdomyosarcoma (RD) cell line[4] was incubated at 37 °C for 4 h in a reaction mixture containing 0.024 mM ^{3}H-dTTP (92.9 Ci mmol^{-1}), 3 mM each of dATP, dGTP, dCTP, 20 μg ml^{-1} actinomycin D, 60 mM KCl, 6 mM $Mg(CH_3COO)_2$, 5 mM dithiothreitol, 40 mM Tris-HCl, pH 8.0, and 0.02% Nonidet P-40. ^{3}H-cDNA was shown to contain representative transcripts by its ability to protect ^{32}P-labelled viral RNA from digestion by RNase A and T_1 (ref. 23). RD-114 ^{3}H-cDNA hybridised with 78% of the viral RNA at a ^{3}H-cDNA to ^{32}P-viral RNA ratio of 1.0. FeLV ^{3}H-cDNA protected 67% of FeLV viral RNA at the same ratio. The viral RNAs were prepared as described previously[24]. The specificity of the probe was shown by the ability of RD-114 cell and viral RNA to protect 95% and 100%, respectively of the RD-114 ^{3}H-cDNA from S_1 nuclease digestion, whereas only 3% and 2% of the probe was protected by FeLV viral- and FeLV-infected RD cell RNA. FeLV ^{3}H-cDNA hybridised at 51% and 56% with homologous infected cell RNA and viral RNA, respectively, whereas only 2% and 5% of the ^{3}H-cDNA hybridised to heterologous RD-114 cell and viral RNA. All hybridisation reactions were carried out in 10 μl containing 0.3 M NaCl, 0.03 M Na citrate, 0.05% SDS, 0.02% diethylpyrocarbonate, 500–800 c.p.m. ^{3}H-cDNA (7.7×10^7 c.p.m. μg^{-1}) and various amounts of tissue RNA in sealed capillary tubes at 68 °C for 16 h. Hybridised fractions of ^{3}H-cDNA were determined by TCA-precipitable radioactivity after digestion with 35 μg ml^{-1} S_1 nuclease in a reaction mixture containing 0.17 M ZnCl, 27 mM Na acetate (pH 4.5), 0.11 M NaCl and 17 μg ml^{-1} heat-denatured salmon sperm DNA for 70 min at 45 °C. Concentration of RNA × time of incubation (C_rt) values up to about 3×10^4 (corrected to a monovalent cation concentration of 0.18 M; ref. 25) were generated with tissue RNA and the concentration of virus-specific RNA per mg cell RNA was determined by comparison of the C_rt value at 20% level of hybridisation with that obtained using viral RNA. The lower limit of sensitivity varied between 5–10 ng virus-specific RNA per mg cell RNA, depending on the amount of tissue RNA available for the assays. Tissues with undetected levels of RNA were arbitrarily listed as 5 ng per mg cell RNA. The thermal denaturation of hybrids formed between the RNA from two tumour tissues and the ^{3}H-cDNA probes of RD-114 and FeLV was determined for comparison with the corresponding T_m values obtained with RD-114- and FeLV-infected cell RNA. The hybrids exhibited a similar T_m (81.5 °C in 0.3 M NaCl, 0.03 M Na citrate, 0.05% SDS), indicating that most of the viral RNA generated in the tissues was closely related to the RNA produced in the virus-infected cell cultures. The values (ng per mg cell protein) of p30 were determined by group-specific competition radioimmunoassays using ^{125}I-labelled p30 antigen of FeLV and RD-114 as probes[26]. Cell extracts were prepared by homogenisation of tissues in equal volumes of 0.01 M Tris-HCl, pH 7.8, 0.1 M NaCl, 0.5 mM EDTA and 0.5% Triton X-100, sonication for 1 min by use of a Biosonic II sonic oscillator, and clarification by centrifugation for 1 h at 100,000g. Antisera prepared in goats to either FeLV or RD-114 and serial twofold dilutions of competing tissue extract were incubated at 37 °C in 0.15-ml reaction mixtures containing 10 mM Tris-HCl, pH 7.8, 10 mM EDTA, 0.4% Triton X-100, 1% bovine serum albumin, 0.1% normal goat serum, 10 mM NaCl, and 300 μg ml^{-1} phenylmethane sulphonyl fluoride. About 10,000 c.p.m. ^{125}I-labelled FeLV or RD-114 p30 in 0.05 ml of the same buffer were added and incubation continued for 3 h at 37 °C and a further 18 h at 4 °C. Antigen–antibody complexes were precipitated by the second antibody technique and radioactivity in the precipitates measured in a Searle model 1285 gamma counter. Levels of p30 in extracts, expressed as ng per mg cell protein, were calculated on the basis of displacement of the competition curve for the unknown relative to that achieved with purified viral antigen. Cell protein determinations were performed according to the method of Lowry[27]. The lower limit of sensitivity of the competition radioimmunoassay was 2 ng per mg cell protein. Tissues with undetectable levels of p30 were arbitrarily listed as 1 ng per mg of cell protein. ○, Histologically normal tissues from cats free of cancer; ●, lymphoma tissues.

kidney; most of the lymphomas were located in the spleen, lymph nodes, kidney, and a few were in the liver, thymus, and other tissues. The presence of infectious FeLV was determined in each cat by the indirect immunofluorescent antibody test for cytoplasmic FeLV p30 antigen in leukocytes and platelets of fixed peripheral blood or bone marrow smears. This test has proved to be a reliable index of systemic infection with FeLV (ref. 15).

The results summarised in Fig. 1 demonstrate that the levels of expression of RNA and p30 of either RD-114 or FeLV generally segregate into two distinct groups, one representing normal and the other lymphoma tissues. The majority of values for the normal tissues cluster below 10 ng per mg cell RNA or protein. In contrast the levels of both RNA and p30 of the endogenous xenotropic virus, RD-114, were considerably higher in the lymphoma tissues. In general, a good correlation was observed between the presence of RD-114-specific RNA and p30 in lymphoma tissues, with the exception of a few tissues which exhibited low but detectable levels of RNA expression in the absence of p30. This finding suggests that, although transcription of the RD-114 genome may occur in certain feline lymphomas, the entire genome is not necessarily translated. Many but not all of the lymphomas also exhibited elevated levels of FeLV RNA and p30 as compared with the normal tissues. Interestingly, most of the FeLV p30-negative lymphomas originated from older cats. As shown in Fig. 2, in which animals ⩽ 5 yr of age have been classified as younger cats and those ⩽ 7 yr as older cats, a general correlation was observed between the age of cats and virus gene expressions in their lymphomas. Whereas RD-114 RNA and p30 were expressed in the lymphomas of both younger and older animals, FeLV expression seemed to be most prevalent among cats ⩽ 5 yr of age. All but two lymphomas from cats of this younger group contained FeLV RNA (⩾ 25 ng mg^{-1}) and high p30 levels (⩾ 180 ng mg^{-1}) Moreover, there was an excellent correlation between elevated p30 levels and systemic infection with FeLV in these younger cats[16]. Thus, the detection of FeLV p30 and RNA expression in these animals probably reflected the presence of horizontally transmitted infectious FeLV. The vast majority of the lymphomas from the older cats, on the other hand, did not contain detectable FeLV p30, although some exhibited levels of RNA significantly higher than those found in normal tissues. The presence of RD-114 gene products and low or no expression of FeLV genes were consistently observed in multiple lymphoma tissues of individual old cats (data not shown).

The geometric mean values of the data and the statistical significance of the observed differences between the normal and lymphoma tissues from old and young cats are summarised in

Table 1 Virus-specific RNA and antigen (p30) expression in normal and lymphoma tissue of cats of different age groups

		Young cats (≤ 5 yr)			Old cats (≥ 7 yr)		
		Normal	Lymphoma		Normal	Lymphoma	
Virus	Assay	(35)	(32)	*P*	(24)	(22)	*P*
RD-114	RNA	7.1	46.1	<0.0005	8.4	65.8	<0.0005
	p30	1.6	48.3	<0.0005	1.3	59.0	<0.0005
FeLV	RNA	5.8	81.7	<0.0005	7.8	17.1	<0.0100
	p30	1.7	414.0	<0.0005	2.4	2.3	<0.5000

Viral RNA and p30 concentrations were determined as summarised in Fig. 1. Values within parentheses represent the number of tissues tested. The geometric mean values listed represent ng virus-specific RNA or p30 per mg cell RNA or protein. *P* values were calculated using paired Student's *t* test of the logarithmic values of the ng mg^{-1} data.

Table 1. The differences in the expression of RD-114 genes in the lymphoma and normal tissues, at RNA or p30 level, are highly significant ($P < 0.0005$) irrespective of the age of the cats. Equally significant is the difference in the FeLV gene expressions in the lymphomas of young cats and the normal tissues from the corresponding age group. In contrast, no significant difference was found in the FeLV expression at the p30 level between the lymphomas from old cats and the corresponding normal tissues. The data suggest, however, a significant transcription of FeLV RNA in the absence of detectable p30 in a few lymphomas of old cats. Since sequences related to FeLV in the absence of infectious FeLV can be detected in the genomes of domestic cats[9,17,18], this transcription could represent either expression of these endogenous FeLV sequences, or subinfectious expression of exogenous FeLV acquired, perhaps, at an earlier age. Thus, it seems that the expression of the endogenous xenotropic RD-114 virus information is closely associated with lymphomas in cats of all ages, whereas FeLV related gene expression is primarily associated with lymphomas of younger cats. The absence of FeLV gene expression in many older and a few younger lymphomatous cats confirms our earlier findings based on other assays for FeLV (ref. 19), and suggests that, in these particular cats, spontaneous lymphoma may not be caused by FeLV. The widespread occurrence of RD-114 viral gene products in lymphomas suggests that expression of certain functions of this endogenous virus may be involved etiologically in the development of spontaneous lymphoid tumours of the cat. The alternative possibility, however, that elevated endogenous viral gene expression may be the result, rather than the cause, of neoplastic transformation cannot be ruled out by the present findings. It is our hope that elevated endogenous viral gene expression, even if not causatively involved in lymphomagenesis, may provide a logical approach towards immunoprevention.

Fig. 2 Virus-specific RNA and p30 expressions in lymphomas from young and old cats. Values were calculated as in Fig. 1. Cats ≤ 5 yr of age were designated as young and ≥ 7 yr of age as old. There were no 6-yr-old cats in this study. ▲, Young; △, old cats.

Persistence of virus-specific memory B cells in mice CNS

IMMUNOGLOBULIN (Ig) populations detected in the cerebrospinal fluid (CSF) in chronic viral infections of the central nervous system (CNS) differ from serum Ig with regard to the relative concentration of antiviral antibodies[1-4], their light chain ratio[5] and their heterogeneity[6,7]. Such observations support the idea that antibodies are produced locally in the CNS[8]. But differences between CSF and serum Ig can also be explained in terms of the selective retention and accumulation of serum antibodies after passage across the blood–brain barrier[9]. Unequivocal proof of the local antibody production requires, however, that plasma cells, or their precursor cells, be isolated from the CNS. Intracerebral inoculation of mice with 6/94, a para-influenza type 1 virus[10], induces an immunologically mediated degeneration of the white matter which is related to infiltration of the brain parenchyma by mononuclear cells[11,12]. In the study reported here, cells recovered from the brains of virus-infected mice were investigated as described previously to analyse memory B cells reactive to influenza viruses[13,14]. Virus-reactive memory B cells, that is immunocompetent cells able to generate, on antigenic stimulation, a clone of antiviral-antibody-producing plasma cells, were demonstrated in the brains of mice infected intracerebrally with 6/94 virus but not in the brains of mice injected intraperitoneally.

BALB/c mice were inoculated intracerebrally or intraperitoneally with 6/94 virus. At various times the 6/94-reactive memory B cells obtained from brain, blood and spleen of individual donor mice were counted in an adoptive transfer system described previously[13]. Cells used for adoptive transfer were prepared as follows. Blood was withdrawn by heart puncture and red cells were lysed by incubation in NH_4Cl (ref. 15). White cells were pelleted through a cushion of calf serum[15] and resuspended in a balanced salt solution (BSS). A spleen cell suspension was prepared by gentle disruption of the spleen in a tissue homogeniser[13]. To obtain brain cells the brain was removed aseptically, rinsed in cold BSS, finely diced with a tissue chopper (McIlvain, Brinkman) and resuspended in ice-cold BSS. Large brain fragments were allowed to settle and the supernatant was withdrawn and spun for 8 min at 800*g* at 4 °C. The pellet was resuspended in BSS and mixed with a solution of bovine serum albumin (BSA) in BSS to give a final BSA concentration of 21%. A discontinuous BSA gradient was prepared, as described by Shortman[15], by underlaying a 32% BSA solution and overlaying BSS. The gradient was spun for 20 min at 3,000*g*. Cells that had accumulated at the interface between 32% and 21% BSA were collected, spun out of the BSA and resuspended in BSS. Between 1 and 4×10^5 viable cells (Trypan blue exclusion) were recovered from a single brain. The BSA purification of the brain extract was necessary because the intravenous injection of crude brain eluate produced a high death rate in recipient mice, probably caused by microemboli. Each cell preparation was then injected intravenously into lethally irradiated syngeneic recipient mice[13]. Splenic fragments of the recipient mice were cultured individually (50–70 fragments per spleen) and analysed by radioimmunoassay (RIA)[14] for the production of antibodies to 6/94 virus after secondary stimulation *in vitro* with 6/94. In these conditions, the number of antibody-producing splenic fragments has been shown to be correlated with the number of transferred precursor B cells[13].

The results of several adoptive transfer experiments with cells from the brain of mice at various times after intracerebral or intraperitoneal inoculation with 6/94 are shown in Tables 1 and 2, respectively. Two points are noteworthy. First, 6/94-reactive memory B cells could be demonstrated in the brain cell eluate from all but two of the intracerebrally inoculated mice. Although the absolute numbers of detected foci per experiment was small (because of the paucity of cells recovered from brain) the relative frequency (per 10^5 transferred cells) of 6/94-reactive memory B cells was, in the positive experiments, of the same magnitude or higher than in circulation or spleen. Second, virus-reactive memory B cells seemed to persist in the brains of individual mice for at least 4–7 months after intracerebral inoculation.

Table 1 6/94-reactive memory B cells from mice inoculated intracerebrally with 6/94 virus

Weeks after i.c. infection of donor mice*	No. of anti-6/94 antibody-producing splenic fragments per 10^5 transferred cells		
	Brain	Circulation	Spleen
4	0.9 (2/2.2)	0.07	0.41
5	10.0 (5/0.5)	0.25	1.0†
7	0.8 (2/2.5)	0.73	0.60
9	< 0.2 (0/4.8)	0.82	2.0†
18	0.6 (3/4.8)	0.70	0.80
31	(10/half brain)	ND	ND
34	(None/half brain)	< 0.2	1.10

To establish that no background antibody production occurred with any given batch of recipient mice, each experiment included fragment cultures from lethally irradiated mice that had not received adoptive transfer of cells. All these control cultures in the experiments included in Tables 1 and 2 were negative.

* BALB/c mice were inoculated intracerebrally (i.c.) with approximately $10^{6.3}$ EID_{50} of 6/94 and were killed at the times indicated and cells prepared for use in the adoptive transfer. Antiviral-antibody-producing splenic fragments were counted 12 and 15 d after their secondary stimulation *in vitro* with 6/94.

† There were too many transferred cells for an accurate determination of precursor cell frequency. ND, not determined. Figures in parentheses show total numbers of foci observed per total number of transferred cells × 10^5.

Our results (excluding the final two lines of Table 1), can be summarised to show that antiviral antibody was produced by 12 splenic foci obtained after transfer of 14.8×10^5 brain eluate cells after intracerebral inoculation; conversely, no antibody was produced by any of the spleen fragments after transfer of 9.7×10^5 brain eluate cells after intraperitoneal inoculation. It is thus evident that 6/94 memory B cells were detected in the brain eluate only after intracerebral inoculation of donor mice. Given that the number of 6/94-reactive memory B cells in the circulation was approximately the same after inoculation by both routes (Tables 1 and 2), and assuming that the degree of contamination of the brain eluate cells by circulating blood cells was the same in both intracerebrally and intraperitoneally inoculated mice, we conclude that the 6/94 memory B cells in the brain eluate cell preparation of intracerebrally inoculated mice were previously localised in the brain parenchyma and did not represent contaminating blood cells. This is supported by the results of experiments done 4 and 5 weeks after intracerebral inoculation when, on adoptive transfer, the brain eluate cells produced 10–40 times (Table 1) more splenic foci than did the same number of white blood cells of the given donor mice.

In the analysis reported here, the comparison was between the number of 6/94-reactive precursor B cells and the total number of

Table 2 6/94-reactive memory B cells obtained from mice inoculated intraperitoneally with 6/94 virus

Weeks after i.p. infection of donor mice*	No. of antibody-producing splenic fragments per 10^5 transferred cells		
	Brain	Circulation	Spleen
3	< 0.4 (0/2.4)	0.27	ND
10	< 0.3 (0/2.9)	0.58	ND
18	< 0.3 (0/2.8)	0.44	1.25
34	< 0.6 (0/1.6)	0.20	0.92

See legend to Table 1.

* BALB/c mice were inoculated intraperitoneally (i.p.) with approximately $10^{7.3}$ EID_{50} of 6/94. ND, not determined.

transferred cells, regardless of type. It would be more useful to correlate the number of 6/94-reactive precursor B cells with the number of transferred B cells. It is not known what proportion of the cells eluted from the brain consists of B cells, but it is presumed to be smaller than the proportion of B cells in white blood cells (approximately 20%, refs 16 and 17) or spleen cells (approximately 40%, ref. 18). Thus our data probably underestimate the actual difference in terms of absolute frequency (per transferred B cell) of 6/94-reactive memory B cells in the brain of intracerebrally infected mice as opposed to the circulation or the spleen.

This study provides the first direct evidence for the presence of virus-reactive memory B cells in brain tissue of mice with a virus-induced neurological disease. A local immune response can thus be maintained within the CNS.

H–2 gene expression is required for T cell-mediated lysis of virus-infected target cells

EFFECTOR T cells generated during the course of virus diseases of mice interact only with virus-infected target cells sharing H–2K or H–2D antigenic specificities with the mouse strain in which the lymphocytes are sensitised[1–3]. The current interpretation[4] of this phenomenon is that the cell membrane component(s) recognised by the T-cell receptor(s) has characteristics of both self (H–2) and non-self (virus). Phenotypic expression of H–2 genes in the target cell would thus be essential for T cell-mediated immunity. Here we test this hypothesis using two teratocarcinoma cell lines (F–9 and PCC4 derived from strain 129 mice[5,6]) infected with lymphocytic choriomeningitis virus (LCMV). We show that the F–9 tumour cells apparently do not express H–2K or H–2D antigenic specificities (Fig. 1, Table 1), and are also resistant to attack by lymphocytes sensitised against LCMV. The PCC4 line, however, has remained multipotential and can give rise to various different cell types, at least some of which show evidence of H–2 gene function (Table 1) and are attacked by the appropriately sensitised lymphocytes.

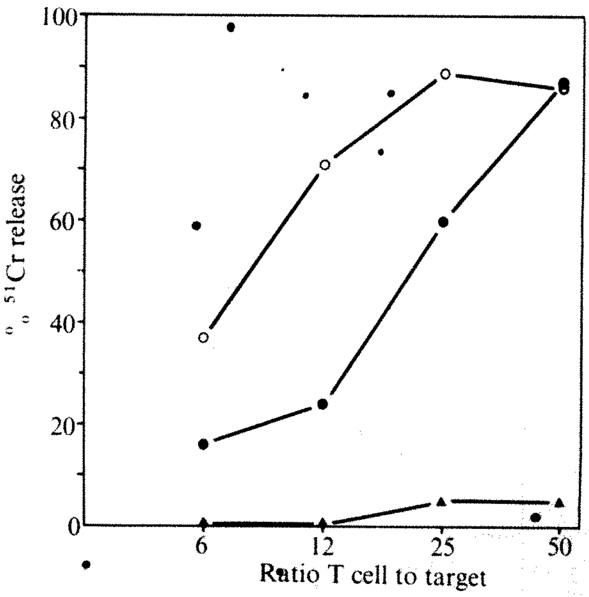

Fig 1 The F–9 teratocarcinoma cell is not lysed by alloreactive T cells specific for H–2^b antigens, expressed on MC57G tumour cells and C57BL primary peritoneal macrophages. Cytotoxic effectors were generated by secondary stimulation of memory lymphocytes from BALB/c mice with mitomycin C-treated (50 μg ml^{-1}) C57BL spleen cells[15]. The assay was incubated for 16 h at 37 °C and results are expressed as % specific ^{51}Cr release.

Equivalent amounts of cell-surface viral antigen are found on immunofluorescent examination[7] of unfixed, LCMV-infected F–9, PCC4 and MC57G (H–2 positive) targets. Maximal virus-specific T-cell effector function is, however, recognised only for the MC57G cell line (Fig. 2). Apparently some PCC4 cells are lysed, but LCMV-infected F–9 cells are evidently not damaged by virus-immune lymphocytes (Fig. 2). Repeated experiments with the PCC4 targets gave extremely variable results (from 21% to 90% of the virus-specific ^{51}Cr release found for MC57G) and, although the two series of observations have not yet been made concurrently, the extent of H–2 antigen expression on PCC4 cells may also vary considerably (from 14% to 56%). The limiting factor in virus-specific T cell-mediated immunity would thus seem to be H–2 gene expression in the target cell. This is in accord with the observation that blocking of tumour-specific effector T cells may be achieved by treating the targets (but not the lymphocytes) with anti-H–2 serum[8,9], and with previous experiments using trinitrophenyl (TNP)-modified F–9 cells[10].

Exposure of the cell membrane to TNP might be thought to induce direct alteration of the H–2 antigen, which would obviously not occur if the antigen is absent. However, infectious virus which

Table 1 Presence of serologically-detectable H–2 antigens

Target cells	Mouse strain and H–2 type	% Positive by immunofluorescence			
		anti-H–2K^b (33, 53, 54)	anti-H–2D^b (2, 28, 59, 56)	anti-H–2D^b (2, 56)	Normal C57BL
F–9	129, H–2^{bc}	< 1	< 1	5	4
PCC4	129, H–2^{bc}	42	16	30	2
MC57G	C57BL, H–2^b	98	ND	91	4
Spleen	129, H–2^{bc}	96	99	ND	32*
Spleen	C3H, H–2^k	27*	32*	ND	33*

Mouse alloantisera 33, 28b and D–2, reactive to the H–2 specificities shown above in parentheses, were supplied by the Transplantation and Immunology Branch, National Institute of Allergy and Infectious Diseases, NIH. Fluorescent rabbit IgG specific for mouse IgG heavy and light chains were purchased from Cappel Laboratories, Downington, Pennsylvania. All sera were used at a dilution of 1:10.

* Reactivity is due to Ig-bearing B cells and antibody-forming cells in the spleen population.

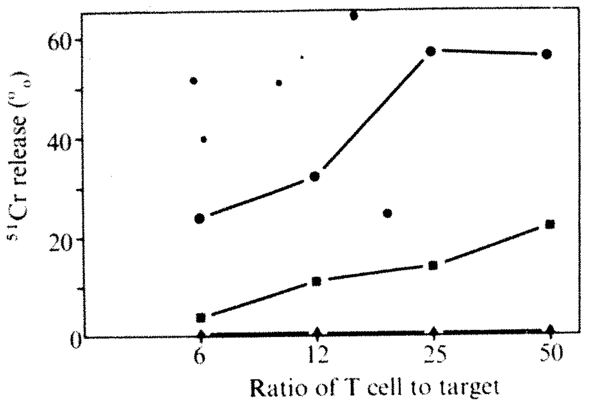

Fig. 2 The extent of specific lysis of virus-infected target cells by virus-immune effector T cells from C57BL mice injected with 1,000 LD_{50} of WE3 LCMV 8 d previously. The assays[16] were incubated for 16 h at 37 °C.

has been introduced to the cell at a relatively low multiplicity (5 LD_{50} per cell 48 h before assay), could potentially modify cell-surface structure in other ways. Perhaps the process of virus growth causes derepression of cryptic genes within the H-2 complex, and the "virus-immune" T-cell response is directed solely against abnormally expressed H-2 antigen[11]. Alternatively some "interaction antigen"[12,13] may be formed, which is partly coded for by H-2 genes and partly by the viral genome. Apparently neither of these mechanisms, which could conceivably be independent of phenotypic expression of normal H-2 antigen, operates in the virus-infected F-9 cell or is obviously relevant to the variability observed with PCC4. Perhaps the necessary genes have been deleted from the F-9 tumour, although these cells express a closely-linked gene product which may be the embryonic equivalent of H-2 (ref. 14).

Use of this experimental system also establishes that absence of H-2K or H-2D cell-surface antigens in no way facilitates lysis mediated by virus-immune T cells (differing in H-2 specificity) (Table 2). It seems likely therefore that the presence of foreign H-2K or H-2D determinants does not inhibit lymphocyte function. Occurence of virus-specific cell-mediated immunity apparently depends on recognition by the lymphocyte of some cell membrane component coded for by the H-2 gene complex. The possibility that H-2K and H-2D antigens function as "self-markers" in cell-mediated immunity[4] must be considered.

Table 2 Absence of H-2 does not facilitate lysis of different H-2 specificity by virus-immune T cells

Immune spleen	% ^{51}Cr release from virus-infected targets		
	MC57G	F-9	B10.A
B10 ($H-2^b$)	39	0	5
B10.A ($H-2^a$)	0	1	78
CBA/J ($H-2^k$)	0	0	25

Mice were injected with 1,000 LD_{50} of WE3 LCMV 8 d previously, and spleen cells and targets were mixed in a ratio of 30:1 (ref. 16). The B10.A and CBA/J mouse strains share $H-2K^k$ antigenic specificities. The B10.A target cells were peritoneal macrophages.

A recombinant in the major histocompatibility complex of the rat

WE report here a recombinant in the major histocompatibility complex (MHC) of the rat, and describe the properties of alloantisera directed at the recombined portions of one haplotype. The results are compatible with a structure for the rat MHC more closely resembling that of man than that of the mouse.

The inbred rat strains used were HO(PVG/c) (AgB5 = $H-1^c$), DA(AgB4 = $H-1^a$) and AO (AgB2 = $H-1^u$). An historical accident has led to the use of two parallel nomenclatures for the rat MHC. We use the AgB terminology of Palm[1] without prejudice to a future reconciliation with the Rat H-1 terminology of Stark *et al.*[2]

The recombinant was discovered among progeny of the backcross HO ♂ × (DA × HO)F_1 ♀. The progeny were screened with three tests defining the segregating AgB4 allele:

(1) For the presence or absence of AgB4 alloantigens on the surface of their blood lymphocytes recognised by the alloantiserum (AO × HO)F_1 anti-DA in a one-stage cytotoxic test assayed by Trypan blue exclusion.
(2) For the ability or inability of their blood lymphocytes to stimulate HO thoracic duct lymphocytes (TDL) in a mixed lymphocyte interaction (MLI).
(3) For the ability or inability of their blood lymphocytes to respond in an MLI against (DA × HO)F_1 spleen cells.

The three tests gave highly concordant results on HO × (DA × HO)F_1 backcross progeny, indicating that all three tests defined a single genetic system (Table 1). One rat showed aberrant behaviour in that her cells, although killed by (AO × HO)F_1 anti-DA serum, responded to (DA × HO)F_1 spleen cells in MLI and did not noticeably stimulate HO TDL. This rat was backcrossed to the HO strain. Of her two litters, 8 out of 21 rats carried serological determinants recognised by (AO × HO)F_1 anti-DA serum, eliminating the slight possibility that the positive result in the serological test of the mother was caused by a rare co-segregation of several minor antigens recognised by the serum. The reactions in the three screening assays of one serologically positive member of these litters are shown in Table 1. The putative recombinant haplotype and tissue will provisionally be called 1R.

The next experiments showed that antigenic products of both the regions of AgB recombined in the 1R chromosome were serologically recognisable, but differed markedly in tissue distribution. First, (AO × HO)F_1 anti-DA serum was absorbed with 1R lymphoid tissue. DA lymphoid tissue absorbed all activity from the serum, whereas even a massive amount of 1R tissue absorbed the serum partly but not completely (Fig. 1*a*). As all the detectable activity of (AO × HO)F_1 anti-DA was directed against AgB4 (Table 1), the absorption result implies that the 1R haplotype carries some serologically detectable AgB4 alloantigens, but lacks others.

Suitable genetic combinations were therefore chosen to raise separate alloantisera against the two adjacent portions of AgB4. (1R × HO) heterozygotes were immunised against DA, and (AO × HO)F_1 rats against (1R × HO) heterozygous lymphoid tissue. In a lymphocytotoxic test the (AO × HO)F_1 anti-1R serum killed all lymphocytes in blood, lymph nodes and

E	4.65 (0.03)	3.22 (0.16)
F	4.22 (0.08)	2.17 (0.11)

Lymphocytotoxic tests were performed in a total volume of 75 μl, containing 5×10^4 target cells and guinea pig serum at a final concentration of 8–11% (v/v). The suspension medium was Dulbecco's A and B salts supplemented with 2% foetal calf serum. Percentage cell lysis was determined by Trypan blue exclusion, more than 270 cells being counted in each test. The complement control lacked any antiserum. Mixed lymphocyte cultures contained 2×10^5 responding cells and 3×10^5 stimulating spleen cells (irradiated with 950 rad of 16 MeV X rays), in RPMI medium supplemented with 5% rat serum and 2.5×10^{-5} M 2-mercaptoethanol in a total volume of 0.2 ml in round-bottomed microtitre plates. Methyltritiated thymidine (16 Ci mmol^{-1}; 0.1 μCi in 10 μl) was added at 90–100 h and cells were collected about 16 h later. For MLI responses to (DA × HO)F_1 spleen, responding lymphocyte populations were prepared from cardiac blood by Ficoll-Isopaque separation[3]. Spleen cells were used to stimulate HO thoracic duct lymphocytes. Mixed lymphocyte responses are expressed as the log$_{10}$ geometric mean c.p.m. of at least three replicate cultures. The standard deviation from the log$_{10}$ geometric mean c.p.m. in replicate cultures is in the first parentheses after the response. In the second parentheses, A–F are names for the experiments for which the response controls and syngeneic controls are given below the main body of the table; in A–C the response control is the response of HO blood lymphocytes to (DA × HO)F_1 spleen; in D–F the response control is the response of HO thoracic duct lymphocytes to (DA × HO)F_1 spleen.

*The results for 1R heterozygote were obtained with one of the original recombinant's second litter by an HO male.

thoracic duct of rats carrying AgB4 (Fig. 1*b*). It was also strongly and specifically lytic for red cells of such rats. The target antigen(s) on both red cells and lymphocytes is AgB-linked as established through five backcross generations of both AgB4 and the 1R haplotype on to the HO background. The target(s) for this antiserum seems therefore to be analogous to the mouse H-2K and H-2D molecules, which are also expressed on both lymphocytes and erythrocytes[4,5].

The (1R × HO) anti-DA serum was considerably different. Although of high titre, it killed only 30–40% of normal lymphocytes (Fig. 1*b*), and was not detectably haemolytic. Furthermore, it seemed that the target for this antiserum was restricted to B lymphocytes. Using lymphocytes collected from the thoracic duct of a thymectomised, irradiated, bone-marrow reconstituted 'B' rat[6] of the DA strain it was found that > 90% of 'B' TDL were killed by (1R × HO) anti-DA serum while only 35–40% of normal TDL were killed in the same test (Fig. 1*b*). Similarly, the (AO × HO)F_1 anti-DA serum absorbed exhaustively with 1R lymphoid tissue killed about 90% of 'B' TDL compared with 35–40% of normal TDL (Fig. 1*a*). (1R × HO) anti-DA serum is thus analogous to some mouse anti-Ia sera in the apparent absence of the target antigens from erythrocytes and from T cells[7,8]. It was necessary to demonstrate that the targets of (1R × HO) anti-DA and (AO × HO)F_1 anti-1R are controlled by linked portions of AgB. For this purpose we returned to the progeny of the HO × (DA × HO)F_1 backcross amongst which the putative recombinant was found. The two antisera were tested on blood lymphocytes of a panel of these rats whose AgB status had already been established. There was complete positive correlation of the activity of the two antisera and both detected antigens of AgB4 (Table 2). Thus (1R × HO) anti-DA and (AO × HO)F_1 anti-1R are directed at antigens controlled by different segments of a single genetic system.

The recombinant haplotype, 1R, has inherited its major serological antigens (analogous to the mouse K and D molecules) from the AgB4 of DA, and lacks antigen(s) of AgB4 seemingly analogous to mouse Ia antigens. It has also inherited its MLI phenotype principally from AgB5, the (1R × HO)

Table 2 Genetic linkage test for the targets of (AO × HO)F_1 anti-1R and (1R × HO) anti-DA using a panel of HO × (DA × HO)F_1 backcross progeny

Rat	AgB4	Complement control (% cells dead)	% cells killed by (1R × HO) anti-DA		% cells killed by (AO × HO) anti-1R	
			1/6	1/24	1/6	1/192
(DA × HO)F_1	+	6.1	ND	23.0	ND	92.1
26	+	7.8	ND	27.7	ND	96.9
30	+	4.2	ND	28.2	ND	94.6
42	+	8.0	ND	23.0	ND	94.4
44	+	11.4	ND	25.2	ND	93.5
45	+	5.5	ND	20.6	ND	93.6
46	+	4.4	ND	20.6	ND	95.3
33	—	7.5	7.3	6.7	5.6	4.9
35	—	11.8	9.9	7.1	8.6	11.1
36	—	3.7	3.5	2.3	3.2	5.1
37	—	7.3	5.5	7.5	6.5	6.9
43	—	5.0	6.9	2.5	5.5	6.6

The AgB status of each of these animals was determined by both serological and MLI tests, as described in Table 1. Lymphocytotoxic scores are based on a sample of > 300 cells. ND, not determined.

Table 3 MLI responses of HO and (1R × HO) heterozygote TDL to (DA × HO)F_1 spleen

Responder TDL (2×10^5)	Stimulator spleen cells (3×10^5)	Response
HO	HO (syngeneic control)	2.58 (0.02)
	(1R × HO) heterozygote*	2.47 (0.08)
	(DA × HO)F_1	4.73 (0.03)
(1R × HO) heterozygote*	HO	2.66 (0.03)
	(1R × HO) heterozygote (syngeneic control)	2.46 (0.05)
	(DA × HO)F_1	4.72 (0.04)

MLI Response data is presented as in Table 1.
*The (1R × HO) heterozygotes used in this experiment were offspring of the original recombinant, previously shown to be carrying DA serological determinants by positive reaction with (AO × HO)F_1 anti-DA serum.

heterozygote behaving just like HO in this experiment (Tables 1 and 3). Five backcrosses of the 1R haplotype on to the HO background have now been completed.

The analysis of this recombinant demonstrates that the region of AgB controlling the MLI and Ia-like antigens can be recombined by a single cross over from the region controlling cell-surface alloantigens of wide tissue distribution analogous to the K and D molecules of the mouse. The properties of the recombinants described by Williams and Moore[9], of the KGH rat strain investigated by Gill and co-workers[10,11] and of the AgB haplotype derived from a wild rat by Gasser[12] support this view. Although the existence of more than one K/D-like locus has not been demonstrated in the rat, it seems that the linear order of genes in AgB is not like that in the H-2 of the mouse, where the D and K loci flank the region controlling the MLI and Ia antigens. The rat may fit better the model established for the human MHC[12]. Indeed, the present study further emphasises the conclusion derived from other more distant mammalian species including man[13], that the gene order in the mouse MHC is exceptional, presumably as a result of a chromosome rearrangement which can now be placed as more recent than the divergence of the mouse and the rat from their common ancestor. We consider, however, that our conclusion on the structure of the rat MHC is still preliminary. Confirmation from other more informative laboratory recombinants is awaited, because special circumstances such as the undetected sharing of a second K/D-like chromosome region by the AgB4 and AgB5 haplotypes could invalidate the conclusion.

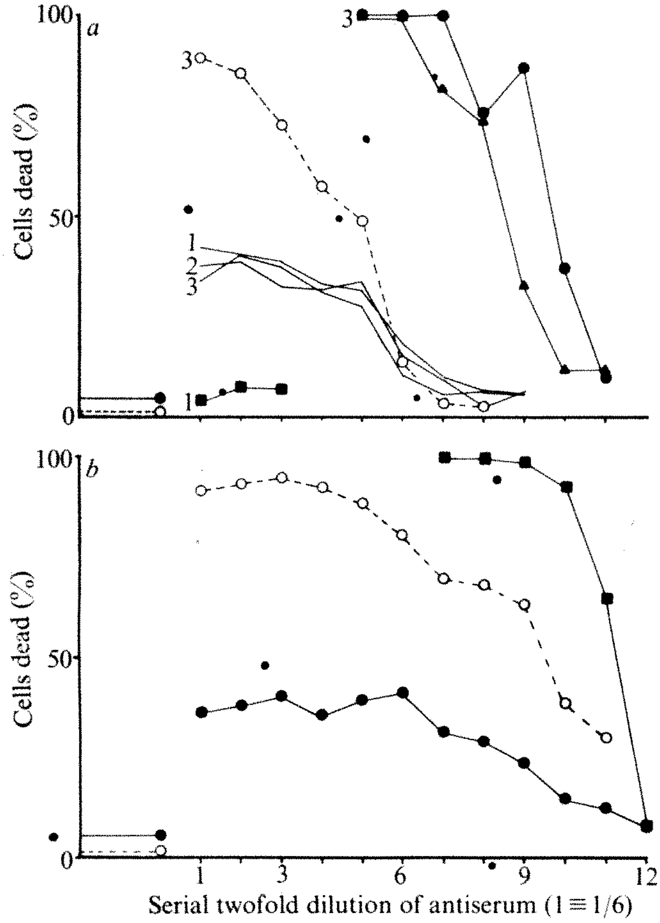

Fig. 1 Titrations of cytotoxic antisera against DA lymphoid cells (methods as in Table 1). *a*, (AO × HO)F_1 anti-DA absorbed with 1R lymphoid tissue. (●———●), (AO × HO) anti-DA tested on DA lymph node cells: (———), (AO × HO) anti-DA absorbed with 1R tested on DA lymph node cells. 1, 2, 3 are successive stages in the absorption. At each stage more than 700×10^6 lymphocytes were used per ml of antiserum; (○— — —○), (AO × HO) anti-DA absorbed with 1R at stage 3 of absorption, tested on 'B' DA TDL; (■———■), (AO × HO) anti-DA absorbed with DA at stage 1; (▲———▲), control absorption with HO at stage 3; (———●), complement control for DA lymph node cells; (— — —○) complement control for 'B' DA TDL. *b*, Recombinant antisera tested on DA TDL. (■———■), (AO × HO)F_1 anti-1R on normal DA TDL; (●———●), (1R × HO) anti-DA on normal DA TDL; (○———○), (1R × HO) anti-DA on 'B' DA TDL. Complement controls as in (*a*).

We thank Diana Suckling for technical assistance, Mr R. C. Bennett for animal care and Mrs J. A. Williams for typing the manuscript. G. W. B. holds an MRC studentship.

Note added in proof: A recombination between AgB4 and AgB2 (H−1^a and H−1^w) has recently been found[15]. This recombinant seems to have similar properties to that we have described.

A surface antigenic marker for rat Schwann cells

THE use of cell-surface antigenic markers to identify and separate distinct subpopulations of lymphocytes has revolutionised immunology in recent years. It seems likely that a similar approach will be fruitful in other areas of biology. For example, recent advances in maintaining and studying cells of the nervous system *in vitro* have created a pressing need for cell-type-specific markers. These would allow unequivocal identification and possible purification of the many different types of neural cells so that their interactions can be studied in culture. Here we describe a cell-surface antigen, defined by an antiserum raised in mice against a rat neural tumour cell line[1] which is present on Schwann cells in dissociated cell culture of neonatal rat sciatic nerve, but not on fibroblasts in the same culture. Another cell-surface antigen, Thy-1.1 (formerly called θAKR)[2] is expressed by the fibroblasts[3] and not the Schwann cells, making it possible to mark both cell types simultaneously in these cultures by using antibodies conjugated to two different fluorochromes.

The mouse antiserum was raised against a cell line (33B) derived from an ethylnitrosourea-induced tumour arising in the spinal cord and nerve roots of a Wistar–Furth (W/Fu) rat[1]. After extensive adsorption with rat liver, spleen and thymus, the original serum defined two surface antigens detected by cytotoxicity testing: (1) a 'common antigen' present in rat brain, embryonic tissues and most tumours or cell lines from the rat nervous system (including Schwannomas, gliomas and neuroblastomas) and (2) a 'restricted antigen' present on a minority of nervous system tumours and cell lines and not detectable in normal or embryonic rat tissues[1]. For the studies described here, we used an antiserum, raised in A/strong mice[4], with cytotoxic activity at least 80% specific for the common antigen. After the usual tissue adsorptions, it was further adsorbed twice with half its volume of packed cells obtained from primary muscle cultures of neonatal W/Fu rats. The antigen detected by immunofluorescence on Schwann cells has a similar distribution on tumour cell lines to that of the common antigen (see below). The exact identity of the Schwann cell antigen and the common antigen is, however, not yet completely established. We shall therefore refer to the antigen detected on Schwann cells as rat neural antigen-1 (Ran-1).

Table 1 Indirect immunofluorescence labelling of Schwann cells and fibroblasts in rat sciatic nerve cultures with anti-Ran-1 and anti-Thy-1 antiserum

Antiserum	Adsorbed with	Labelling of Schwann cells	Labelling of Fibroblasts
Mouse anti-Thy-1.1	—	0	+
Mouse anti-Thy-1.1	CBA (Thy-1.2) brain	0	+
Mouse anti-Thy-1.1	AKR (Thy-1.1) brain	0	0
Rabbit anti-Thy-1	—	0	+
Rabbit anti-Thy-1	Rat (W/Fu) thymocytes	0	0
Mouse anti-Ran-1	—	+	0
Mouse anti-Ran-1	Rat neural tumour line 33B	0	0
Mouse anti-Ran-1	Rat neural tumour line 21A	0	0
Mouse anti-Ran-1	Rat neural tumour line B28	+	0
Mouse anti-Ran-1	Rat foetus	0	0
Mouse anti-Ran-1	Rat liver	+	0

Cells were labelled with mouse anti-Thy-1.1 (1:5) or mouse anti-Ran-1 (1:50) and then G anti-MIg-Rd (1.20), or with rabbit anti-Thy-1 (1:20) and mouse anti-Ran-1 (1:50) simultaneously, followed by F(ab)$_2$ G anti-RIg-Fl (1:10) and G anti-MIg-Rd (1:20) applied simultaneously.

Anti-Thy-1.1 alloantiserum was raised in CBA mice against AKR thymocytes as described before[5]; in indirect immunofluorescence assays it labelled AKR and rat thymocytes but not CBA thymocytes, and all of this activity could be adsorbed by brain from AKR but not from CBA mice. Rabbit anti-Thy-1 antiserum was raised by immunising rabbits with rat brain glycoproteins (obtained after lentil lectin affinity chromatography) and boosting with purified Thy-1 5 months later[6]. It was adsorbed twice with 50% (v/v) packed rat spleen cells and twice with 50% (v/v) packed neonatal rat brain homogenate (both of which are known[7,8] to contain relatively little Thy-1). For indirect immunofluorescence assays, rhodamine-conjugated goat anti-mouse IgG (G anti-MIg-Rd) and fluorescein-conjugated goat anti-rabbit IgG (G anti-RIg-Fl) antibodies Nordic batch no. 2–773 and 27–175, respectively) were used. In most experiments, the F(ab)$_2$ fragments of these conjugates were used. They were prepared by dialysing the undigested reagents in 0.1 M acetate *p*H 4.5 and incubating them with 2% (w/w) pepsin (Sigma) for 12 h at 37 C, dialysing in phosphate buffered saline and passing them through an XM50 Amicon filter to remove the Fc fragments. All antisera were centrifuged at 100,000*g* for 30 min before use, and for double labelling experiments the G-anti-MIg-Rd was adsorbed with rabbit IgG and the G anti-RIg-Fl with mouse IgG. The rabbit and mouse IgG were coupled to Sepharose 6B.

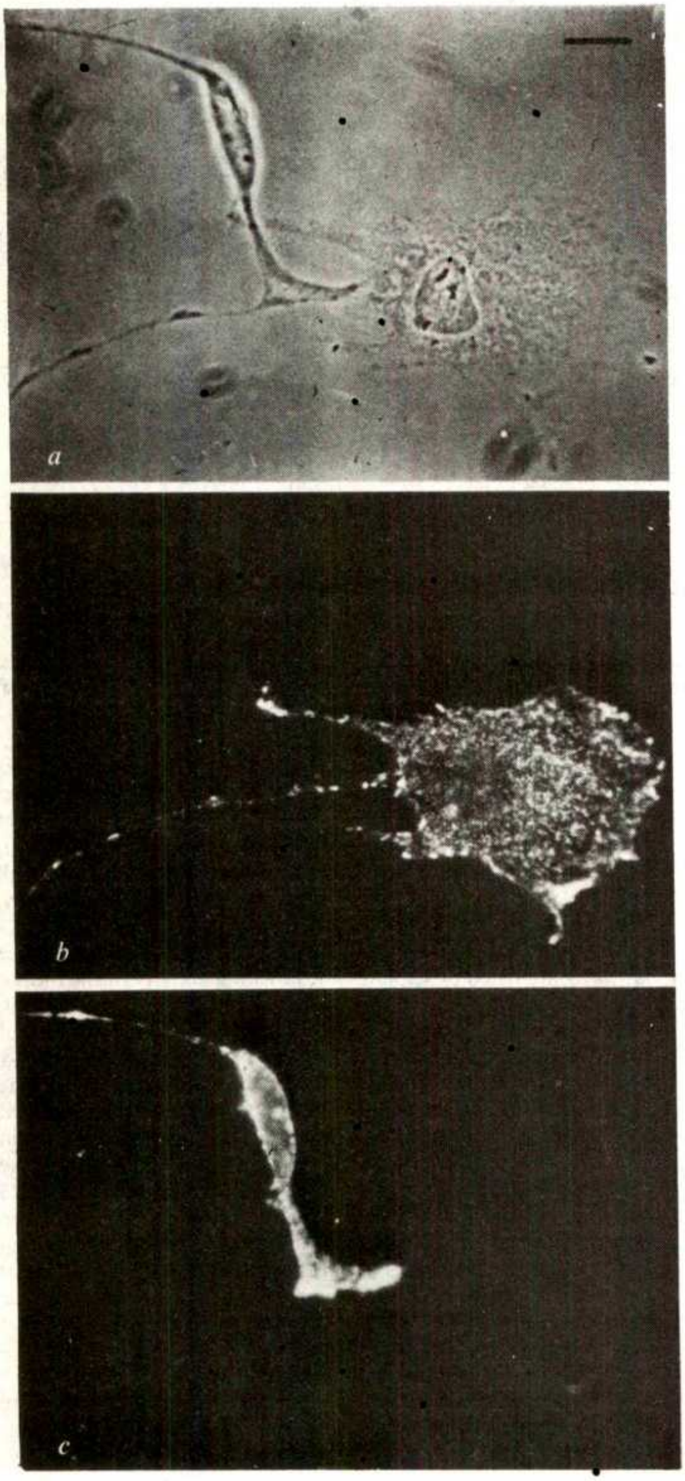
Sciatic nerves were removed aseptically from neonatal W/Fu rats, digested with trypsin and collagenase, and dissociated by passage through a No. 23 hypodermic needle. The cells were grown on collagen-coated glass coverslips in Linbro dishes (Flow Labs.) in Dulbecco's modified Eagle's medium, containing penicillin (100 IU per ml), streptomycin (100 μg ml^{-1}), 10% heat inactivated foetal calf serum and 2% chick embryo extract. A full account of this procedure will be published elsewhere. After 3–5 d of culture, the cells on the coverslips were incubated in anti-Ran-1 or anti-Thy-1 antisera for 30 min at room temperature, washed well and incubated with the appropriate fluorescent anti-Ig antibodies for a further 30 min at room temperature. After washing, the cells were fixed in 5% glacial acetic acid in 95% ethanol at 4 °C for 10 min, mounted in Elvanol on a glass slide and examined using a Zeiss fluorescence microscope equipped with phase contrast and incidence fluorescence optics.

In 3-d-old cultures, the majority of cells had a bipolar morphology characteristic of Schwann cells in culture[9] with a tendency to line up end-to-end; by 5 d the long processes of these cells tended to form interconnected networks. The other cells in the culture had the appearance of fibroblasts; initially sparse, they tended to proliferate and form a confluent underlayer by 7 d. Every one of the characteristic bipolar Schwann cells was brightly labelled by the anti-Ran-1 serum and did not label with the mouse or rabbit anti-Thy-1 antiserum. On the other hand, all of the typical fibroblasts were labelled by both of the anti-Thy-1 sera, and not by the anti-Ran-1 serum. In all cultures, there were cells with an intermediate morphology, which stained as typical Schwann cells.

The controls for the specificity of the immunofluorescence labelling are listed in Table 1. The labelling activity of the mouse anti-Thy-1.1 antiserum was removed by adsorption with AKR but not CBA brain, confirming the Thy-1.1 specificity of the antiserum. The labelling activity of the rabbit anti-Thy-1 serum was removed by adsorption with rat thymocytes. The labelling of Schwann cells by anti-Ran-1 could be removed by adsorption with cell line 33B, which has both the common and the restricted antigen, or by line 21A, which has the common antigen but lacks the restricted antigen. Line B28 (derived by D. Schubert at the Salk Institute from a brain tumour) lacks both antigens and does not adsorb the Schwann cell labelling. Adsorptions with rat brain, which contains less of the antigen than the tumour lines or rat foetus, have thus far been inconclusive. With this reservation, these data suggest that the immunofluorescent labelling of Schwann cells is detecting the common antigen.

To prove that the anti-Ran-1 and anti-Thy-1 antisera were not labelling the same cells, cultures were exposed to rabbit anti-Thy-1 and mouse anti-Ran-1 antisera simultaneously, washed and then incubated in G-anti-RIg-Fl and G anti-MIg-Rd simultaneously; after washing, the cells were examined for fluorescein and rhodamine fluorescence. In most cultures, all cells labelled with one or other fluorochrome but not both (Fig. 1; also see cover). In an occasional culture, a small proportion (< 5%) of the cells were labelled with both fluorochromes; these cells had a distinctive round morphology and were also doubly labelled when normal mouse and rabbit sera were used in the first incubation in place of the antisera. They could be damaged cells or macrophages.

Fig. 1 Indirect immunofluorescence using antibodies against Thy-1 and Ran-1. Cells from sciatic nerve cultures were stained with a mixture of rabbit anti-Thy-1 and mouse anti-Ran-1, followed by a second incubation with $(Fab)_2$ G-anti-RIg-fluorescein and $F(ab)_2$ G anti-MIg-rhodamine, as described in the text. A pair of cells was photographed with phase optics (a) or ultraviolet illumination and filters to detect the fluorescein (anti-Thy-1)-labelled fibroblast (*b*), or filters to detect the rhodamine (anti-Ran-1)-labelled Schwann cell (*c*) Scale bar, 10 μm.



In preliminary experiments, the double labelling method has been used to investigate cell division in the two populations. Two-day cultures were incubated with ^{3}H-thymidine for 24 h, stained with the two fluorochromes, and coated with emulsion for conventional light microscope autoradiography. Whereas approximately 90% of the Thy-1 positive cells had labelled nuclei, only 20% of the Ran-1 positive cells had them. The latter result is comparable with that obtained in neonatal mouse sciatic nerve *in vivo*[10]. This method should be useful in the search for possible Schwann cell mitogens.

We conclude from these studies that in dissociated cell cultures of newborn rat sciatic nerve it is possible to distinguish Schwann cells from fibroblasts by means of surface antigenic markers: the Schwann cells express the previously described[1] Ran-1 but not detectable amounts of Thy-1, while fibroblasts do not express detectable amounts of Ran-1 but do express Thy-1. Although the Thy-1 positive cells had a typical fibroblastic morphology, it is possible that this category may include other cell types. Thus, endothelial cells are present in peripheral nerve[10,11] and they have not been typed for the presence of Thy-1. The identity of the Ran-1 positive cells with intermediate morphology is not seriously in doubt. Studies in culture with time-lapse cinematography[12] have shown that bipolar Schwann cells may undergo a morphological transition to a fibroblast-like form. Although the detailed distribution of Ran-1 in the nervous system is not known, it is not detectable by immunofluorescence on any major class of cells in dissociated cultures of cerebellum or cerebral hemispheres (unpublished observations of K.L.F); thus it is not a general glial marker. It will be of interest to compare the characteristics of this antigen and the recently described surface antigen on human Schwann cells[13].

Since the fibroblasts[3], but not Schwann cells, can be killed by anti-Thy-1 and complement (unpublished observations) it should be possible to remove the fibroblasts from sciatic nerve cultures; alternatively, the Schwann cells could be positively selected by the use of a fluorescence activated cell sorter[14]. In either case, the availability of surface markers for both cell types should prove useful in studies of myelination *in vitro*, and of other interactions with nerve[15] and muscle[16]. Moreover, the availability of one neural cell marker should facilitate the search for others.

We thank Dr A. F. Williams for the gift of rabbit anti-Thy-1 antiserum, Dr P. K. Thomas for helpful discussions, and Ann Hornby-Smith, Carolyn Haresign and Janet Winter for technical assistance. We also thank Dr B. Gamperts for assistance with colour printing.

Developmentally regulated lectin in neonatal rat brain

WE report the identification of a developmentally regulated agglutinin of erythrocytes present in neonatal rat brain. Specific inhibition by a number of saccharides with a galactose configuration suggest that multivalent carbohydrate-binding proteins, 'endogenous brain lectins', may be responsible for the observed agglutination activity. We are presently investigating the functional role of this lectin-like activity in brain, since molecules with similar carbohydrate-binding properties seem likely to mediate intercellular recognition and adhesion in certain lower eukaryotic organisms.

The ability of cells to recognise other cells and specifically adhere to them is a central problem in developmental neurobiology and the subject of intense investigation. Moscona[1], more than a decade ago, proposed that specific macromolecules at the cell surface are responsible for specific adhesion. Specific cell recognition and adhesion could then be achieved by a cell-surface macromolecule, a carbohydrate-binding protein[2] or an enzyme[3] with a particular recognition specificity, and a carbohydrate-containing receptor, one or both of which is under a temporal metabolic regulation. The lectin hypothesis of cell recognition and adhesion[2] has gained support in recent studies[4–8] with the cellular slime moulds (for review, see ref. 9). Developmentally regulated carbohydrate-binding proteins, "discoidin"[4] and "pallidin"[6] accumulate on the cell surface of *Dictyostelium discoideum* and *Polysphondylium pallidum* as these species differentiate from a vegetative single cell state to a cohesive aggregation-competent state, and substantial evidence[2,4–8] indicates that these slime mould lectins may mediate intercellular recognition and adhesion by interacting with specific cell-surface receptors[7]. Teichberg *et al.*[10] reported the presence of a β-D-galactoside-binding protein in *Electrophorus electricus* and in a number of mammalian tissues and tissue culture cells, and Nowak *et al.*[11], and Gartner and Podleski[12], have studied a β-D-galactoside binding protein in embryonic chick muscle and myogenic cell lines, a protein, purified and characterised by Den and Malinzak[13].

The functional components of intercellular recognition and adhesion are generally thought to be glycoproteins[14] and in brain tissue in particular, the synaptic specialisation is enriched by carbohydrate-containing macromolecules which may function in synaptogenesis[14,15], in conjunction with carbohydrate-binding molecules of appropriate specificity.

Soluble extracts of developing neonatal rat brain contain a 'lectin-like' agglutination activity which is measured with trypsinised glutaraldehyde-fixed rabbit erythrocytes. In brain extracts prepared from 1–30-d-old rats (Fig. 1) a marked increase in agglutination activity was observed from day 1–10, followed by a decline to undetectable levels between 10 and 21 d. Only trace amounts of activity were found in adult animals. The time course seen in Fig. 1 was reproduced with different sets of brain extracts, and different preparations of rabbit erythrocytes, although the absolute value of the titre varied somewhat with the particular preparation of erythrocytes. Variable agglutinability of erythrocyte preparations could result from individual donor differences or from minor variations in the conditions of trypsinisation or glutaraldehyde fixation. Specific agglutination activity—that is, agglutination activity per mg protein—parallels the curve seen in Fig. 1. The possibility that the observed time course was a function of changes in the extracting reagent (DES) or in the agglutinability of the erythrocyte preparation over the time course of the study was eliminated by preparing extracts at the individual time points, freezing and assaying them together on the same day, or by simultaneously preparing extracts of animals at various ages and assaying on the same day. Mixing experiments in which day 1 and 10 extracts and day 10 and 30 extracts were mixed, incubated and assayed, gave intermediate values suggesting that enzymatic modification in crude soluble extracts was not responsible for the ascending or descending portions of the time course. No agglutination was observed when serum from 10-d-old rats was tested for this activity.

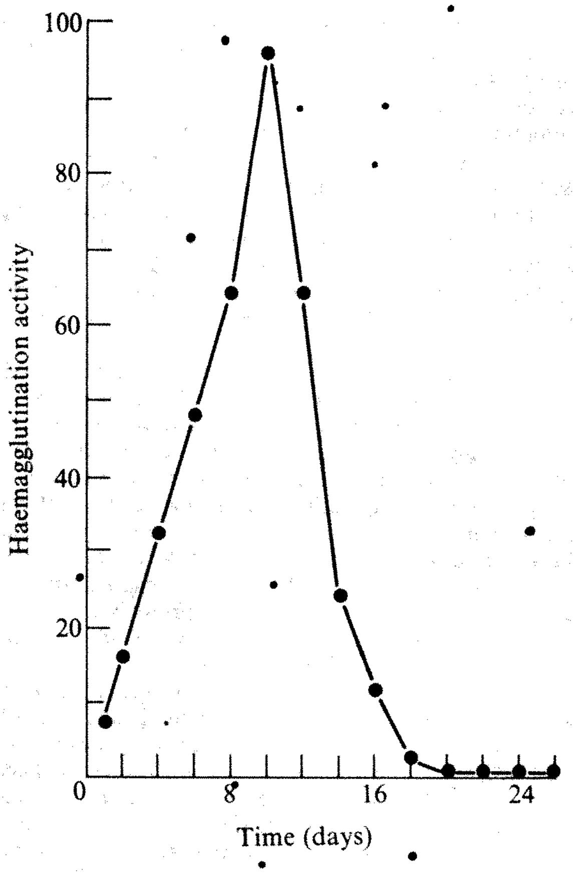

Fig. 1 Sprague–Dawley pups from litters normalised to eight pups per mother at birth, to ensure that all had equal and sufficient nutrition, were killed by decapitation. Brains were homogenised at 4 °C in 4 volumes of freshly prepared 2 mM dithiothreitol, 2 mM EDTA, 0.15 M NaCl, abbreviated DES, in a Potter–Elvejhem tissue homogeniser. Dithiothreitol at 10 mM did not improve the extractability of activity but served to stabilise the activity extracted. The homogenate was centrifuged 60 min at 40,000 r.p.m. and the supernatant assayed for agglutination activity using trypsinised glutaraldehyde-fixed rabbit erythrocytes. Erythrocytes for agglutination assays were prepared from rabbit blood (Colorado Serum Labs) collected in Alsever's solution. Cells were washed 4 times with 5 volumes saline. Erythrocytes were suspended 4% (v/v) in 0.1 M sodium phosphate–0.05 M NaCl, *p*H 7.4, and trypsin from bovine pancreas (Sigma) 0.1 mg ml, was added, and the suspension incubated at 37 °C for 60 min. Cells were then washed 5 times with 10 volumes saline. Washed erythrocytes were suspended in 5 volumes 0.075 M Na, K phosphate–0.075 M NaCl, *p*H 7.2 (PBS 7.2), containing 1% glutaraldehyde (Sigma, grade I), and incubated with shaking for 1 h at room temperature. The cross-linking reaction was terminated by addition of 5 volumes 0.1 M glycine in PBS 7.2 at 4 °C. Erythrocytes were sedimented and washed 3 times with 5 volumes 0.1 M glycine in PBS 7.2. Finally, cells were washed 4 times in 5 volumes cold PBS 7.2. Agglutination activity in brain extracts was measured with trypsinised glutaraldehyde-fixed rabbit erythrocytes as follows. A twofold dilution series of brain extract was made in DES. Either 25 μl PBS 7.2 or 25 μl an appropriate hapten inhibitor in PBS 7.2 was added to wells of a microtitre *V* plate (Cooke Engineering). Aliquots (25 μl), of the serial dilutions of extract were added to wells followed by 25 μl 1% solution bovine serum albumin in 0.15 M NaCl. After gentle mixing, 25 μl of a 2.5% suspension of erythrocytes in PBS 7.2 was added to wells. Plates were shaken vigorously, covered with transparent tape, and left at room temperature for 90 min before agglutination patterns were evaluated. The agglutination endpoint was taken as the first dilution of extract at which erythrocytes settled into a clearly circumscribed dot at the bottom of the well. Agglutination activity is defined as the reciprocal of the endpoint dilution.

A number of other types of erythrocytes were tested for their ability to calibrate agglutination activity. Fresh rabbit erythrocytes were not agglutinable, nor did trypsinisation of fresh erythrocytes render them agglutinable. Fixation with glutaraldehyde or formalin was required to sensitise the rabbit cells to agglutination, whereas trypsinisation before fixation gave 50% higher titres suggesting that such treatment, although insufficient in itself, does increase the agglutinability of fixed cells. Trypsinised formalin-fixed rabbit erythrocytes and trypsinised glutaraldehyde-fixed or formalin-fixed sheep erythrocytes were four times less sensitive to agglutination than the trypsinised glutaraldehyde-fixed rabbit erythrocytes, whereas formalin-treated human type O erythrocytes were eleven times less sensitive.

Agglutination activity of 10-d-old rats was specifically inhibited by a number of monosaccharides and disaccharides with a galactose configuration, in addition to hexosamines, mannose, and a brain glycopeptide fraction[16], as seen in Table 1. This non-dialisable glycopeptide fraction was found to be the most potent inhibitor of agglutination, being nearly 150 times greater on a molar basis than the most effective monosaccharide inhibitor, galactosamine. The glycopeptide fraction, with an average molecular weight of 8,000, was prepared from lipid-extracted whole brain by extensive proteolytic digestion, followed by quantitative precipitation of contaminating glycosaminoglycans with cetylpyridinium chloride[16]. The potent inhibition by hexosamines is interesting in view of the report by Yamada *et al.*[17], that the CSP protein or LETS protein, an agglutinin of formalin fixed erythrocytes, which has been identified as a surface antigen in cultured glial cells[18], was also inhibited by hexosamines. Careful re-examination of the hexosamine inhibition in brain extracts by measuring hexosamine inhibition at various amino sugar concentrations in parallel with equimolar concentrations of NaCl, suggested that the inhibition at high concentrations was predominantly a charge effect, whereas studies at lower hexosamine concentrations revealed a galactosamine-specific inhibition. Agglutination by the brain extract is probably not due to LETS protein since EDTA or EGTA, potent inhibitors of the LETS mediated agglutination[17], were not potent inhibitors of the brain activity. Nevertheless, we cannot absolutely rule out the possibility that the brain activity, in part, is LETS mediated, since a different cell type was used to test agglutination by purified LETS protein. An accurate comparison to the hapten inhibition specificity of the LETS protein, awaits purification of the brain agglutinin.

Although the sugar concentrations required to inhibit agglutination by brain extracts are relatively high, unlike those of many lectins derived from plant sources, a number of lectins do require concentrations in this range. The carbohydrate specificity, although generally galactose specific, is not absolute suggesting that several carbohydrate-binding proteins with distinct specificities may be present in crude extracts from 10-d-old rats.

Table 1 Glycopeptide and sugar effects on agglutination of erythrocytes by brain extracts

Sugar concentrations (mM) that inhibit agglutination by 50%			
Brain glycopeptides	0.1	*N*-acetylglucosamine	>125
Galactosamine	15	*N*-acetylmannosamine	>125
α-lactose	30	Glucose	>125
Thiodigalactoside	30	L-fucose	>125
Mannosamine	30	L-rhamnose	>125
Glucosamine	30	α-methyl-D-galactose	>125
Mannose	60	α-methyl-D-glucose	>125
Galactose	60	α-methyl-D-mannose	>125
N-acetylglactosamine	>125	2-deoxy-D-glucose	>125

Brain extract from 10-d-old rats was assayed for agglutination activity as described in Fig. 1 in the presence of a series of concentrations of various sugars in PBS 7.2 to determine the sugar concentration that would inhibit agglutination activity by 50%. In addition, brain glycopeptides, prepared as described by Simpson *et al.*[16], were tested as inhibitors of agglutination. The molarity of the glycopeptide was based on an average molecular weight of 8,000, determined by gel-filtration on Sephadex G-50.

Extracts containing agglutination activity were subjected to a variety of enzymatic and chemical treatments described in Table 2. The carbohydrate-binding protein was extremely sensitive to trypsin and chymotrypsin and somewhat less sensitive to neuraminidase. No decrease in activity was observed after incubation with a variety of other enzymes. Agglutination activity was quantitatively inactivated by heating at 100° C for 5 min. Mild periodate oxidation in controlled conditions[19] also quantitatively destroyed the agglutination activity. The effects of trypsin, chymotrypsin, neuraminidase and periodate oxidation suggests that both protein and carbohydrate components are in some way required for agglutination.

Table 2 Enzymatic and chemical characterisation of carbohydrate-binding activity in developing rat brain

Enzymatic or chemical treatment	Concentration (μg ml^{-1})	Decrease in activity (%)
Trypsin	0.1	25
	1	100
	10	100
	100	100
Chymotrypsin	0.1	0
	1	100
	10	100
	100	100
Neuraminidase	200	75
	100	50
β-glucosidase	200	0
Collagenase	200	0
Hyaluronidase	200	0
Phospholipase D	200	0
Ribonuclease	200	0
Deoxyribonuclease	200	0
Heat (5 min, 100 °C)	—	100
Sodium periodate (1 h, 4 °C)	0.012 M	100

Rat brain extract from 10-d-old pups was incubated with a series of enzymes at the specified final concentrations for 1 h at 37 °C. Controls without enzyme and without extract were incubated and assayed for agglutination activity in parallel experiments. Trypsin sensitivity was also demonstrated when the action of trypsin was terminated after incubation by addition of excess trypsin soybean inhibitor before assay, or when a Sepharose–trypsin conjugate (Sigma) was used. Also a decrease in agglutination could be demonstrated in experiments using a Sepharose–neuraminidase conjugate (Sigma), although this effect may be due in part to the action of protease contaminates. Mild treatment with sodium periodate in controlled conditions quantitatively inhibited agglutination activity. Incubation conditions used were designed for the selective oxidation of terminal sialic acid residues[19].

The heat lability, enzyme studies, and the hapten inhibition specificity suggest that the observed agglutination is not a result of the adventitious association of glycosaminoglycans or nucleic acids with erythrocytes. The activity we have identified in rat brain does not seem to be related to an agglutinin of formalin treated chick erythrocytes which accumulates in chick brain during embryonic development[20]. Agglutination produced by this extremely large proteoglycan-like complex cannot be inhibited by specific saccharides and its activity is insensitive to boiling.

The peak of agglutination activity (Fig. 1) is coincident with the time course of maximum synapse formation in developing rat brain cortex[21]. It is also interesting that the agglutination activity seems to parallel the temporal course of maximum *in vitro* cohesiveness of homotypic interactions of disassociated neuronal cells[22,23]. These parallels are at best suggestive, and further experiments are required to implicate functionally this agglutination activity in the specific cellular interactions required for synapotogenesis and neuronal development.

We thank Dr S. D. Rosen for discussions and Dr Rosen and

Developmentally regulated lectin in neonatal rat brain

WE report the identification of a developmentally regulated agglutinin of erythrocytes present in neonatal rat brain. Specific inhibition by a number of saccharides with a galactose configuration suggest that multivalent carbohydrate-binding proteins, 'endogenous brain lectins', may be responsible for the observed agglutination activity. We are presently investigating the functional role of this lectin-like activity in brain, since molecules with similar carbohydrate-binding properties seem likely to mediate intercellular recognition and adhesion in certain lower eukaryotic organisms.

The ability of cells to recognise other cells and specifically adhere to them is a central problem in developmental neurobiology and the subject of intense investigation. Moscona[1], more than a decade ago, proposed that specific macromolecules at the cell surface are responsible for specific adhesion. Specific cell recognition and adhesion could then be achieved by a cell-surface macromolecule, a carbohydrate-binding protein[2] or an enzyme[3] with a particular recognition specificity, and a carbohydrate-containing receptor, one or both of which is under a temporal metabolic regulation. The lectin hypothesis of cell recognition and adhesion[2] has gained support in recent studies[4–8] with the cellular slime moulds (for review, see ref. 9). Developmentally regulated carbohydrate-binding proteins, "discoidin"[4] and "pallidin"[6] accumulate on the cell surface of *Dictyostelium discoideum* and *Polysphondylium pallidum* as these species differentiate from a vegetative single cell state to a cohesive aggregation-competent state, and substantial evidence[2,4–8] indicates that these slime mould lectins may mediate intercellular recognition and adhesion by interacting with specific cell-surface receptors[7]. Teichberg *et al.*[10] reported the presence of a β-D-galactoside-binding protein in *Electrophorus electricus* and in a number of mammalian tissues and tissue culture cells, and Nowak *et al.*[11], and Gartner and Podleski[12], have studied a β-D-galactoside binding protein in embryonic chick muscle and myogenic cell lines, a protein, purified and characterised by Den and Malinzak[13].

The functional components of intercellular recognition and adhesion are generally thought to be glycoproteins[14] and in brain tissue in particular, the synaptic specialisation is enriched by carbohydrate-containing macromolecules which may function in synaptogenesis[14,15], in conjunction with carbohydrate-binding molecules of appropriate specificity.

Soluble extracts of developing neonatal rat brain contain a 'lectin-like' agglutination activity which is measured with trypsinised glutaraldehyde-fixed rabbit erythrocytes. In brain extracts prepared from 1–30-d-old rats (Fig. 1) a marked increase in agglutination activity was observed from day 1–10, followed by a decline to undetectable levels between 10 and 21 d. Only trace amounts of activity were found in adult animals. The time course seen in Fig. 1 was reproduced with different sets of brain extracts, and different preparations of rabbit erythrocytes, although the absolute value of the titre varied somewhat with the particular preparation of erythrocytes. Variable agglutinability of erythrocyte preparations could result from individual donor differences or from minor variations in the conditions of trypsinisation or glutaraldehyde fixation. Specific agglutination activity—that is, agglutination activity per mg protein—parallels the curve seen in Fig. 1. The possibility that the observed time course was a function of changes in the extracting reagent (DES) or in the agglutinability of the erythrocyte preparation over the time course of the study was eliminated by preparing extracts at the individual time points, freezing and assaying them together on the same day, or by simultaneously preparing extracts of animals at various ages and assaying on the same day. Mixing experiments in which day 1 and 10 extracts and day 10 and 30 extracts were mixed, incubated and assayed, gave intermediate values suggesting that enzymatic modification in crude soluble extracts was not responsible for the ascending or descending portions of the time course. No agglutination was observed when serum from 10-d-old rats was tested for this activity.

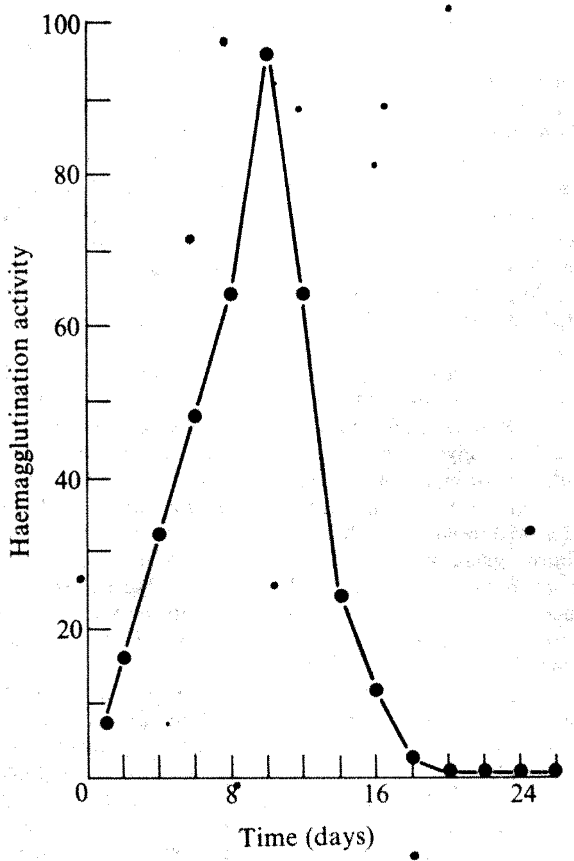

Fig. 1 Sprague–Dawley pups from litters normalised to eight pups per mother at birth, to ensure that all had equal and sufficient nutrition, were killed by decapitation. Brains were homogenised at 4 °C in 4 volumes of freshly prepared 2 mM dithiothreitol, 2 mM EDTA, 0.15 M NaCl, abbreviated DES, in a Potter–Elvejhem tissue homogeniser. Dithiothreitol at 10 mM did not improve the extractability of activity but served to stabilise the activity extracted. The homogenate was centrifuged 60 min at 40,000 r.p.m. and the supernatant assayed for agglutination activity using trypsinised glutaraldehyde-fixed rabbit erythrocytes. Erythrocytes for agglutination assays were prepared from rabbit blood (Colorado Serum Labs) collected in Alsever's solution. Cells were washed 4 times with 5 volumes saline. Erythrocytes were suspended 4% (v/v) in 0.1 M sodium phosphate–0.05 M NaCl, *p*H 7.4, and trypsin from bovine pancreas (Sigma) 0.1 mg ml, was added, and the suspension incubated at 37 °C for 60 min. Cells were then washed 5 times with 10 volumes saline. Washed erythrocytes were suspended in 5 volumes 0.075 M Na, K phosphate–0.075 M NaCl, *p*H 7.2 (PBS 7.2), containing 1% glutaraldehyde (Sigma, grade I), and incubated with shaking for 1 h at room temperature. The cross-linking reaction was terminated by addition of 5 volumes 0.1 M glycine in PBS 7.2 at 4 °C. Erythrocytes were sedimented and washed 3 times with 5 volumes 0.1 M glycine in PBS 7.2. Finally, cells were washed 4 times in 5 volumes cold PBS 7.2. Agglutination activity in brain extracts was measured with trypsinised glutaraldehyde-fixed rabbit erythrocytes as follows. A twofold dilution series of brain extract was made in DES. Either 25 µl PBS 7.2 or 25 µl an appropriate hapten inhibitor in PBS 7.2 was added to wells of a microtitre *V* plate (Cooke Engineering). Aliquots (25 µl), of the serial dilutions of extract were added to wells followed by 25 µl 1% solution bovine serum albumin in 0.15 M NaCl. After gentle mixing, 25 µl of a 2.5% suspension of erythrocytes in PBS 7.2 was added to wells. Plates were shaken vigorously, covered with transparent tape, and left at room temperature for 90 min before agglutination patterns were evaluated. The agglutination endpoint was taken as the first dilution of extract at which erythrocytes settled into a clearly circumscribed dot at the bottom of the well. Agglutination activity is defined as the reciprocal of the endpoint dilution.

A number of other types of erythrocytes were tested for their ability to calibrate agglutination activity. Fresh rabbit erythrocytes were not agglutinable, nor did trypsinisation of fresh erythrocytes render them agglutinable. Fixation with glutaraldehyde or formalin was required to sensitise the rabbit cells to agglutination, whereas trypsinisation before fixation gave 50% higher titres suggesting that such treatment, although insufficient in itself, does increase the agglutinability of fixed cells. Trypsinised formalin-fixed rabbit erythrocytes and trypsinised glutaraldehyde-fixed or formalin-fixed sheep erythrocytes were four times less sensitive to agglutination than the trypsinised glutaraldehyde-fixed rabbit erythrocytes, whereas formalin-treated human type O erythrocytes were eleven times less sensitive.

Agglutination activity of 10-d-old rats was specifically inhibited by a number of monosaccharides and disaccharides with a galactose configuration, in addition to hexosamines, mannose, and a brain glycopeptide fraction[16], as seen in Table 1. This non-dialisable glycopeptide fraction was found to be the most potent inhibitor of agglutination, being nearly 150 times greater on a molar basis than the most effective monosaccharide inhibitor, galactosamine. The glycopeptide fraction, with an average molecular weight of 8,000, was prepared from lipid-extracted whole brain by extensive proteolytic digestion, followed by quantitative precipitation of contaminating glycosaminoglycans with cetylpyridinium chloride[16]. The potent inhibition by hexosamines is interesting in view of the report by Yamada *et al.*[17], that the CSP protein or LETS protein, an agglutinin of formalin fixed erythrocytes, which has been identified as a surface antigen in cultured glial cells[18], was also inhibited by hexosamines. Careful re-examination of the hexosamine inhibition in brain extracts by measuring hexosamine inhibition at various amino sugar concentrations in parallel with equimolar concentrations of NaCl, suggested that the inhibition at high concentrations was predominantly a charge effect, whereas studies at lower hexosamine concentrations revealed a galactosamine-specific inhibition. Agglutination by the brain extract is probably not due to LETS protein since EDTA or EGTA, potent inhibitors of the LETS mediated agglutination[17], were not potent inhibitors of the brain activity. Nevertheless, we cannot absolutely rule out the possibility that the brain activity, in part, is LETS mediated, since a different cell type was used to test agglutination by purified LETS protein. An accurate comparison to the hapten inhibition specificity of the LETS protein, awaits purification of the brain agglutinin.

Although the sugar concentrations required to inhibit agglutination by brain extracts are relatively high, unlike those of many lectins derived from plant sources, a number of lectins do require concentrations in this range. The carbohydrate specificity, although generally galactose specific, is not absolute suggesting that several carbohydrate-binding proteins with distinct specificities may be present in crude extracts from 10-d-old rats.

Table 1 Glycopeptide and sugar effects on agglutination of erythrocytes by brain extracts

Sugar concentrations (mM) that inhibit agglutination by 50%			
Brain glycopeptides	0.1	*N*-acetylglucosamine	> 125
Galactosamine	15	*N*-acetylmannosamine	> 125
α-lactose	30	Glucose	> 125
Thiodigalactoside	30	L-fucose	> 125
Mannosamine	30	L-rhamnose	> 125
Glucosamine	30	α-methyl-D-galactose	> 125
Mannose	60	α-methyl-D-glucose	> 125
Galactose	60	α-methyl-D-mannose	> 125
N-acetylglactosamine	> 125	2-deoxy-D-glucose	> 125

Brain extract from 10-d-old rats was assayed for agglutination activity as described in Fig. 1 in the presence of a series of concentrations of various sugars in PBS 7.2 to determine the sugar concentration that would inhibit agglutination activity by 50%. In addition, brain glycopeptides, prepared as described by Simpson *et al.*[16], were tested as inhibitors of agglutination. The molarity of the glycopeptide was based on an average molecular weight of 8,000, determined by gel-filtration on Sephadex G-50.

Extracts containing agglutination activity were subjected to a variety of enzymatic and chemical treatments described in Table 2. The carbohydrate-binding protein was extremely sensitive to trypsin and chymotrypsin and somewhat less sensitive to neuraminidase. No decrease in activity was observed after incubation with a variety of other enzymes. Agglutination activity was quantitatively inactivated by heating at 100° C for 5 min. Mild periodate oxidation in controlled conditions[19] also quantitatively destroyed the agglutination activity. The effects of trypsin, chymotrypsin, neuraminidase and periodate oxidation suggests that both protein and carbohydrate components are in some way required for agglutination.

Table 2 Enzymatic and chemical characterisation of carbohydrate-binding activity in developing rat brain

Enzymatic or chemical treatment	Concentration (μg ml^{-1})	Decrease in activity (%)
Trypsin	0.1	25
	1	100
	10	100
	100	100
Chymotrypsin	0.1	0
	1	100
	10	100
	100	100
Neuraminidase	200	75
	100	50
β-glucosidase	200	0
Collagenase	200	0
Hyaluronidase	200	0
Phospholipase D	200	0
Ribonuclease	200	0
Deoxyribonuclease	200	0
Heat (5 min, 100 °C)	—	100
Sodium periodate (1 h, 4 °C)	0.012 M	100

Rat brain extract from 10-d-old pups was incubated with a series of enzymes at the specified final concentrations for 1 h at 37 °C. Controls without enzyme and without extract were incubated and assayed for agglutination activity in parallel experiments. Trypsin sensitivity was also demonstrated when the action of trypsin was terminated after incubation by addition of excess trypsin soybean inhibitor before assay, or when a Sepharose–trypsin conjugate (Sigma) was used. Also a decrease in agglutination could be demonstrated in experiments using a Sepharose–neuraminidase conjugate (Sigma), although this effect may be due in part to the action of protease contaminates. Mild treatment with sodium periodate in controlled conditions quantitatively inhibited agglutination activity. Incubation conditions used were designed for the selective oxidation of terminal sialic acid residues[19].

The heat lability, enzyme studies, and the hapten inhibition specificity suggest that the observed agglutination is not a result of the adventitious association of glycosaminoglycans or nucleic acids with erythrocytes. The activity we have identified in rat brain does not seem to be related to an agglutinin of formalin treated chick erythrocytes which accumulates in chick brain during embryonic development[20]. Agglutination produced by this extremely large proteoglycan-like complex cannot be inhibited by specific saccharides and its activity is insensitive to boiling.

The peak of agglutination activity (Fig. 1) is coincident with the time course of maximum synapse formation in developing rat brain cortex[21]. It is also interesting that the agglutination activity seems to parallel the temporal course of maximum *in vitro* cohesiveness of homotypic interactions of disassociated neuronal cells[22,23]. These parallels are at best suggestive, and further experiments are required to implicate functionally this agglutination activity in the specific cellular interactions required for synapotogenesis and neuronal development.

Effects of glycolipids on *in vitro* development of neuromuscular junction

THE nervous system has a unique distribution of glycolipids[1], which changes markedly during growth of the animals[2] and in various inherited metabolic disorders[3]. No physiological roles for glycolipids in neural function are known, however. But, in nonneural cells glycolipids of the cell membrane are essential for cell recognition and interaction[4]. For example, some gangliosides act as receptors for various bacterial toxins[5] and globoside has been identified as the human P blood type antigen[6]. When administered in the medium, ganglioside can be incorporated into cell membranes and function as toxin receptors[5,7]. Ganglioside added to the medium competes with membrane receptors by binding to the toxins[5]. We reported previously[8,9] that the effects of some drugs and sera on the formation of neuromuscular junction in culture could be evaluated by recording the endplate potential (e.p.p.) from muscle cells combined with the spinal cord. We describe here the effect of glycolipids on the development of neuromuscular junction in culture of skeletal muscle and the spinal cord. Globoside had biphasic effects, an inhibitory effect at the higher concentration and a facilitatory one at the lower concentration or on brief exposure at the beginning of the cultivation. Our evidence suggests that glycolipids are involved in formation of the neuromuscular junction.

Pectoral muscles and spinal cords were obtained from 10–11-d and 5–7-d chick embryos (White Leghorn) respectively. The muscles were dissociated to single cells by incubation in 0.25% trypsin and $2.5–5 \times 10^5$ cells were plated into a plastic culture dish (35 mm diameter, Falcon). After 2 or 3 d of culturing muscle cells alone, fragments (about 15 pieces) of the spinal cord were added to each dish. The cord fragments were obtained by slicing the whole length of the hemisected spinal cord. The culture medium was Eagle's minimum essential medium (MEM, Nissui) supplemented with 10% foetal calf serum, 5% chick serum (both Flow Labs.), 6 mg ml^{-1} glucose and 0.06 mg ml^{-1} kanamycin. The cultures were maintained at 37 °C in a humidified atmosphere of 95% air and 5% CO_2. At the time of plating the cord the medium was renewed and glycolipid (Table 1) was added. In some experiments globoside was added according to the schedule described in Table 3. Glycolipids were prepared as before[10–13]. Galactosylceramide, sulphatide and gangliosides (a mixture of G_{M1}–G_{T1} and G_{M1}) were from bovine brain[10,11]. Glucosylceramide was isolated from the spleen of a patient with Gaucher's disease, and purified by Florisil and silicic acid column chromatography. Haematoside (*N*-glycolylneuraminyl-galactosyl-glucosyl-ceramide) and globoside (*N*-acetylgalactosaminyl-galactosyl-galactosyl-glucosyl-ceramide) were isolated from equine and human erythrocytes respectively[12,13]. The sugar chain of globoside (*N*-acetylgalactosaminyl-galactosyl-galactosyl-glucose) was obtained by ozonolysis and mild alkali treatment of globoside[14,15], and further purified by charcoal column chromatography. The purity of the oligosaccharide was checked by gas–liquid chromatography[15].

After further 2 d of coculture, the culture dish was mounted on the stage of an inverted phase-contrast microscope and membrane potentials of myotubes (multinucleated muscle cells) were recorded intracellularly with a KCl-filled electrode (resistance 15–20 MΩ). The experiments were usually performed in the fresh MEM without serum and glycolipid at 35–38 °C. The presence of glycolipid in the medium, however, did not interfere with measurement of electrophysiological parameters, and did not alter the results.

A proportion of myotubes, cultured for 2 d in combination with the spinal cord explant, spontaneously generated e.p.ps (ref. 8) (Fig. 1). The e.p.ps varied in amplitude from myotube to myotube (range 1–10 mV) and in frequency (0.5–30 per s). As in the previous studies[8,9], the presence of spontaneous e.p.ps was regarded as indicating the formation of a neuro-

Table 1 Spontaneous e.p.p.s in myotubes cultured for 2 d with the spinal cord in the presence of glycolipids

Glycolipid	Concentration (mM)	No. of myotubes tested	Myotubes with e.p.ps (%)
None (control)		435	55
Galactosylceramide	0.5	60	63*
Glucosylceramide	0.5	57	56*
Haematoside	0.5	56	41*
Sulphatide	0.05	62	63*
Gangliosides (G_{M1}–G_{T1})	0.5	88	45*
G_{M1}	0.5	57	21†
Globoside	0.5	52	23†

* $P > 0.05$, compared with control by χ^2 test on 2×2 contingency tables.
† $P < 0.01$.

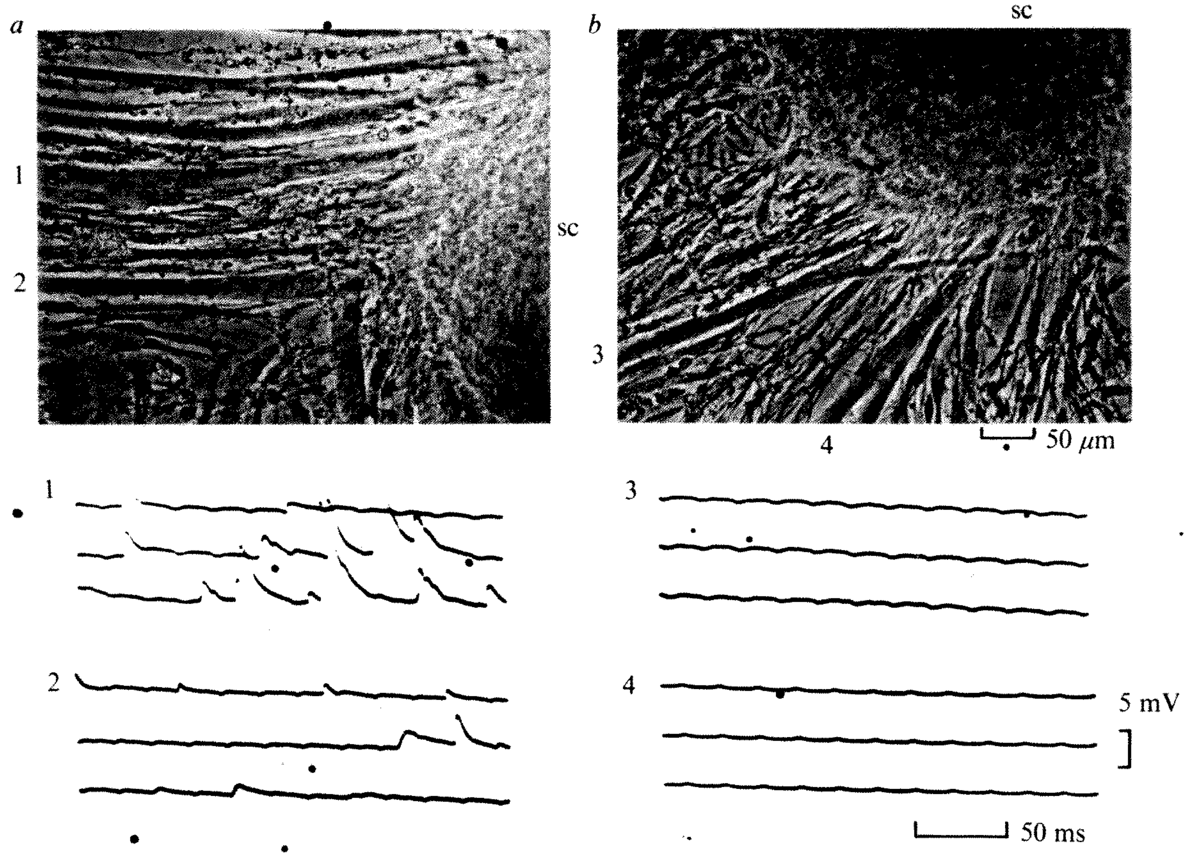

Fig. 1 Photomicrographs of cultures of skeletal muscle and the spinal cord (sc) from the chick embryo, incubated for 2 d. *a*, Without addition of glycolipid, and *b*, in the presence of 0.25 mM globoside. Potential records 1–4 were obtained from myotubes 1–4 respectively, as indicated in the photomicrographs. Spontaneous e.p.ps were obtained from myotubes 1 and 2 but not from 3 and 4.

muscular junction. The myotubes which were partially covered with the spinal cord explants or with numerous nerve processes were chosen for electrode penetration. Myotubes with a recorded resting potential lower than –40 mV were not included in the study. Four independent myotubes were sampled for each explant and 10–12 myotubes were studied in each culture dish. Percentages of myotubes generating spontaneous e.p.ps were compared for seven glycolipid samples (Table 1) at a concentration of 0.5 mM, except for sulphatide. Sulphatide at concentrations over 0.1 mM was toxic to growth of muscle cells and nerve processes, so the effect on junction formation was studied at 0.05 mM. The results are summarised in Table 1. Compared with the control cultures grown without glycolipids, galactosylceramide and sulphatide showed high values and glucosylceramide was without change. Cultures grown with haematoside, the mixture of gangliosides, G_{M1} and globoside were lower in percentages of myotubes with e.p.ps than controls. This difference was statistically significant only for globoside and G_{M1}, although growth of nerve and muscle did not seem to be impaired (Fig. 1 and see later). Further analyses were mainly made using globoside.

Effects of globoside varied with concentration (Fig. 2); an inhibitory effect was observed at higher concentrations (0.25–0.5 mM), but junction formation was augmented at lower concentrations (8–63 μM). Biphasic effects were also observed with the sugar chain of globoside, although the transition from facilitation to depression occurred at a higher concentration than with globoside (Fig. 2). The experiments to determine whether there was a direct effect of globoside on the growth of nerve and muscle are summarised in Table 2. Outgrowth of nerve processes was not affected. High concentrations (0.25–0.5 mM) of globoside sometimes impaired the growth of myotubes but resting potential, input resistance and acetylcholine sensitivity were the same in cells cultured with and without globoside. Globoside thus has a rather selective effect on the junction formation. The incidence of junction formation was low in the presence of 0.5 mM G_{M1}, but high at 0.25 mM (myotubes with e.p.ps constituting 72% of 40 cells tested).

Globoside was also added to cultures for various times as shown in Table 3, at a constant concentration of 0.25 mM. In contrast with depression induced by exposure to globoside throughout the culture period (48 h), exposure to globoside

Fig. 2 Effects of globoside (○) and its sugar chain (●) on the development of neuromuscular junction in culture. Myotubes were cultured with the spinal cord for 2 d in the presence of various concentrations of test substances. Ordinate shows percentage of myotubes which were spontaneously generating e.p.ps. A dotted line indicates level of the control (55%, Table 1). The numbers of myotubes tested are shown in parentheses.

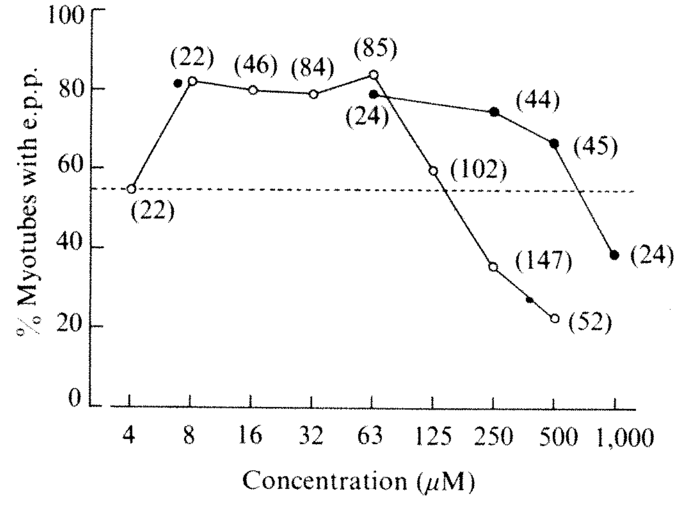

Table 2 Globoside effect on nerve and muscle cell culture growth

Globoside concentration (mM)	0	0.05	0.25
Process outgrowth from the spinal cord explants			
Density	1.7±0.11	1.4±0.17	1.6±0.13
Length	2.1±0.12 (46)	2.0±0.23 (24)	1.9±0.17 (28)
Electrical properties of myotubes			
Resting potential (mV)	−56.5±18.1 (184)	−57.9±19.6 (71)	−54.7±20.9 (155)
Input resistance (mΩ)	2.5±1.0 (3)		2.6±0.7 (3)
Acetylcholine sensitivity (mV nC^{-1})	425±436 (6)		483±287 (13)

Explants of the spinal cord from 6 d chick embryo were cultured for 2 d without muscle cells, with or without globoside. The extent of process outgrowth in fibre density and length was rated on an arbitrary scale of 0–3, a score of 3 indicating the maximum (modified from Mizel and Bamburg[17]). Electrical properties of myotubes were obtained from the same cultures as for the junction formation. Input resistance was measured by two intracellular electrode method. Acetylcholine was applied electrophoretically through micropipettes. In parentheses are numbers of the spinal cord explants or myotubes tested. No statistical significance was found when compared with the control (globoside, 0 mM).

during the first 12–24 h markedly potentiated junction formation. In these experiments the culture was repeatedly washed after the exposure, because even at a very low concentration globoside would affect the succeeding culture (see Fig. 2). Exposure for the first 6 h in a small number of experiments also showed mild augmentation of junction formation (not shown). Table 3 also shows that junction formation was low when globoside was applied later (12–24 h after plating the spinal cord). In a further experiment (not shown) globoside was applied to muscle culture for 24 h before the spinal cord was added. When studied after 2 d of coculture with the cord, e.p.ps were observed in 40% of 50 myotubes. Growth of myotubes was slightly impaired in these cultures. This suggests that the facilitatory effect was exerted on the nerve rather than on the muscle cells.

Table 3 Effect of time of globoside application (0.25 mM) on development of the e.p.ps in 48-h culture of muscle and the spinal cord

Exposure time (h)	No. of myotubes tested	Myotubes with e.p ps (%)
0–48	147	36
0–12	86	85*
0–24	95	78*
12–48	72	40†
24–48	89	44†

*$P < 0.01$ when compared with 0–48-h value by χ^2 test on 2×2 contingency tables.
†$P > 0.05$.

Judging from the onset of appearance of the spontaneous e p.p.s, neuromuscular junctions in these cultures were formed 12–48 h after plating the spinal cord (most being formed at 20–30 h). The fact that junction formation was stimulated by globoside during first 12 h of exposure suggests that, before junction formation, globoside or its sugar chain induces changes in nerve and muscle which resulted in subsequent facilitation of junction formation. Globoside is probably incorporated into cell membrane in a way analogous to that of ganglioside[5,7], although incorporation of globoside has not been studied. The globoside sugar chain, however, is probably not incorporated as a constituent of membrane globoside (as it is a saccharide, and not a glycolipid). Hence the facilitatory effect of globoside and its sugar chain may not necessarily be accounted for by an increased level of membrane globoside.

High concentrations of globoside were inhibitory when added at the time of the junction formation (12–48 h after plating of the spinal cord). It is possible that the inhibitory effect may overcome the facilitatory one which has been exerted in advance.

Development of the chick embryo neuromuscular junction *in vitro* was thus markedly affected by globoside and G_{M1}. Further investigation is required to elucidate the mechanism of their action and also to find their role in the development of the neuromuscular system *in vivo*. The glycolipid composition of skeletal muscle is quite different from that of the nervous tissue[16]. The effects of other glycolipids on junction formation will be studied later.

Antipsychotics block muscarinic acetylcholine receptor-mediated cyclic GMP formation in cultured mouse neuroblastoma cells

ANTIPSYCHOTIC drugs (for example, phenothiazines, butyrophenones) have side effects similar to those of atropine[1], suggesting that they block the muscarinic acetylcholine receptor. Receptor-binding studies with radioactively-labelled ligands have been used to study the muscarinic acetylcholine receptor and to show that antipsychotic drugs vary in their potency at displacing the ligand from binding sites in rat brain homogenates[2,3] In all receptor binding studies it is essential to demonstrate that binding data in fact reflect a drug-receptor interaction in a pharmacological sense[4] These correlations are ideally determined using the same tissue for binding and for biological studies such as was done for certain polypeptide hormone receptors[4] and for the β-

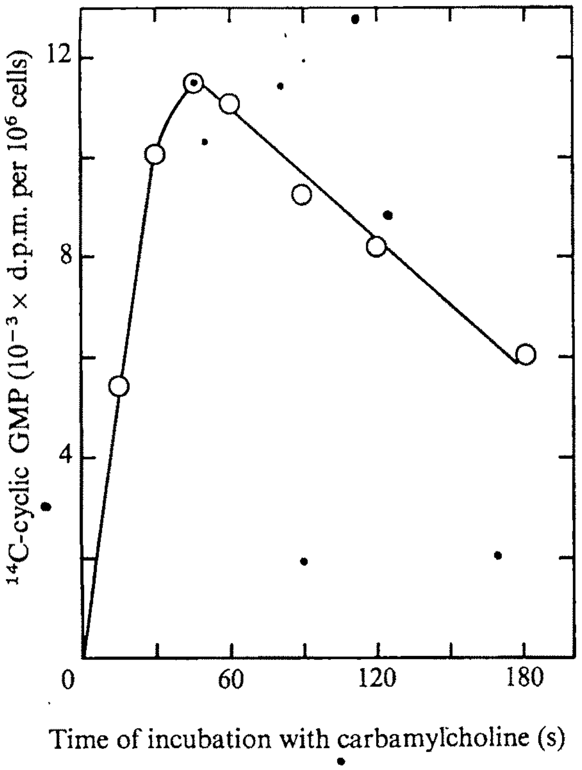

Fig. 1 The effect of carbamylcholine on cyclic GMP formation in cultured mouse neuroblastoma cells. Clone N1E-115 cells were cultured in Dulbecco–Vogt modification of Eagle's medium (high glucose, no pyruvate, Grand Island Biological) supplemented with 10% (v/v) foetal calf serum without antibiotics at 37 °C in an atmosphere of 10% CO_2 and 90% humidified air Cells were grown to confluency in flasks (75 cm² per 250 ml) with 20 ml of medium and maintained in stationary phase (requiring daily medium change) for 6 d before assay For the assay cells were dissociated from the surface of flasks by incubation in a modified Puck's D_1 solution[8], collected by low-speed centrifugation (500 r p m in Damon/IEC CRU-5000 centrifuge) and resuspended at a density of 8 × 10^6 cells per ml in 2.0 ml of phosphate buffered saline (PBS)-HEPES solution containing 110 mM NaCl, 5 3 mM KCl, 1 8 mM $CaCl_2$, 1.0 mM $MgCl_2$, 2 0 mM Na_2HPO_4, 25 mM glucose, 50 mM sucrose and 20 mM HEPES *N*-2-hydroxyethyl-piperazine-N_2-ethane titrated to *p*H 7 4 with 1 N NaOH The osmolality of this solution was 335–340 mOsm The cell suspension was then placed in a 25-ml Erlenmeyer flask to which was added U ^{14}C-GTP (specific activity 523 mCi mmol^{-1}) to give a final concentration of 5 μM (1 25 μCi ml^{-1}), and rotated at 37 °C for 45 min at 80 r p m. Cells were then collected by low-speed centrifugation, washed three times with 10 ml of PBS-HEPES to remove extracellular radioactivity, and resuspended in 5 ml of PBS-HEPES containing 0 5 mM IBMX (Aldrich) The radioactive-cell suspension was then distributed in 250-μl aliquots into wells of a multi-well tray and incubated at 37 °C for 30 min at 80 oscillations per min in a shaker bath. A solution of carbamylcholine (Sigma) was then added in 50 μl to give a final concentration of 1 mM. At the indicated times the reaction was stopped by the addition of 100 μl of ice-cold 50% (w/v) trichloroacetic acid (TCA) The TCA solution in each well was then sonicated briefly (3 s at setting no 3, Ultrasonic Cell Disrupter, Kontes Glass) before the addition 0 02 μCi of 8-^{3}H-cyclic GMP as internal standard Each sample was then placed over an 0 8 × 8 cm column of Dowex 50 (AG 50 W-X2, 200–400 mesh, Bio-Rad) which had been washed with water Each well was rinsed once with 500 μl of 5% TCA and this wash was placed over the column. Radioactive cyclic GMP was isolated from each column as described by Fujimoto *et al*[9] Recovery of ^{3}H-cyclic GMP internal standard averaged 86% The ^{14}C-radioactivity in the fraction of the column containing ^{3}H-cyclic GMP was identified as ^{14}C-cyclic GMP by high voltage electrophoresis on Whatman No 1 paper (25 mM NH_4HCO_3 buffer, 1 kV, 5 mA for 60 min) and thin-layer chromatography (PEI-cellulose in two solvent systems *n*-propanol 1 N LiCl (1/1) and 2 N formic acid/2 M LiCl (1/1) Of the recovered ^{14}C-radioactivity, 86–94% electrophoresed or chromatographed with authentic cyclic GMP (Sigma) All time points were determined in duplicate. Corrections were made for recovery of the internal standard and the zero-time point value (5,800 d p m per 10^6 cells) was subtracted from each time point

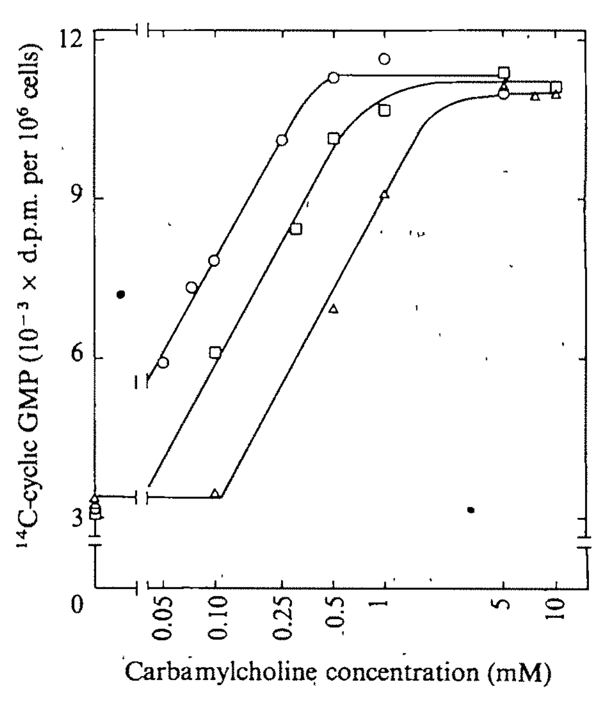
adrenergic receptor[5]. For the muscarinic acetylcholine receptor of nervous tissue, however, a direct correlation of binding data with pharmacological data has not been shown[6]. Thus, there remains a question whether the displacement by antipsychotic drugs of a radioactively-labelled muscarinic receptor antagonist from brain homogenates reflects blockade by these drugs of this receptor. We report here that antipsychotic drugs block the muscarinic acetylcholine receptor in cultured nerve cells.

For these studies we developed a technique to assay rapidly muscarinic acetylcholine receptor-mediated formation of cyclic GMP in intact cells of adrenergic mouse neuroblastoma clone N1E-115. We have studied this clone in cell culture as a model for the adrenergic neurone using biochemical, pharmacological and electrophysiological techniques[7]. The assay for cyclic GMP (to be described in detail elsewhere) involves radioactively-labelling intracellular pools of GTP and isolation of radioactively-labelled cyclic GMP over a cation exchange resin column

The formation of ^{14}C-cyclic GMP from ^{14}C-GTP in living mouse neuroblastoma cells occurred rapidly after addition of carbamylcholine to the cells (Fig. 1). The peak of ^{14}C-cyclic GMP was at about 45 s in the presence of the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (IBMX) (Fig. 1) and at about 30 s in the absence of IBMX (data not shown). Since stimulation of the formation of radioactively-labelled cyclic GMP in intact clone N1E-115 cells was inhibited by atropine ($K_B = 2 \times 10^{-9}$ M, E.R , unpublished data) and unaffected by hexamethonium (0.1 mM, E.R., unpublished data) we concluded that this effect was mediated through the muscarinic acetylcholine receptor. Others have found similar results with this clone[10], autonomic ganglia and brain tissue[11] A possible role of muscarinic cholinergic regulation of cyclic GMP in synaptic transmission has been proposed[11].

Fig. 2 Effect of an antipsychotic drug on the carbamylcholine dose–response curve. Mouse neuroblastoma clone N1E-115 (subculture 14) was assayed for carbamylcholine-stimulated cyclic GMP formation as described in the legend to Fig 1 except for the following modifications. Cells in PBS-HEPES with 0 5 mM IBMX were distributed in 250 μl aliquots to each well, 30 μl of PBS-HEPES was added with or without thioridazine (Sandoz) and the cells were incubated for 30 min before addition of carbamylcholine in 20 μl There were approximately 3 1 × 10^5 cells and 224 μg of protein per well. Cell counts were determined with Coulter counter; protein was determined by the modification of the method of Lowrey *et al*[13], using bovine serum albumin as standard ○, No antagonist, □, thioridazine 1 × 10^{-7} M; △, 5 × 10^{-7} M thioridazine



Dose–response curves for carbamylcholine (Fig 2) were shifted to the right in the presence of antipsychotic drugs (as for example, by the piperidine phenothiazine, thioridazine, Fig. 2). The parallel shift of the dose–response curve indicates competitive inhibition and allows the determination of the equilibrium dissociation constant for the antagonist–receptor complex from the equation $K_B = (DR - 1)/[B]$ where DR = dose ratio and $[B]$ = concentration of antagonist[13,14]. In this manner, K_B values for a number of antipsychotic drugs were determined (Table 1). The potency of these antipsychotic drugs varied over a broad range Thus, the most potent drug, clozapine (a dibenzodiazepine) was about 10^4 times more active than the least potent drug prochlorperazine (a phenothiazine) The rank order of potency of these drugs in our system was much the same as that obtained using receptor-binding studies with rat brain homogenates[2,3]. Thus, using a biological assay for the muscarinic acetylcholine receptor, we have demonstrated that antipsychotic drugs competitively block this receptor, thereby blocking muscarinic receptor-mediated formation of cyclic GMP.

Table 1 Equilibrium dissociation constants (K_B) for antipsychotic drugs and the muscarinic acetylcholine receptor

Compound	(K_B) (M)
Clozapine	3×10^{-9}
Thioridazine	6×10^{-8}
Mesoridazine	6×10^{-8}
Promazine	2×10^{-6}
Chlorpromazine	2×10^{-6}
Fluphenazine	2×10^{-6}
Perphenazine	4×10^{-6}
Acetophenazine	4×10^{-6}
Haloperidol	7×10^{-6}
Trifluoperazine	2×10^{-5}
Prochlorperazine	4×10^{-5}

Each compound was tested at 2 different concentrations in a manner similar to that for Fig 2 K_B values were calculated from the shift in the dose–response curves as described in the text Average values are reported

It is likely that *in vivo* antipsychotic drugs block both acetylcholine-stimulated guanylate cyclase activity and dopamine-stimulated adenylate cyclase activity. Effects of antipsychotic drugs on receptor-mediated formation of both cyclic GMP and cyclic AMP may relate to the therapeutic effects as well as the side effects (such as drug-induced Parkinsonism and tardive dyskinesia) of these compounds

Response of acetylcholine receptors to rapid photochemically produced increases in agonist concentration

SYNAPTIC transmission to muscle fibres and electroplaques takes place on a millisecond timescale To study the molecular events leading to activation of the cholinergic receptor channel, we have developed a method to produce similarly rapid, spatially uniform steps of agonist concentration near intact postsynaptic membranes. *Electrophorus* electroplaques in a voltage-clamp apparatus were exposed to a solution containing a photochromic compound Initially the compound was in a predominantly *cis* form, which had little effect on the membrane. During a brief light flash, some of the compound was isomerised to the *trans* isomer, which is a cholinergic agonist. As a result the membrane conductance increased along a timecourse which reflects the rate processes underlying activation of the cholinergic receptor channel.

Bartels *et al.*[1] first described the photochemistry and pharmacology of 3,3'-*bis*-[α-(trimethylammonium)methyl]azobenzene (*bis*-Q, see Fig. 1) In confirmation of their results, we have found that a curare-sensitive conductance is induced in the innervated membrane by bath application of solutions containing *trans-bis*-Q (ref 2) We have also exploited the fact that for a given concentration of any agonist the steady-state number of open receptor channels increases as the voltage is made more negative After a voltage jump the agonist-induced current relaxes exponentially to a new equilibrium value, at low agonist concentrations the relaxation time constant equals the lifetime of the elementary change ('channel') caused by agonist[3–6] With *trans-bis*-Q, this time constant was about 11 ms at 10 °C and − 150 mV, and about 2.5 ms at 24 °C and the same voltage. Roughly equal values are obtained with acetylcholine (ACh) itself in similar conditions

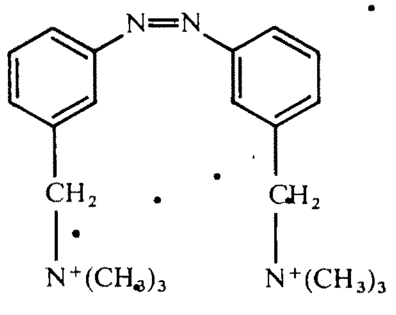
Many quaternary ammonium compounds possessing aromatic groups produce an apparent non-competitive, voltage-dependent blockage of ACh receptors[2,7], but such effects are small or absent with *bis*-Q at the concentrations used here

We have also confirmed the observation[1] that the *cis* isomer has much less effect on ACh receptors, although its precise pharmacology is uncertain because it has not yet been isolated in pure form The *cis* and *trans* isomers are stable in the dark but readily interconvert when exposed to light of appropriate wavelengths (Fig 1). This property affords the opportunity to observe the response to rapid 'agonist concentration jumps'.

Before such experiments the *bis*-Q solutions were converted to a predominantly *cis* form by exposure to 360-nm light until no further changes in optical density were noted at 318 nm. Bartels *et al*[1] estimated that the resulting 'photostationary' state consists of 85% *cis* and 15% *trans* (active) isomer. Consequently, small agonist-induced currents appeared when this solution was allowed to equilibrate with the innervated face of an electroplaque, at

Fig. 1 Bis-Q, a photochromic agonist

$$cis\text{-}bis\text{-}Q \underset{\text{Ultraviolet}}{\overset{\text{Visible}}{\rightleftharpoons}} trans\text{-}bis\text{-}Q$$



−150 mV these initial agonist-induced currents were roughly 2 mA cm^{-2} in the cell of Fig. 2*a*, and 5 mA cm^{-2} in Fig. 2*b* After a voltage jump, relaxations of the agonist-induced current resembled those seen with low concentrations of *trans-bis*-Q There are at least two components. A fast (< 500 μs) phase is kinetically not resolvable and accounts for 10–25% of the relaxation amplitude. This component probably results from instantaneous rectification in the small number of channels opened by *trans-bis*-Q at positive potentials[4] The slower part of the relaxation follows an exponential timecourse, and arises because the number of open receptor channels increases after the voltage jump[4].

We then compared the behaviour of the conductance during voltage-jump relaxations and agonist concentration-jump relaxations induced by light flashes (Fig. 2) An energy of 75 J was discharged through a xenon-filled 'short-arc' flash tube. The light was led through a fibre optic bundle to the pool, roughly a 1-cm cube, bathing the innervated face of the voltage-clamped electroplaque. The fibre bundle filtered out most of the ultraviolet light. Between light flashes the preparation was kept in the dark When the pool contained *cis-bis*-Q, we found with spectral measurements that each flash converted about 2 5% of the *cis* to the *trans* isomer.

Although 'voltage-jump' relaxations occurred with all known agonists[3–6], conductance changes following a light flash were observed only when the solution contained *cis-bis*-Q and not in the presence of agonists, such as suberyldicholine or pure *trans-bis*-Q, which are photostable at the wavelength used. The agonist concentration jump produces an increase of membrane conductance. (We have not yet succeeded in generating ultraviolet flashes strong enough to produce rapid conductance decreases due to *trans*→*cis* isomerisation.) Like the voltage-jump relaxations, the concentration-jump relaxation amplitudes are reversibly diminished about fivefold by (+)-tubocurarine (1 μM).. Thus there seems little doubt that the agonist concentration-jump relaxations reflect a rate-limiting process in the activation of channels controlled by nicotinic acetylcholine receptors

As shown in Fig. 2, the conductance increase is substantially complete within the first few milliseconds following the flash and stable at least until the next episode (4 s later in the experiment of Fig. 2, several minutes later in other experiments) The voltage- and concentration-jump relaxations have similar timecourses at a given membrane potential and temperature. Presumably the rate of *cis*→*trans* isomerisation is at least as fast as the flash, which lasted about 2 ms, after the flash the agonist concentration-jump relaxations followed an exponential timecourse. For the six traces of Fig. 2*a*, measured at 10 °C, the major, exponential component of the voltage-jump relaxation had a time constant of 6.94 ± 0.29 ms (mean ± s e.). The agonist concentration-jump relaxation had a time constant of 6.80 ± 0.28 ms. At 24 °C (Fig. 2*b*), the values were 1.78 ± 0.09 ms for the voltage jump and 1.75 ± 0.14 ms for the agonist concentration jump. On average, the time constants decreased by about 1% after each flash for the first 20 flashes; this observation is not surprising since voltage-jump relaxation times decrease with increasing agonist concentration[3,4]. The time constants vary markedly with temperature, suggesting that channel opening and closing are rate-limited by a chemical, probably macromolecular, process rather than by simple diffusion of newly created agonist molecules toward their site of action.

Several electrophysiological techniques are now available for probing the opening and closing kinetics of acetylcholine receptor channels Thus it is possible to compare (a) the decay of neurally evoked postsynaptic currents and of spontaneous miniature postsynaptic currents[3,4,8–10] (b) the duration of single-channel currents[11]; (c) the power spectrum of ACh-induced conductance fluctuations[5,12,13], (d) voltage-jump relaxations[3–6], and (e) the present agonist concentration-jump relaxations. For the first two experimental procedures, kinetic data are dominated by the closing rates, data from the last three procedures sometimes have comparable contributions from the opening rates as well[4]. The time constants derived from all these experiments agree well in comparable conditions of agonist, concentration, voltage, and temperature. These facts suggest that the opening and closing of the channel are governed either by true first-order processes such as intramolecular isomerisations, or by pseudo-first-order processes such as binding of agonist molecules whose concentration remains essentially constant during the measurement. To distinguish among these possibilities, we require improvements in the agonist concentration-jump technique coupled with similarly rapid measurements of binding and of conformational changes[14].

We thank D. Williams for assistance with the animals, W. L. Crowder for help with electronics, D. D. Koblin for participating in some of the experiments, M A. Raftery for the use of a spectrophotometer, E. Neumann for helpful discussion, and the Chadwick-Helmuth Corporation (Monrovia, California) for the loan of a flash tube and power supply. This work was supported by the NIH, by the Muscular Dystrophy Association, and by an Alfred P. Sloan Fellowship to H.A.L.

Fig. 2 Voltage-and agonist-jumps in the presence of *bis*-Q (0 4 μM) Two cells at different temperatures, note different timescales for *a* and *b* Each panel shows six superimposed episodes repeated at intervals of 4 s Top trace shows voltage, during each episode, the voltage was jumped from +50 to −150 mV A light flash also occurred later in each episode and was monitored by a phototransistor (middle trace). The episodes shown here included the first six light flashes Bottom traces show agonist-induced currents Separate control trials, measured with the same voltages but without Bis-Q present, gave the leakage and capacitative current alone These currents have been subtracted from the traces shown[4]. Zero current levels were off scale in the original records, they were determined from simultaneous low gain records and are shown as dashed lines Before the first flash about 15% of the *bis*-Q was in the *trans* state, consequently there was an initial level of agonist-induced current Each flash resulted in an increment of *trans-bis*-Q concentration As a result agonist-induced current increased by about 20% of the initial level with each flash

Release of dopamine *in vivo* from cat substantia nigra

THE central aminergic neurones present some original characteristics. By means of quantitative autoradiographic studies, it has been demonstrated that serotoninergic terminals projecting into the cerebral cortex and the locus coeruleus exhibit very few classical synaptic contacts[1,2]. This has also been seen with cortical noradrenergic terminals[1] It has been suggested that the amines could be released not only in synapses, but also from varicosities devoid of synaptic junctions. they could thus act as neuromodulators at some distance from the release sites. It has also been proposed that dopamine could be released from dendrites of nigrostriatal dopaminergic neurones[3] Indeed, a release of endogenous dopamine (Cuello, personal communication) or of labelled dopamine[4,5] previously taken up in tissues, has been demonstrated using slices of the rat substantia nigra exposed to a high concentration of potassium (30 mM). This process was calcium dependent An indication of possible dendritic release was also obtained indirectly *in vivo* by measuring dopamine metabolites in the rat substantia nigra[6]. Dihydroxyphenylacetic acid and homovanillic acid levels were increased after stimulation of the medial forebrain bundle, which contains axons of various ascending aminergic pathways including the nigrostriatal dopaminergic system Therefore, dopamine could be released not only from nerve terminals in the striatum, but also from dendrites in the substantia nigra. If the latter mechanism was occuring in physiological states, it could have important implications for the understanding of the regulatory processes involved in the control of the activity of the dopaminergic neurones. It thus seemed necessary to demonstrate directly an *in vivo* release of dopamine in the substantia nigra.

Experiments were carried out in halothane-anaesthetised cats. A push-pull cannula was inserted into the substantia nigra (stereotaxic coordinates: $A = 3.5$; $L = 4$, $H = -4$) allowing the superfusion of the structure with artificial cerebro-spinal fluid containing 20–25, μCi per 500 μl L-3, 5-^{3}H-tyrosine (40–50 Ci mmol^{-1}, Radiochemical Centre, Amersham, UK) at a rate of 500 μl per 15 min. ^{3}H-dopamine formed and released extraneuronally, was estimated in serial 15-min superfusate fractions using an isolation procedure as described previously[7] In some experiments the push-pull cannula was introduced into the left caudate nucleus ($A = 16$, $L = 5$; $H = +5$). This experimental approach for the study of dopamine release from nerve terminals has already been used successfully[8]

When the tip of the push–pull cannula was positioned precisely in the substantia nigra, as revealed by postmortem histological control, ^{3}H-dopamine could be easily estimated in the superfusates One hour after the beginning of the experiments, ^{3}H-dopamine release reached a steady-state level (about 20 times the blank value), which persisted during the entire course of the superfusion (Fig 1) As checked by cochromatography, ^{3}H-dopamine was the only labelled catecholamine released (Fig. 2) The quantity of ^{3}H-dopamine spontaneously released into the substantia nigra was 3–4 times lower than that found in comparable experiments carried out in the left caudate nucleus (Table 1).

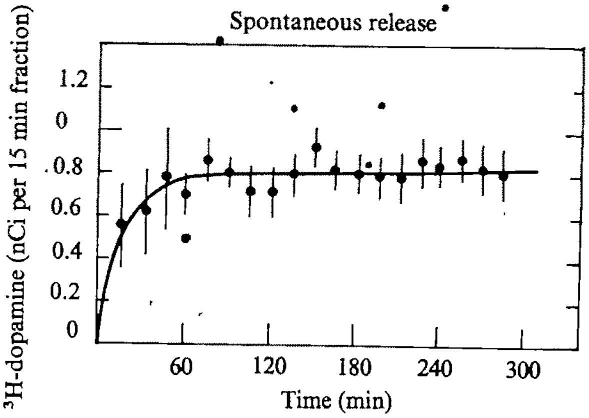

Fig. 1 Spontaneous release of ^{3}H-dopamine from substantia nigra in halothane-anaesthetised cat ^{3}H-dopamine was estimated in serial superfusate fractions (15 min each) collected from a push–pull cannula during the continuous local superfusion of the left substantia nigra with an artificial CSF containing L-3,5-^{3}H-tyrosine (20–25 μCi per 500 μl for 15 min) in halothane-anaesthetised cats Data represent mean ± s e m of results obtained in four experiments

We attempted to demonstrate that various treatments could influence the spontaneous release of endogenously synthesised ^{3}H-dopamine in the substantia nigra When potassium (30 mM) was introduced for 15 min on the CSF, the release of ^{3}H-dopamine was markedly enhanced This stimulating effect was of short duration, the qualities of ^{3}H-dopamine released returned to the steady-state value as early as 15 min after the end of the potassium application (Fig 3A)

(D)-amphetamine and benztropine markedly enhanced the release of ^{3}H-dopamine synthesised from L-3,5-^{3}H-tyrosine in the caudate nucleus[8–10] by stimulating the transmitter release and inhibiting its reuptake It was therefore of interest to determine whether these drugs were exerting similar effects in the substantia nigra, rich in dopaminergic dendrites Both drugs, introduced for 15 min into the superfusing fluid immediately enhanced the transmitter release. The effect was of short duration with (D)-amphetamine, but persisted with benztropine even though the drug had been removed from the artificial CSF (Fig 3*b* and *c*)

These results provide the first direct demonstration of the spontaneous and evoked release of dopamine endogenously synthesised in the substantia nigra in physiological states It can be assumed that the transmitter is released from dendrites, as suggested initially by Bjorklund and Lindvall[3] on the basis of

Table 1 Effects of TTX on ^{3}H-dopamine release from caudate nucleus and substantia nigra of the cat

Structure		n	nCi per 15 min successive fractions 0–15 min.	15–30 min	30–45 min	45–60 min

histochemical studies. Indeed, these authors observed a dopamine-containing varicose dendritic network well organised in the pars reticulata of the rat substantia nigra. Our results confirm and extend the *in vitro* findings of Geffen *et al.*[5] and Cuello and Iversen[4]. ^{3}H-dopamine release was not only enhanced by potassium, but also by drugs affecting the release and/or re-uptake of dopamine in nerve terminals. It seems that dopamine released from dopaminergic dendrites can be partly inactivated by a potent re-uptake process, as observed in nerve terminals. The presence of an active dopamine uptake process in dendrites has already been suggested in biochemical[5], histochemical[3] and autoradiographic studies[11,12]. Exogenous dopamine can be taken up in slices of the rat substantia nigra[4] and visualised in dendrites[3]; labelled dopaminergic dendrites were seen after an intraventricular[11,12] or local injection of ^{3}H-catecholamines[4]. The dopaminergic dendrites contain tyrosine hydroxylase as indicated by a recent

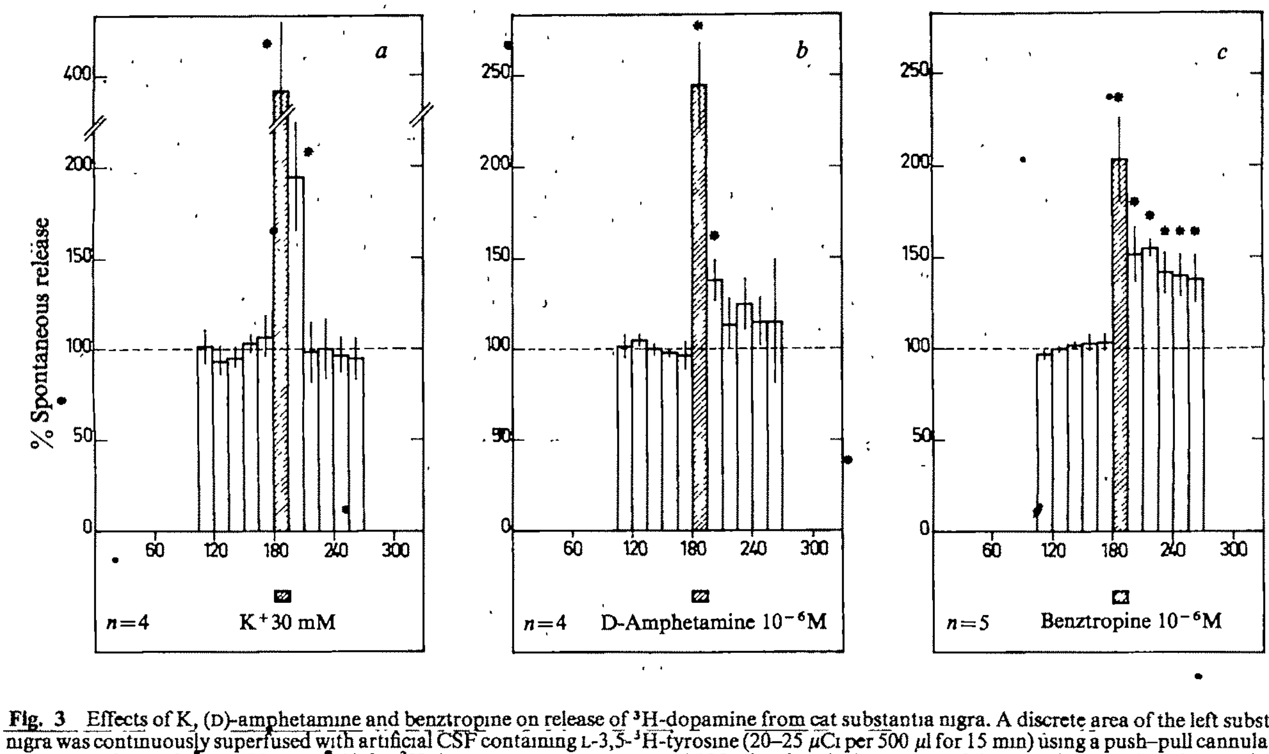

Fig. 3 Effects of K, (D)-amphetamine and benztropine on release of ^{3}H-dopamine from cat substantia nigra. A discrete area of the left substantia nigra was continuously superfused with artificial CSF containing L-3,5-^{3}H-tyrosine (20–25 μCi per 500 μl for 15 min) using a push–pull cannula The collection of superfusates (15 min each) for ^{3}H-dopamine estimation started 105 min after the beginning of the superfusion. Three hours after the onset of the superfusion, K (30 mM), (D)-amphetamine (10^{-6} M) or benztropine (10^{-6} M) was added for 15 min (hatched bars) to the medium introduced into the substantia nigra In each animal, ^{3}H-dopamine in each successive fraction was expressed as a percentage of an average spontaneous release calculated from the five fractions collected before the drug application (105–180 min). Data are mean ± s.e.m. of results obtained with groups of *n* animals *$P<0.05$ when compared with corresponding control values obtained in four animals.

immunohistochemical study[13]. Our results suggest that the local rate of the transmitter synthesis is important and can efficiently supply the release process. In fact, the steady-state level of ^{3}H-dopamine synthesised from L-3,5-^{3}H-tyrosine was reached even faster than in the caudate nucleus[8]

The push–pull cannulae used allowed the superfusion of an area of approximately 2.6 mm^3. Therefore, ^{3}H-dopamine released could originate from the pars reticulata as well as from the pars compacta. It cannot be excluded that ^{3}H-dopamine is partly released from dopaminergic cell bodies or axonal collaterals, or even from hypothetical dopaminergic intrinsic neurones In any case, the release of dopamine at the level of the substantia nigra seems to be somewhat different from that observed in nerve terminals. This could be shown using tetrodotoxin (TTX). By blocking sodium channels, TTX suppressed the nerve impulse flow and subsequently the release of transmitters from nerve terminals. Thus, when TTX was introduced into the CSF superfusing the caudate nucleus, the release of ^{3}H-dopamine was reduced by about 50%, as shown previously[8]. Surprisingly, an opposite effect was observed when TTX was introduced into the substantia nigra In most superfusate fractions, the release of ^{3}H-dopamine was significantly increased (Table 1). This original finding may be interpreted as follows: TTX, by blocking nerve impulse flow in afferences, may suppress tonic inhibitory influences on the activity of dopaminergic neurones. It obviously cannot suppress, however, the release of dopamine from dendrites as seen in nerve terminals, since ^{3}H-dopamine release was increased in the presence of TTX. Therefore, it may be suggested that dopamine release from dendrites is not impaired by blocking sodium channels.

Dopamine released into the substantia nigra seems to have a physiological role. On the basis of microiontophoretic electrophysiological studies, Aghajanian and Bunney[14] postulated that the amine inhibits the activity of dopaminergic cells by acting on dopaminergic autoreceptors This dopamine effect is supported by recent experiments using our cat preparation. Dopamine (10^7 M) introduced into the substantia nigra inhibited the release of newly synthesised ^{3}H-dopamine in the ipsilateral caudate nucleus[15]. This effect was also observed with concentration of (D)-amphetamine and benztropine similar to those used in the present study. Since dendrodendritic contracts have been observed in the substantia nigra[4,16], it can also be speculated that dopamine released from dendrites may affect the activity of neighbouring dopaminergic neurones: lateral inhibition is a process which has been extensively described by neurophysiologists[17] Finally, a dopamine-sensitive adenylate cyclase has been found in the substantia nigra[18–20], particularly in the pars reticulata[20]. Lesion studies have indicated that this adenylate cyclase system is not located in dopaminergic neurones but on descending neuronal afferents[20] which are presumably GABA-ergic or substance P-ergic[4]. The dopamine postsynaptic receptors associated with this dopamine-sensitive adenylate cyclase could be influenced by dopamine released from dopaminergic dendrites It can thus be postulated that local interneuronal feedback processes participate in the control of the dopaminergic neuronal activity Dopamine released *in vitro* from dopaminergic dendrites may modulate nigral afferents at a presynaptic level

High affinity uptake of glutamate in terminals of corticostriatal axons

GLUTAMIC ACID (glu) may be the transmitter of a large proportion of excitatory synapses in the brain[1], but glu is also important in cell metabolism, and the apparent lack of biochemical 'markers' associated with the role of glu as a synaptic transmitter has until recently hampered the localisation of potential 'glutamergic' neurones. High affinity uptake of glu[2,3] is, however, highly specific[3] and seems to be selectively localised in the excitatory granular cell terminals in the cerebellum[4], and in three systems of excitatory nerve endings in the hippocampal formation, as shown by autoradiography[5] and quantitative measurements[6]. In the conditions used in these studies, glial uptake of glu[7,8] was found not to be quantitatively important. In the hippocampal systems, iontophoretic studies[9] and release experiments[10] strongly suggest that glu, and/or aspartic acid (asp), may be the transmitter. It thus seems that high affinity uptake of glu may be useful as a marker for putative glutamergic and/or aspartergic nerve endings. The question of whether the uptake of [^{3}H]glu, as measured *in vitro,* represents net accumulation or homoexchange[11] is not crucial in the present context. The neostriatum (nucleus caudatus–putamen) receives a large excitatory projection from the neocortex[12,13]. Iontophoretic studies suggest that this could use glu or asp as its transmitter[1,14]. We here demonstrate that high affinity uptake of glu is selectively reduced in the neostriatum after lesions in the neocortex.

Male Wistar rats (250 g) were used. The frontal cortex, between the frontal pole and the frontoparietal suture, was removed down to white matter by suction through a fine needle under microscopic guidance. In sham-operated animals the skull was opened, but no lesion made; unoperated controls were only anaesthetised. After 7 or 14 d the animals were decapitated and frontal slices (about 1 mm) of the brains were prepared in the cold on a Sorvall tissue sectioner. The caudatus–putamen (avoiding the nucleus accumbens) was dissected from the rostral 1–2 slices containing the nucleus to obtain samples receiving cortical afferents predominantly from the lesioned part of the cortex[12]. Histological preparations from other operated animals showed that the caudatus–putamen was not directly damaged by the lesions. The dissected samples were weighed on a Mettler microbalance and homogenised in 50 volumes 0 32 M sucrose solution with 5 mM Na phosphate buffer, *p*H 7.4, in a glass-Teflon homogeniser, to produce suspensions containing nerve ending particles.

High affinity uptakes of glu and γ-aminobutyric acid

Table 1 Selective reduction in high affinity uptake of glu in neostriatum after cortical lesions

Sample	n	Uptake of glu	Uptake of GABA	glu decarboxylase	Choline acetyltransferase	DOPA decarboxylase
L	6	113±12*	30±3	1,970±180	3,590±210	863±72
N	6	193±14†	34±3	1,740±120	3,580±310	870±118
C	7	239±10	32±2	1,800±160	3,480±370	913±53

Results are presented as nmol/min/g protein±s.e.m. of n samples.
L and N, lesioned and contralateral side, respectively, in operated animals; C, right and left sides in sham-operated (2) and unoperated animals (2).
*$P < 0.001$ compared with C; $P < 0.005$ compared with N (Student's t test, both tails).
†$P < 0.025$ compared with C. Other differences were non-significant ($P > 0.2$).

(GABA) were measured by incubating 5 µl homogenate with 500 µl Krebs–phosphate solution at 25 °C for 3 min[6]. The reaction was started by adding 50 µl Krebs solution containing L-[3-^{3}H]glu (New England Nuclear, Boston, Massachusetts, 15.8Ci mmol^{-1}, diluted with unlabelled monosodium glutamate to give a specific radioactivity of 1.14 Ci mmol^{-1}) and [U-^{14}C]-γ-aminobutyric acid (Radiochemical Centre, Amersham, UK, 224 mCi mmol^{-1}) to give final concentrations of 1 µM. Separate studies have shown that GABA and glu do not interact with each other's uptake in such conditions[2,15]. After incubation the samples were diluted with 4 ml ice-cold 0.9 NaCl, collected on Millipore filters (0.45 µm), and rinsed with another two portions of 4 ml NaCl. The filters were eluted in 1.2 ml 10% Triton X-100 and counted with 10 ml Diluene (Packard) in a Packard liquid scintillation spectrometer (model 3380) fitted with an absolute activity analyser (model 544) giving d.p.m. for ^{3}H and ^{14}C separately. Samples incubated at 0 °C, but otherwise treated identically, served as blanks. Experimental and control samples were run together. Uptake of glu and GABA were linear with the amount of striatal tissue up to at least 100 µg wet weight. Protein[16], glutamate decarboxylase[17], choline acteyltransferase[18] and DOPA decarboxylase[19], were determined essentially as described previously.

After lesions of the frontal cortex there was a selective reduction in glu uptake in the nucleus caudatus–putamen, by 41% when the operated side was compared to the contralateral side, or by 53% compared with unlesioned animals (Table 1). The slight reduction on the side contralateral to the lesions compared with unlesioned animals is probably due to the fact that the corticostriatal projection is partly crossed[20]. The reduction in glu uptake on the lesioned side was somewhat larger at 14 d (64% reduction compared with intact controls, 2 animals) than at 7 d survival time (49% reduction, 4 animals), but the results were pooled in Table 1. The lack of change in GABA uptake suggests that the reduction is not due to an unspecific interference with uptake processes. The absence of change in markers for alleged GABAergic (glu decarboxylase, GABA uptake), cholinergic (choline acetyltransferase) and dopaminergic neurones (DOPA decarboxylase) demonstrates that the reduction in glu uptake is not due to a general effect on neurones in the caudatus–putamen. The possibility that the selective reduction in glu uptake could be due to transsynaptic changes—for example, in other excitatory afferents—can not be completely ruled out, but seems rather unlikely.

Since the acidic amino acids, glu and asp, have similar or identical high affinity uptake systems[2,4], and since glu uptake, measured in our conditions, seems to be a useful marker for nerve endings utilising acidic amino acids as transmitters[4,6], our results suggest that the neocortico–neostriatal projection could use glu or asp as its transmitter.

We thank Ms M. Woxen for assistance.

Benzo[*a*]pyrene 7,8-dihydrodiol is more carcinogenic than benzo[*a*]pyrene in newborn mice

THE pioneering research by James and Elizabeth Miller relating the carcinogenic effects of many chemicals to the metabolism of these compounds to reactive intermediates which bind to critical cellular compoeenents[1,2] led to studies of the nature and chemical structure of these reactive metabolites (ultimate carcinogens) and their metabolic precursors (proximate carcinogens). The environmental carcinogen benzo[*a*]pyrene (BP) is metabolised by microsomal enzymes to arene oxides, phenols and dihydrodiols. Metabolic activation of the BP metabolite (±)-*trans*-7,8-dihydroxy-7,8-dihydrobenzo[*a*]pyrene (BP 7,8-dihydrodiol) by liver microsomes resulted in more binding to DNA than did the metabolic activation of BP (ref 3). The reactive metabolite involved in the binding to DNA was a *trans*-7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydro BP (BP 7,8-diol-9,10-epoxide) (ref. 4). Both stereoisomers of this diol epoxide, which are enzymatically formed from BP 7,8-dihydrodiol (refs 5–8), were highly mutagenic to bacterial and mammalian cells[9-15] suggesting that a BP 7,8-diol-9,10-epoxide might be an ultimate carcinogenic metabolite of BP. We report here that administration of BP 7,8-dihydrodiol to newborn mice caused more malignant lymphomas and pulmonary adenomas than did administration of benzo[a]pyrene. This is the first demonstration of a metabolite of a polycyclic aromatic hydrocarbon that is more carcinogenic than the parent compound

Table 1 Carcinogenic activities of BP, BP 7,8-dihydrodiol and diol epoxide-*2* in newborn mice

*Two mice with fibroma of the skin

†Two mice with skin papillomas.

‡One mouse with fibroma of the skin

Swiss Webster mice [BLU.Ha(ICR)] were injected i p with BP and BP derivatives One-seventh of the indicated total dose of hydrocarbon was given on d 1 of life, two-sevenths on d 8 and four-sevenths on d 15. Control animals were given the vehicle, DMSO. The mice were weaned when 25 d old. The data were obtained from the survivors of experiments 1 and 2 described in Fig. 1 Animals more than 25 d old which died during the course of the study and animals killed at the end of the study (when the animals were 21–24 weeks old) were subjected to histological examination A few animals which died after weaning were cannibalised and could not be examined.

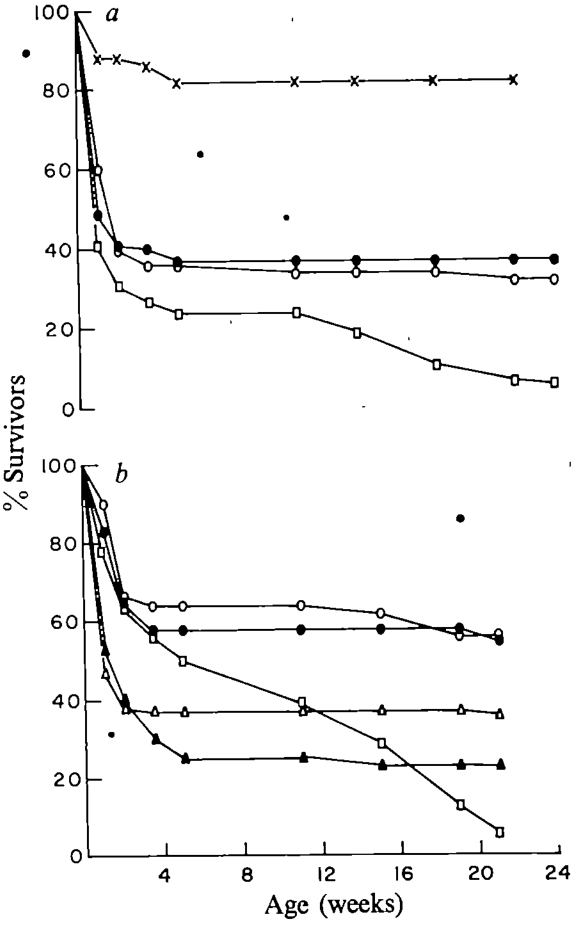

Fig. 1 Toxicity of benzo [*a*]pyrene derivatives in newborn mice Swiss–Webster mice [BLU·Ha (ICR)] were injected i.p. with BP or BP derivatives One-seventh of the total dose of each compound was given on d 1 of life, two-sevenths on d 8 and four-sevenths on d 15. In experiment 1 (*a*), 50 animals were each injected with 1,400 nmol of BP (○), 70 animals with 1,400 nmol of BP 7,8-dihydrodiol (□), 70 animals with the vehicle (DMSO) (●) and 50 animals were untreated controls (×) In experiment 2 (*b*), 50 animals were treated with the above dose of BP, 80 animals received the above dose of BP 7,8-dihydrodiol and 40 animals were given DMSO Diol epoxide-*1* (28 nmol) (▲) was injected into 40 animals, and diol epoxide-*2* (28 nmol) (△) was injected into 100 animals The mice were weaned when 25 d old.

One of the stereoisomeric BP 7,8-diol-9,10-epoxides ((±)-*trans*-7β,8α-dihydroxy-9α,10α-epoxy-7,8,9,10-tetrahydro BP; diol epoxide-*2*; also termed diol epoxide I (ref. 11) or anti-isomer (ref. 16)) produced about the same number of pulmonary adenomas as a 50-fold higher dose of BP.

BP 7,8-dihydrodiol, diol epoxide-*1* [(±)-*trans*-7β,8α-dihydroxy-9β,10β-epoxy-7,8,9,10-tetrahydro BP; also termed diol epoxide II (ref 11) or syn isomer (ref. 16)] and diol epoxide-*2* were synthesised as previously described[17,18], and all chemicals were of analytical-grade purity Pregnant Swiss–Webster BLU:Ha (ICR) mice (Blue Spruce Farms) delivered their babies within 2–5 d after arrival in our laboratory. The healthiest-looking newborns were selected, and each mother was left with 10 babies. BP and BP 7,8-dihydrodiol were dissolved in anhydrous dimethylsulphoxide (DMSO) (ref. 10) at a final concentration of 200 nmol per 5 μl. The compounds were injected intraperitoneally (i.p.) as follows: 200 nmol on the first day of life, 400 nmol 1 week later, and 800 nmol at 15 d of age. Control animals were given 5, 10 and 20 μl of DMSO using the above schedule. The newborn mouse is very sensitive to i.p. injections, and many animals died within 2 weeks following injection with the control vehicle or with the various compounds on days 1, 8 and 15 of life. The animals were weaned at 25 d of age. Large differences in survival among animals treated with DMSO, BP or BP 7,8-dihydrodiol did not occur until after the animals were 25 d old (Fig. 1). The experiments were ended 21–24 weeks after their initiation. After the initial deaths in all groups during the first 2 weeks of age, most of the remaining BP 7,8-dihydrodiol-treated animals died by 24 weeks of age, whereas most of the BP- and DMSO-treated animals that survived until weaning were still alive. Complete histopathological examination was performed on most animals (see Table 1 legend). The examination included routine study of the hematopoietic tissues and counting of macroscopic pulmonary adenomas. Seventy per cent of the BP 7,8-dihydrodiol-treated animals thus examined developed malignant lymphoma (leukaemia), which was apparently a major cause of death of these animals (Table 1). Almost all cases of malignant lymphoma were generalised with involvement of the thymus, spleen, bone marrow, lymph nodes, liver and other organs. Of special interest was the very short latency period for the development of malignant lymphoma. The first diagnosis of malignant lymphoma was made in an animal treated with BP 7,8-dihydrodiol, which died at 5 weeks of age. No cases of malignant lymphoma were recorded among the BP- and DMSO-treated animals. BP 7,8-dihydrodiol also induced pulmonary adenomas. Although the first pulmonary adenoma was found at an early age (14 weeks), induction of this type of tumour was slower than that of the malignant lymphomas. Among the BP 7,8-

dihydrodiol-treated animals which died and were autopsied between 4 and 17 weeks of age, 31% had lung adenomas, and 65% had malignant lymphomas. Among the BP 7,8-dihydrodiol-treated animals which died or were killed at the age of 18–24 weeks, 92% had lung adenomas and 75% had malignant lymphomas. The BP-treated animals also developed lung adenomas, but the number of pulmonary adenomas per animal was much lower when compared to BP 7,8-dihydrodiol-treated animals (Table 2). Only 4% of the DMSO-treated animals developed pulmonary adenomas. Three animals treated with BP 7,8-dihydrodiol developed a total of two skin papillomas and one skin fibroma. Fibroma of the skin was also found in two of the BP-treated animals. There were no significant differences in death rate or tumour incidence between male and female animals.

Table 2 Pulmonary adenomas in newborn mice treated with BP, BP 7,8-dihydrodiol and diol epoxide-*2*

Treatment	Total dose (nmol)	Sex	No. of animals	Adenomas/animal (mean ± s.e.)
Control	0	♂	32	<0.1
		♀	16	0
		Total	48	<0.1
BP	1400	♂	24	5.1±1.6
		♀	20	7.7±1.3
		Total	44	6.3±1.0

		♀	6	72±27
		Total	14	75±14
Diol epoxide-*2*	28	♂	17	2.8±1.0
		♀	20	6.8±1.1
		Total	37	4.9±0.8

Swiss–Webster mice [BLU.Ha (ICR)] were injected with BP and BP derivatives (Fig 1, Table 1) Animals that were killed at the end of the study, at 21–24 weeks of age, were used for determination of the number of adenomas per lung.

In a preliminary experiment, newborn mice were injected separately with each of the two diastereomers of BP 7,8-diol-9,10-epoxide (diol epoxide-*1* and diol epoxide-*2*). These compounds were very toxic, and 80–90% of the animals died within 48 h after a single injection of 200 nmol of diol epoxide-*1* or -*2*. A reasonable survival of animals was achieved only after decreasing the dose of these diol epoxides to 2% of the dose of BP or BP 7,8-dihydrodiol. Four nmol of diol epoxide-*1* or -*2* was given on d 1 of life, 8 nmol on d 8 and 16 nmol on d 15. However, this dose of diol epoxide was still more toxic to the animals than a 50-fold higher dose of BP or BP 7,8-dihydrodiol (Fig. 1, experiment 2). The experiment was ended when the mice were 21 weeks old, and lung adenomas were found in 81% of the animals treated with diol epoxide-*2* (Table 1). For diol epoxide-*2*-treated animals which had survived until weaning, about the same incidence of pulmonary adenomas had occurred as with a 50-fold higher dose of BP (Table 2) Diol epoxide-*2* did not induce malignant lymphomas in the newborn mice Diol epoxide-*1* was more toxic than diol epoxide-*2* in the newborn mice (Fig 1 and unpublished observations), and there were not enough survivors available for determining the carcinogenicity of diol epoxide-*1*. Additional studies are now in progress to determine the comparative carcinogenicity of these two diol epoxides of BP.

Studies on the carcinogenicity of BP metabolites on mouse skin showed that BP 7,8-oxide was carcinogenic[19] and that BP 7,8-dihydrodiol was a more potent carcinogen than BP 7,8-oxide (ref 20). H_4-BP 7,8-epoxide, however, which is related to BP 7,8-oxide but lacks the double bond in the 9,10-positions of the molecule, did not show any carcinogenic effect, suggesting that a BP 7,8-diol-9,10-epoxide might indeed be an ultimate carcinogenic metabolite of BP Since these earlier studies with BP 7,8-dihydrodiol and BP were performed with doses which were at the top of the dose–response curves, no conclusion was reached as to whether BP 7,8-dihydrodiol was more carcinogenic than BP. Our results here indicate that BP 7,8-dihydrodiol is a more potent carcinogen than BP when injected into newborn mice and is therefore a proximate carcinogenic metabolite of BP. Diol epoxide-*2*, a very potent mutagen derived from BP[10–12], has the same carcinogenicity as BP at a 50-fold lower dose in newborn mice. The extremely high carcinogenic activity of diol epoxide-*2* suggests that it is an ultimate carcinogenic metabolite of BP.

We thank Drs Norio Hirota and Gary Williams and the staff of the Naylor Dana Institute for Disease Prevention, American Health Foundation, Valhalla, New York, for the histological studies. We thank Mrs Mary Ann Augustin and Mrs Arlene Ott for their assistance in the preparation of this manuscript.

Lunar and meteoritic palaeomagnetism: common origin contested

BANERJEE and Mellema[1, 2] (BM) have suggested that both the lunar crust and the primitive carbonaceous chondrites (CC) have been magnetised simultaneously by strong ($\lesssim 1$ Oe) magnetic fields associated with an early T-Tauri active phase of the Sun. Here I argue that this conclusion is untenable. Their basic premises are, first, similar ages of, and, second, comparable palaeofield strengths for, lunar rocks and CC.

The CC and their constituents are among the oldest solar system objects dated thus far[3-7] ($\sim 4.6 \times 10^9$ yr). Sensitive ^{129}I chronometry revealed sharp isochronism for CC magnetite formation (within 2×10^6 yr) and indicated rapid aggregation and brief metamorphism, lasting at most 1 Myr (ref. 5). An upper limit on the duration of a precompaction irradiation episode of CC component grains (by solar wind and solar flares) was recently estimated at < 4.5 Myr, but typically $\lesssim 1$ Myr, at nominal heliocentric distances of 10 AU (ref. 8). These and the enrichment of solar-wind implanted gases in CC magnetite[9] strongly support my earlier suggestion that an enhanced early solar wind, convecting strong magnetic fields[10], could account well for several observed magnetic features of CC[11]. Moreover, recent results on the electrical properties of CC[12] seem to link their magnetic and thermal history satisfactorily in the framework of solar-wind induction heating of asteroids with carbonaceous surfaces, which at present dominate by number in the main-belt[13]. Observations of young active stars[14] and calculations of 'T-Tauri lifetimes' for $\sim 1 M_\odot$ stars[15,16] show that an epoch of intense mass loss for an evolving Sun could have lasted 1–10 Myr. This is compatible with the above chronology of CC, but raises a major difficulty for BM in the case of lunar rocks.

First, the early chronology of lunar crust differentiation cannot be similarly established due to an early intense bombardment, which lasted up to $\sim 3.9 \times 10^9$ yr ago and led to its extensive brecciation and metamorphism[17]. Second, since BM assume implicitly that lunar rocks carry a thermoremanence (TRM) acquired at cooling in an external magnetic field, it is reasonable to date it by the crystallisation ages of lunar basalts and breccias, which range from ~ 3.3 to $\sim 4 \times 10^9$ yr (ref. 17). This requires an excessively long (0.6–1.3×10^9 yr) active phase for maintenance of strong fields. Also, it is unlikely that an older magnetisation (4.6×10^9 yr) has survived the violent impact metamorphism of the ancient lunar crust[17]. Furthermore, a strong case was recently made for excluding any external source field for globally magnetising the ancient lunar crust[18, 19], so that the BM suggestion is weakened on both theoretical and observational grounds.

Table 1 Palaeofield intensities from carbonaceous chondrites

Meteorite (type, subtype)	Palaeofield (Oe)	pTRM (T °C, H Oe)	NRM fraction matched	NRM type	Ref.
Orgueil (I, C1)	0.67	(120, 0.5)	$T_B < 73$ °C	TRM	21
	0.02	(250–120, 0.5)	$120° < T_B < 250$ °C	CRM	21

	1.09(0.96–1.23)	(110–130, 0.5)	$20° T_B < 130$°C	TRM	21
	1.1(0.93–1.3)	(150, 0.59)	$30 < T_B < 150$°C	TRM, TCRM	22

H_{AF}<peak alternating field value which gives microcoercivity of remanence; T_B, blocking temperature; (p) TRM, (partial) thermoremanent magnetisation; TCRM, thermochemical remanence; CRM, chemical remanence; DRM, depositional remanence.

The claim that comparable paleaofield estimates of $\lesssim 1$ Oe for lunar rocks and CC should be taken at face value can also be challenged. Before discussing palaeointensities we must be concerned with the presence of a demonstrably ancient NRM component. CC evidence looks quite convincing[11,20-22], but it is still doubtful that any lunar rocks have preserved an indigenous palaeoremanence[23, 24]. The mechanism by which this NRM was imprinted is also at issue: the CC are compositionally the most primitive and thermally the least altered extraterrestrial samples known. Their NRM is admittedly a low temperature magnetisation, although detailed interpretations differ[11,21,22] (Table 1). In contrast, most lunar rocks for which palaeointensities have been obtained are thermally and mechanically modified by impacts.

It is even doubtful whether lunar rocks are capable of acquiring TRM in the conventional sense[26, 27].

In this light, the fact that entirely different experimental techniques have yielded similar values for the ancient field strength (~1 Oe) in several CC[11, 20] (Table 1) inspires confidence in their validity. In contrast, the lunar palaeointensity determinations are notoriously controversial[23,25–27]. Some of the new techniques used (refs 25, 28, 29) are not yet established even for terrestrial rocks, whose magnetic mineralogy is more familiar and better understood. Banerjee and coworkers fuelled the debate with 'reliable' palaeofield estimates of ~0.01 Oe for three Apollo 15 basalts[28, 29], including one (15535) which they had earlier shown to contain no useful remanence at all[30,31]. Their later work on an Apollo 17 foliated breccia boulder produced no less than three distinct sets of paleointensities (0.18–0.74 Oe)[32, 33], differing significantly both within and between adjacent foliation layers. These and divergent directions of 'stable' palaeoremanence forced the conclusion that the lunar magnetising field must have changed considerably both its direction and its intensity during the assembly of this 2-m boulder 4.0 × 10⁹ yr ago. It seems more plausible to argue that the magnetic data are not internally consistent, or to ascribe the magnetic behaviour of breccias to textural effects of compaction shock[24].

Another corollary to the BM hypothesis is that similar palaeofield strengths imply a common source for lunar rocks and CC. Such reasoning could lead to the fallacious conclusion that the oldest (3.85 × 10⁹ yr) terrestrial rocks were also magnetised by extended solar wind fields. Within the BM context, comparable magnetic field strengths imply that the Moon and the carbonaceous meteorites condensed and accreted at the same heliocentric distance, in contradiction to most current chemical nebular models[34]. If the CC have originated in the asteroid belt[13] (3–5 AU), whereas the Moon accreted near 1 AU, the present radial dependence of the solar wind magnetic fields would require at least 3–5 Oe for a tightly wound spiral configuration, but up to 10–25 Oe for radial flow. These values are high even by the currently inflated lunar-magnetic yardstick.

A. BRECHER

Department of Earth and Planetary Sciences,
Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139

BANERJEE REPLIES—There was one major point that we had wanted to make in our original communication[1]. Before, and even since the publication of our note, there have been no lunar palaeointensity experiments in which, first, a direct, thermal method had been used on three sub-samples from one rock and, second, magnetic monitoring by Anyhsteretic Remanent Magnetization (ARM had been carried out on the samples before and after the heating. In spite of the well-known magnetic variability of lunar samples, as underlined by Dr Brecher[2], what was amazing to us was that our three samples were magnetised homogeneously enough to yield an average palaeointensity of 0.4 Oe with a s.d. of about 40%. In contrast, in the lunar palaeointensity measurements, the highest reliability that one usually hopes to achieve is the order of magnitude of the field!

Our second point was that if the palaeointensity was indeed of the order of 0.4 Oe at about 4.0 × 10⁹ yr (the average radiometric age of the rock), and if the field was internally generated from the Moon, the Sonnett and Runcorn[3] dynamo in a small, early lunar iron core could be the only plausible internal source. We then drew attention to the similarity of the size of this field to that postulated earlier for carbonaceous chondrites (age ~ 4.4 × 10⁹ yr) by us[4], and by Dr Brecher[6]. I agree wholeheartedly with her that "the fact that entirely different experimental techniques have yielded similar values for the ancient field strength (~1 Oe) in several CC (carbonaceous chondrites) inspires confidence in their validity. In contrast, the lunar palaeointensity determinations are notoriously controversial". But, we have done our best in searching for better methods, used multiple subsamples and published the details of our technique[6]. Our interpretation, and that of any other groups of scientists, must necessarily be a function of our knowledge at the time of writing. None of the references quoted by Brecher can convince anyone that "it seems more plausible to argue that the magnetic data (that is, the data of refs 1 and 6) are not internally consistent", specifically when such a search for internal consistency of palaeointensities has not been undertaken.

Our hypothesis that both the meteorites and the ancient lunar samples could have been magnetised by external solar fields is admitted by the fact that the upper limit T-Tauri phase solar wind pressure would correspond to a magnetic pressure of the order of a few Oe at 1 AU. But, as we pointed out, whether this was actually so cannot be proved without more extensive and reliable data on both meteorites and lunar samples. We had also suggested that the apparently large (0.4 Oe) field could be the result of a smaller ambient solar field, magnetohydrodynamically amplified by plasma dynamos operating on the lunar crust during the intense collisioning stage, at and before 4.0 × 10⁹ yr. I am sure there are others who could think up more alternative explanations. The purpose of our communication was to alert other workers about the existence of our data and to encourage them to think of plausible models.

Digynic triploidy after superovulation

DIGYNIC triploidy after superovulation in mice reported by Takagi and Sasaki[1] may be closely related to the aging of eggs at fertilisation rather than superovulation through the administration of exogenous gonadotrophins. It is well known that the fertile life of eggs after ovulation is about 10 h and that ageing of eggs results in a decrease of fertilisation rate, an increased incidence of abnormal fertilisation and subsequent degeneration of embryos. Suppression of the second polar body formation resulting in digynic fertilisation occurs when eggs age in the hamster[3], mouse[3] and other species[4]. Since the ovulation of a large number of eggs is not expected to occur simultaneously and the time of ovulation for each individual egg would be more spread out during superovulation than after normal ovulation, the chances of delayed fertilisation and digynic triploidy would be higher after superovulation than normal ovulation. Most of the fertilised eggs from superovulated rabbits, however, can develop into normal young after transferring them to several recipient rabbits[5].

Nitrate reductase as predictive test of crop yield

THE report of Johnson, Whittington and Blackwood[1] on using nitrate reductase as a predictive test of crop yield is probably valid but there are several problems with both the *in vitro* and *in vivo* assay they used which deserve attention.

The maximal *in vitro* activity shown in Fig. 1 of ref. 1 is about 0.1 μmol g^{-1} h^{-1}, a value considerably lower than the activities (~10–12 μmol g^{-1} h^{-1}) commonly observed in leaves of wheat[2-4]. The disparity is so large as to cause concern about the assay procedure. Although the latter activities were obtained without casein in the extraction medium it is conceivable that the inordinately low activities obtained by Johnson *et al.* were partially due to failure to protect nitrate reductase from a constitutive serine protease which rapidly degrades nitrate reductase *in vitro*[2,5,6]. In *Escherichia coli* a serine protease acts to remove nitrate reductase from membranes[7] and in higher plants this may be a reason why its half life is in the order of 2–4.2 h (refs 8, 9). Incorporation of casein or phenylmethylsulphonylfluoride (PMSF) into the extraction media[5,6] obviates this protease activity and yields activities approximately 100 times[10,11] those reported by Johnson *et al.* Therefore, if *in vitro* nitrate reductase activity is to be used as a predictive assay, it should be assayed as described above to avoid complications resulting from differential degradation during extraction.

The problem with the *in vivo* assay of nitrate reductase is also serious. This assay may or may not be proportional to the *in vitro* activity[12,13], but typically represents only about 20% of the *in vitro* activity[13]. Also, the electron donor for the *in vivo* assay has never been identified, nor is it clear that the electron donor *in situ* is identical to that which serves in the conditions employed in the *in vivo* assay. Therefore, it seems unwise to use this assay to estimate any parameter associated with nitrate assimilation unit it is established exactly what the *in vivo* assay is measuring.

JOHNSON *et al.* REPLY—While a number of interesting points are raised by Butz, it is difficult to see why his criticisms are directed specifically at our work. In any study where enzyme activities are measured either *in vitro* or by the so-called *in vivo* assays it is difficult to state categorically whether or not the measured rates reflect accurately the true activities of the enzymes within the cells. The essential point surely is that our experiments[1] and in the many experiments from Hageman's group in Illinois[2,3], a correlation has been shown between nitrate reductase activity as measured, and the yield of a crop. For such a correlation to be valid or useful the precise biochemical basis is not necessarily important. In this case, however, the correlation does provide valuable evidence that the enzyme activity measured is related to the process of nitrogen metabolism.

Some of the points raised by Butz do require some further comment. First, the references to the work of Schrader *et al.*[4,5] are misleading. In their investigations the improvement in nitrate reductase activity obtained using casein was strongly dependent on the type and age of the tissue employed. With the youngest leaf tissue (similar to that used in our study) the improvement was only 10% compared with the 100-fold quoted. This latter value was obtained only with old tissue of one particular variety of maize and cannot be considered in any way typical. In our investigation some of the *in vitro* wheat nitrate reductase assays were duplicated with *in vivo* assays. These gave substantially similar results. Casein is nevertheless a useful protector of nitrate reductase *in vitro*, although it is by no means the most effective one in all tissues.

Second, Butz speculates that the protease which attacks nitrate reductase does so by removing the enzyme from membranes. This seems unlikely as neither in *E. coli* nor, judged by the majority of the available evidence[6], in higher plants is assimilatory nitrate reductase membrane bound.

Third, in view of the problems known to be associated with the *in vitro* assay of nitrate reductase, of which those referred to by Butz are by no means all, it seems to us unwise to criticise an *in vivo* merely because it sometimes produces results differing from those obtained with an *in vitro* procedure. The fact that the electron donor is not known does not seem important in this context. Recent reports of differences between results obtained using the two procedures may have obscured the fact that in the majority of cases very similar results are obtained with both methods. For example, Hageman's group[3] showed a correlation of 0.99 between *in vitro* and *in vivo* assays of nitrate reductase in several varieties of wheat. Furthermore, a good correlation was obtained between nitrate reductase activity and nitrogen assimilation, thus confirming our observations.

Control of feline leukaemia virus

HARDY *et al.*[1] report the success of a programme for preventing spread of feline leukaemia virus (FeLV) among pet cats by screening for FeLV viraemic individuals, removal of carriers and quarantine of contacts. Although evidence that the programme was of some success seems strong, the study's methodology deserves comment. Major problems concern the comparisons between 'treated' and 'untreated' groups.

(1) The groups were 'self-selected' by owners. Though it is probable that pet owners' responses to such a programme reflect different approaches to the care of pets, we are given no information on the cluster-size distribution, location, management, sex or age structures of the groups—though each such variable has major implications for the spread of an infectious agent.

(2) The only information given as to the previous status of the groups is that the treated group had a lower initial prevalence rate of FeLV carriers than did the untreated control (0.224–0.312). This indicates that the treated group was at a lower risk of infection even before the programme and thus it is improper to attribute subsequent differences in incidence rates to the programme alone.

(3) The report of a 0.193 incidence rate in the untreated group over three months is surprising, as it implies an annual incidence rate of $1.0-(1.0-0.193)^4$ or 0.576, which is far higher than the prevalence rate in either group—though the authors claim that most viraemic cats remain viraemic for life, they report a low natural mortality rate for viraemic individuals and they make no reference to reversions to virus negative among the untreated group cats.

(4) The programme entailed both removal of viraemic individuals and also quarantine of contacts. As neither action was imposed upon the untreated group it is improper to attribute the lowered incidence rate to removal of FeLV carriers alone.

(5) Mortality 'rates' are given without reference to time period or to background mortality among 'uninfected' cats. Without such references they are uninterpretable.

(6) The authors' conclusion that infection in most cats occurred between 18 and 24 months of age does not follow logically from their data on median ages—and, if it did, it would emphasise the necessity to adjust for age when comparing incidence and mortality rates. No such adjustments have been made.

The implications of Hardy *et al.*'s study are important. Though some of the problems mentioned here may have arisen due to the demands of brevity in publication, it should be stressed that such studies deserve a careful methodology. This is especially true in the context of current interest in the epidemiological implications of oncornaviruses.

P. E. M. FINE

Ross Institute,
London School of Hygiene and Tropical Medicine
Keppel Street,
London, UK

---

[1] Hardy, W.D. *et al.* Nature 263, 326–328 (1976).

HARDY AND MCCLELLAND REPLY—We agree with Dr Fine that a 42-fold decrease in feline leukaemia virus infection (FeLV) in the households which implemented our FeLV test and removal programme is evidence that our programme was successful[1]. Our study was not a strict epidemiological survey, indeed, an epidemiological study of lymphosarcoma in cats failed to detect the contagious nature of the disease[2]. But, we would like to answer Dr Fine point by point.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

(1) All the owners were given the same advice regardless of whether or not they chose to have their infected cats removed. The management of the households was the same for both groups and the average number of cats per household (Fine definition of cluster) in those households in which the cats were removed was 16.6 cats per household while in the other group it was 16.5 cats per household (Table 2, ref. 1). Households in both groups were located throughout the USA. The two groups are thus quite comparable.

(2) Although it is true that the initial FeLV infection rate of the two groups was different, the difference in the rates of FeLV infection between the two household groups after our programme had been implemented was much greater and was statistically highly significant ($P<0.001$).

(3) Dr Fine should not assume that the FeLV infection rate of 19.3% in the first 3 months will be perpetuated. The infection rate decreases because, as we reported, approximately 41% of the exposed cats in a household develop protective FeLV neutralising antibody titres though they never test positive for FeLV. We reported previously that 33% of healthy exposed cats became FeLV infected[3]. This figure was the result of a single sampling of many households in which the cats had been exposed to FeLV for varying periods of time. In some households, 100% of the cats were infected, while in others only 10% were infected, which shows that the FeLV infection rate can vary greatly. In contrast to Dr Fine we do not think that our observed mortality rate of 52% for secondarily infected cats and 8.5% for first test FeLV uninfected cats is low. With regard to his other points in this area; most cats do remain viraemic for life and reversions happened only rarely among the cats in this study.

(4) Both groups of households were quarantined as referred to in refs 13 and 16.

(5) The observation period for the study was 2 y, as mentioned in the paper[1].

(6) The median age of cats which became infected with FeLV was simply our observation on 49 cats—we did not make any conclusions about age susceptibility of pet cats in the general population.

In conclusion, we would like to add that removal of the carrier host is a common method for controlling and preventing the spread of many infectious veterinary diseases when vaccination is not available. For instance, bovine tuberculosis, brucellosis, foot and mouth disease, hog cholera, African swine fever, vesicular exanthema, rinderpest and glanders are controlled by test and removal programmes. Thus, the concept of preventing the spread of the contagious feline leukaemia virus by a similar programme should not, we think, be difficult to accept.

Announcing a new Series

Development in Mammals

an advanced, informative and critical work of reference.

DEVELOPMENT IN MAMMALS, Vol. 1.

edited by MARTIN H. JOHNSON, *Lecturer in Anatomy, University of Cambridge, Cambridge, U.K.*

1977. viii + 386 pages. US $ 34.50/Dfl. 84.00. ISBN 0-7204-0631-5

The study of development in mammals is in the process of transition from the essentially descriptive approaches of classical embryology to the sophisticated experimental approaches of contemporary molecular and cellular biology.

This volume, the first in a new series which attempts to record the developments, problems and controversies arising during this exciting growth phase, is devoted primarily to consideration of preimplantation stages of development and to the interaction between embryo and maternal uterus. The titles of contributions reflect the diversity of interests involved in the study of development. Many of the authors are either younger scientists making new contributions to the study of mammalian development or established scientists contributing chapters in areas in which they have only recently started working and developing interests.

This judicious mix of experience and freshness of approach has produced a stimulating, controversial but authoritative volume which will be of great value to workers and students actively interested in the subject of mammalian development. Rapid publication has ensured the availability of up-to-date technical and theoretical data.

CONTENTS: Development in Mammals *(M. H. Johnson).* Surface Changes of the Developing Trophoblast Cell *(T. Ducibella).* Transport Processes in the Mammalian Blastocyst *(R. M. Borland).* Protein Synthesis and Gene Expression in Preimplantation Rabbit Embryos *(G. A. Schultz and E. B. Tucker).* RNA Polymerase Activity in Preimplantation Mammalian Embryos *(C. M. Warner). Effects of Anaesthetic Agents* on Eggs and Embryos *(M. H. Kaufman).* The Role of the Endometrium in Blastocyst Implantation *(J. E. O'Grady and S. C. Bell).* Cellular and Molecular Approaches to Blastocyst Uterine Interactions at Implantation *(M. A. H. Surani).* Embryonic Diapause *(R. J. Aitken).* Hormonal Control of Uteroglobin Biosynthesis *(M. Beato).* **Subject Index.**

Details of Volume 2 can be obtained from the Publisher.

HYPERTENSION

Two Key Books

Hypertension and Brain Mechanisms

edited by W. DE JONG, A. P. PROVOOST *and* A. P. SHAPIRO

PROGRESS IN BRAIN RESEARCH, Vol. 47

1977. about 380 pages.
US $ 57.95/Dfl. 142.00. ISBN 0-444-41534-3

This book contains contributions by over forty international authorities on the control of arterial blood pressure by the brain. These centre on three main areas: 1) integration of neuroanatomy, neurophysiology and neurotransmission of the central nervous system in relation to cardiovascular control and emotional behavior in man and animal; 2) brain damage, i.e. infarction, blood flow disturbances, stroke, etc, resulting from hypertension and vice versa; 3) evaluation of brain mechanisms in drug and non-pharmacological treatment of hypertension, including bio feedback, relaxation techniques and the role of the social environment.

The wide scope of this book makes it of interest to researchers concerned with hypertension as well as to those engaged in its treatment. It will be of great value to clinicians, physiologists and pharmacologists and also to neurologists and psychologists.

CONTENTS: Neuroanatomy and neurophysiological mechanisms of central cardiovascular control. Neurotransmission in relation to cardiovascular control. Brain damage and hypertension: experimental and clinical. Integrated brain function and hypertension. Pharmacological aspects of central acting antihypertensive drugs and influence on peripheral effector mechanisms. Subject Index.

Control Mechanisms in Essential Hypertension

by W. H. BIRKENHÄGER *and* M. A. D. H. SCHALEKAMP

1976. xviii + 182 pages.
US $26.75/Dfl. 65.00. ISBN 0-444-41452-5

from the introduction

"Professor Birkenhäger and Dr. Schalekamp have themselves made great contributions to knowledge by their wide researches into haemodynamic, renal, functional and humoral influences in essential hypertension. They are particularly fitted therefore to collate the rapidly expanding corpus of world knowledge in this field and this they have done with commendable fairness and critical appraisal."

CONTENTS: Blood pressure as a variable. Systemic haemodynamics. Renal haemodynamics and renal function. Body fluids in essential hypertension. The adrenergic system in essential hypertension. Renin, angiotensin and aldosterone. Autoregulation: a factor in the genesis of hypertension? Cardiovascular reactivity and volume control during antihypertensive drug treatment. The pathophysiological profile of essential hypertension as a guide to treatment. Speculations. Subject index.

"Professor Birkenhäger and Dr. Schalekamp have made a substantial contribution to our knowledge of the regulation of the circulation in hypertension, and their book is a balanced review of this difficult and contentious subject."

Entering the genetic arena

William J. Schull

Who Do You Think You Are? Man or Superman. The Genetic Controversy. By Oliver Gillie Pp. 255. (Hart-David, MacGibbon: London, 1976.) £4.95.

OF LATE, genetics, and particularly human genetics, has found itself increasingly involved in controversial social issues; these include the roles of heredity and environment in the origin of the apparent differences in performance on intelligence tests, and the relationship, if any, of an extra Y chromosome to criminality. The scientific discussion of these issues has been characterised by more intellectual arrogance and humbug than seems generally to prevail. I had hoped that this little volume might redress these excesses in a trenchant way. It does not. *Who do you think you are?* has a catchy title, a few provocative thoughts, but is generally disappointing. We are confronted with clichés, and an overly pejorative division of the world into hereditarians and environmentalists. The attributes imputed to these groups would be worthy of a medieval scholastic obliged to account for the presence of evil in a world produced by a deity intrinsically good. What of value can possibly come from further polarisation of the attitudes toward these problems? These are strong, possibly intemperate remarks to some. Let me document them.

We find on p14 such simple clichés about political beliefs as, " 'Liberal' or 'radical' scientists tend to be 'environmentalists' and 'conservative' scientists tend to be 'hereditarians' who believe that heredity is of preeminent importance in deciding character. This is exactly what we might expect when we reflect that it is conservatives who always have the greatest interest in property and titles—that is, the greatest vested interest in non-biological inheritance." Or on pp109–110 we are treated to an analysis of Johannes Lange's personal prejudices and how the latter coloured not only the data on criminality he collected but his interpretations of these data as well. These accusations may indeed be true, but the cast of the argument seems to indict all "hereditarians" but exonerate "environmentalists" of this not so admirable human failing. One wonders whose prejudices are showing here. The larger issue, or so it seems to me, is not whether Lange or others exhibit prejudices but what is the sequence of events or experiences, cultural or biological, which gives rise to them. Self-serving irrelevancies are everywhere. The late Trofim Lysenko is described as being "from a simple peasant background" (p24); arguments which the author favours are prefaced with remarks such as "few serious scientists now dispute' (p128)—the implication is clear. Darlington's *Genetics and Man* doubtlessly deserves the criticisms which Gillie levels, but who other than he has ever characterised *Genetics and Man* as a "major work on the biology of man" (p95)?

There are, moreover, simple mistakes. DNA is said to have been discovered in 1953 (p20); this is the year in which its structural form was first identified but its chemical composition had been known for almost a century at that time. The inheritance of aryl hydrocarbon hydroxylase as here described (p129), has not been confirmed although the relationship of the inducibility of this enzyme to lung cancer seems still to hold. Although the book is generally well produced from the printer's vantage point, there are a few ludicrous misprints. I'll cite one. The dust jacket identifies William Shockley as Schockley, which in view of the racism of which he is charged, or at best the naive succour of racists ascribed to him, borders on shtick.

I cannot urge the reader of this review to dash out and purchase *Who Do You Think You Are?* for unless he or she belongs to the uncertain audience to which it is addressed he (or she) will be disappointed. As I attempted to imply at the outset, the book could have been more, and Oliver Gillie could have written one which would serve our time importantly. I fear, however, he has pandered where he should have been principled; has been simplistic where he should have been simple; has polarised where he should have been understanding; and has generally failed to appreciate the power of satire, if his intent is to serve a particular cause or point of view. I would urge, as a model, he read (or reread) Haldane's *Politics and Heredity*, an opus of the 30s, before he ventures into this arena again. ☐

Nucleic acid treatise

Photochemistry and Photobiology of Nucleic Acids Edited by Shih Yi Wang Vol. 1: Chemistry. Pp xv+576. (Academic: New York and London, 1976.) $54, £29.50.

THIS is the first of a two-volume treatise the purpose of which is to summarise our present knowledge of the photochemistry and photobiology of nucleic acids. The present first volume deals with the physical and chemical processes induced by absorption of a photon in nucleic bases—including rare and synthetic ones—as well as their monomeric and polymeric derivatives. The second volume is devoted to the DNA photochemistry and the photobiological aspects.

Each chapter is written by a group of workers, who are specialists in their respective fields The basic concepts in the domain of photochemistry are first outlined, followed by a complete and up-to-date review on the excited states of nucleic acids. Emphasis is, of course, placed on the new and exciting developments concerning room temperature emission.

The main core of the volume is the description of those photoproducts known so far Particularly pertinent is the analysis of the photohydrates and of the cyclobutane-type photodimers. The volume succeeds in presenting a balanced point of view on conflicting datas or interpretations coming from different groups, and discloses to the reader the problems that remain to be resolved.

Interesting chapters are devoted to the other pyrimidine adducts, the list of which is rapidly expanding, and to the purine photochemistry. In particular, the spectroscopic and photochemical properties of nucleic acids in frozen aqueous solution are reviewed. Finally, there are three chapters concerned with the methodology which has proved to be so useful in establishing the chemical structure and detailed conformation of the photoproducts—mass and nuclear magnetic resonance spectrometry, and X-ray crystallography. Also included is a chapter on radiation chemistry.

The publication of this book is particularly opportune, coming at a time when the repair mechanisms of nucleic acids are so extensively studied. It should therefore serve as an important source of references. Some aspects are redundantly treated, and some others of peripheral interest to the authors are briefly and in a few cases inaccurately mentioned. More fundamentally I would have expected a more integrated presentation of the chemical and biological data for a book intended to be a classical treatise.

Alain Favre is Chargé de Recherches, at the Institut de Recherche en Biologie Moléculaire du CNRS et de l'Université Paris, France.

View from space

Earth Sciences in the Age of the Satellite. By J. Pouquet. Pp. ix+169. (D. Reidel Dordrecht and Boston, Massachusetts, 1976.) Dfl.58; $22.50.

THE view from space of the Earth's surface is providing a distinctive new source of environmental information. This distinctiveness is based firstly on the overview of large areas which makes possible the detection of large scale features that cannot be easily recognised either on the ground or from aircraft, and secondly on the possibility of monitoring rapidly changing phenomena using the regular repetitive imagery obtained from many satellites. Although imagery from satellites has been available for some years, many earth scientists have been rightly sceptical of (perhaps because of) the over-optimistic claims made for remote sensing. The more cautious, more carefully considered study of remote sensing that is now becoming increasingly common is leading many earth scientists to examine its potential, not as a panacea, but as one of several alternative data sources.

Earth Sciences in the Age of the Satellite, was first published in 1971, and has more recently been published in an updated form in this translation. This may well account for many of the naive hopes expressed about the role of remote sensing and satellites.

In the first of the book's three parts, properties of radiation from various parts of the electromagnetic spectrum and their interaction with the Earth and atmosphere are briefly described. The second part on the role of satellites is out of date, although it is a very useful compilation of information about the earlier satellites. The final part concentrates on the applications to the earth sciences, with greatest emphasis being placed on geopedological examples (*sic*). Many of the examples are superficial or even trivial and will convince few that remote sensing has any substantial potential. No proper evaluation of the remote sensing methods is presented, nor is there any sensible objective comparison of their merits relative to other more conventional data gathering methods. In this and previous sections, the illustrations are often unhelpful and more and better photographic reproductions are clearly needed.

The idiosyncratic style of writing will be annoying to most readers and does not merely arise as a result of poor translation. Finally, the book is costly (£14.50) considering its length (169 pages), and fortunately there are other much better books now available.

Infrared and Raman spectroscopy

Infrared and Raman Spectroscopy. Part A. Edited by E. G. Brame and J. Grasselli. Pp. ix+345. (Dekker: New York and Basel, 1976.)

THIS is the first of a projected set of three volumes on infrared and Raman spectroscopy. The set is intended to cover all possible applications of these techniques in such diverse fields as the food industry, petroleum, textiles, biology, environmental science, and so on. This, the first volume, is more concerned with academic, rather than with industrial uses, but a sound understanding of the basic principles is obviously necessary before these techniques can be properly applied.

The first chapter is an introduction to molecular vibrations by Crawford and Swanson. It introduces the basic concepts in a manner suitable for those new to this field, with all the clarity and good humour one would expect from such a source. The chapter covers the origins of infrared and Raman spectra, and the experimental techniques, and introduces such concepts as selection rules, coupled oscillators, group frequencies, intensities and quantitative analysis.

The second chapter by Carter deals with inorganic materials. This delves more deeply into group theory, symmetry, and the selection rules, and shows in detail how the infrared and Raman spectra can be used to derive the structures of some specific inorganic molecules. It deals also with site-and-factor group analysis and with the spectra of oriented crystals. It concludes with some useful comments on experimental methods and with some character and correlation tables.

Chapter three, by Edgell, covers the vibrational analysis of organometallics. It extends the discussion of the selection rules to cover the concept of hidden symmetry, and again illustrates the application of the technique to a number of specific molecules. Finally, it discusses the derivation and significance of force constants in molecules of this kind.

Chapter Four, also by Edgell, is on ionic organometallic compounds. This deals almost entirely with a relatively new field, as the bands arising from the translational modes of ions in solution were not observed until 1965. The author shows that the study of the translational and intramolecular vibration bands can yield some very valuable information on the structure of solutions, on the motions in them and on the nature of the short range forces involved. This is a very highly specialised topic and includes some previously unpublished research by the author Nevertheless it is a topic which is very properly included if the whole work is to meet its stated objective of covering all possible applications.

It is all too common to find that texts written by a number of different authors contain a good deal of overlap and repetition. It is therefore a pleasure to be able to report that this is not so in this case. The editors have done an excellent job of integration so that topics such as the selection rules are introduced in a preliminary way in the first chapter, carried further in the second and yet further in the third. The text is well presented, the diagrams are clear and the standards of proof reading have been high. I could detect only one error, the misplacing of DCN in Fig. 4.

New entrants to this field will find the first chapter comfortingly simple and non-mathematical, but they must be prepared for increasing complexity as the book proceeds. This is however, a necessary requirement for the academic topics covered and they should not feel deterred from exploring the future volumes if their interests are primarily in industrial applications. Altogether this is an excellent start to what promises to be a very good and authorative series.

INTERSCIENCE

MEDICAL IMAGES: FORMATION, PERCEPTION AND MEASUREMENT

Proceedings of the 7th L. H. Gray Conference, Leeds, April 1976

edited by **G. A. Hay.**

In the past 25 years there has been a proliferation of physical methods, based on the use of transducers, for obtaining quantitative information about the structure and function of the human body. In many instances it has been found useful to extend the scope of the transducer, in various projection modes, so that it forms a two-dimensional image of the body. Consequently, the traditional X-ray apparatus and the microscope are now supplemented by powerful imaging devices that play increasingly important roles in medical diagnosis. The object of the conference was to draw together the physics of imaging systems, the structural concepts underlying the nature of both object and image, the perception of the image by the human observer and the numerical analysis of the image by computer.

0471 99447 2 378 pages March 1977 £12.50/$24.00

Published in conjunction with the Institute of Physics.

TOPICS IN BIOELECTROCHEMISTRY AND BIOENERGETICS Vol. 1

edited by **D. G. Milazzo,** *Instituto Superiore di Sanita Viale Regina Elena, Rome, Italy.*

This series gathers together reviews of topics concerned with energy transduction and electrochemical processes in biological systems, and techniques for their investigation. The volumes of the series will include discussions of fundamental biochemical mechanisms of such processes as phosphorylation, photosynthesis, electron and ion transport, various metabolic redox reactions, membrane phenomena, certain pharmacological and pharmacodynamical properties, and transmission of information at cellular level.

0471 01356 0 394 pages March 1977 £19.50/$38.00

PHARMACOLOGY OF SLEEP

edited by **R. L. Williams,** and **I. Karacan,** *both of Baylor College of Medicine.*

This gives an organized presentation of available data on the subject. Various contributors discuss such topics as the effects of drugs on sleep, biochemistry in human sleep, psychological aspects of sleep pharmacology, preclinical evaluation of hypnotics, and statistical considerations in the design of sleep studies.

0471 94856 X 368 pages January 1977 £19.30/$33.00

LIVING NUTRITION 2nd Ed.

by **F. J. Stare,** *Harvard University,* and **Margaret McWilliams,** *California State University.*

This provides a socio-cultural approach to the basic aspects of nutrition and the sociological/psychological influences on human eating habits, which discusses nutrition and world food problems, basic physiological nutrition, and applications of nutritional information to everyday life. Examines nutrition requirements at all stages of the life cycle and is completely updated to include the latest nutritional information.

0471 82081 4 510 pages February 1977 £8.70/$14.90

AN INTRODUCTION TO THE CHEMISTRY OF HETEROCYCLIC COMPOUNDS 3rd Ed.

by **R. M. Acheson,** *Queen's College, Oxford.*

Gives a concise and up-to-date account of the more important properties and chemical reactions of the basic heterocyclic systems. This edition has been completely revised and refers to many 1975 papers, particularly the most recent specialist reviews and key papers.

0471 00268 2 522 pages December 1976 £17.00/$28.70

MODERN METHODS OF CHEMICAL ANALYSIS 2nd Ed.

by **R. L. Pecsok,** *University of Hawaii;* **L. D. Shields,** *California State University;* **T. Cairns,** *University of California, Riverside,* and **I. McWilliam,** *Swinburne College of Technology.*

This describes the principles and typical applications of nearly all the commonly used analytical methods exercised in chemical research and commercial laboratories. The first part of the book deals with separation based on phase equilibria and distribution phenomena with extensive discussions of all forms of chromatography. The second part studies the several methods based on the interaction of electromagnetic radiation with matter. This edition stresses inorganic applications.

0471 67662 4 592 pages December 1976 £12.65/$21.50

CYCLIC NUCLEOTIDES AND THE REGULATION OF CELL GROWTH

edited by **M. Abou-Sabe,** *Rutgers University.*

This book presents recent advances in cyclic nucleotide research and discusses the current view of cyclic nucleotide involvement in the regulation of cell growth in different cell systems. It provides the first detailed analysis of cyclic nucleotide regulation of prokaryotic cell growth.

0470 98953 X 312 pages March 1977 £15.00/$26.00

Published by Dowden, Hutchinson & Ross Inc., and distributed by John Wiley & Sons Ltd.

CARBONIUM IONS Vol. 5: Miscellaneous Ions, Theory and Structure

edited by **G. A. Olah,** *Case Western Reserve University,* and **P. R. Schleyer,** *Princeton University.*

A compact review of the subject that studies the formation, isolation, physical characterization, and reactions of miscellaneous ions. Topics include: Tertiary Oxonium Ions, Acylium Ions, Halogenated Carbocations, Carbonium Ions Pi Complexed to Metal Atoms, Molecular Orbital Theory of Carbocations, and Crystal Structures of Carbonium Ions (Reactive Intermediates in Organic Chemistry).

Thermodynamics and surface chemistry

Equilibrium in Solutions; Surface and Colloid Chemistry. By G. Scatchard. Pp. xxxv+306. (Harvard University: Cambridge, Massachusetts and London, 1976.) £20.40.

THE foundations of theoretical thermodynamics laid by Willard Gibbs represent a truly great intellectual and artistic achievement, perhaps marred a little for most of us by the feeling that it seems to require almost as much effort to understand or use or teach thermodynamics as we imagine to have been required for the original creation. George Scatchard devoted a lifetime of effort to the subject, understood it better than anyone else, and used it for a series of definitive research papers on the thermodynamics of complex systems, often systems of biochemical interest. He also taught a graduate course on the thermodynamics of solutions at MIT and an undergraduate course on surface and colloid chemistry. This book contains the text of lecture notes for these courses, originally prepared around 1950 and made available to students in mimeographed form. They were corrected by Scatchard before his death in 1973 and published in the present form with the aid of a grant from the Commonwealth Fund. Walter Stockmayer is quoted in the preface as stating that publication of a text 20 years after it is written "implies that it is unique and in some measure timeless", an assessment with which this reviewer fully concurs.

The goal of the section on *Equilibrium in Solutions* reflects the attitudes of the author's research papers. It is to be meticulously correct in theoretical concepts and equations, and at the same time to be completely practical in the sense that the discussion always focuses on real experimental data and procedures There is no patience with theoretical "ideas" that do not relate to experimental measurement; on the other hand, when measurements are *more precise* than theory, then the theory must be empirically extended and it is important that the extension does not violate physical laws in simple limiting situations.

All the chapters are in a highly compressed style, difficult to read unless one is already somewhat familiar with the subject But it is very rewarding once one gets the hang of it because all the essentials are actually there; in fact they stand out with greater clarity than they generally do in more comprehensive texts.

Electrolyte solutions are treated in greater depth than other topics, and the treatment covers ion transport as well as equilibrium properties. The problems inherent to a definition of single ion activities are discussed, as are the various ways of extending the Debye–Huckel limiting law to higher concentrations. On the other hand, there is no mention of polyelectrolytes. Chemical equilibria are treated with extreme brevity (little more than a definition) and the reader will find no mention of practical aspects of treating chemical equilibria, such as are involved in 'Scatchard plots'.

The *Surface and Colloid Chemistry* section has six chapters: Introduction; Surface tension and interfacial tension; Polycomponent field surfaces; Adsorption on solids; Physical properties of colloid solutions, Electric effects at surfaces and in colloid solutions. It is even more compressed than *Equilibrium in Solutions*, being only 67 pages long, but again the essentials are there, with the notable exception that micellisation and other self-association processes are not considered. There are no literature references, so that these notes need to be read together with more modern texts (the plural is used advisably here because at least two separate texts will be needed to cover the material).

In addition to the scientific texts, we are provided with an appreciative introduction by I. Herbert Scheinberg, an autobiographical note, and a list of Scatchard's publications. The major portion of the autobiography consists of a brief explanation for every paper listed in the bibliography, as befits a man for whom work was clearly a labour of love. Because of his own deep involvement, he had no patience with superficial science, and he labels a number of his papers as "polemics", designed to expose shallow thinking and fallacy. He also used book reviews as a vehicle for criticism, and both the reviews and the polemics are useful reading because the fundamental core of a subject, that Scatchard was always striving to reach, sometimes emerges especially clearly in relation to a point of contention.

This volume will have strong appeal to all who love to shape equations into a description of the real world (in preference to pictures), for it is the record of a man with unique facility for doing so. It also should be read by anyone who ever has to teach thermodynamics or surface chemistry, for it cannot help but sharpen his insight and ability to transmit it.

Hans Mohr is a natural scientist with a deep-rooted interest in the nature of scientific thought and in the significance of science. His first book on this subject entitled „Wissenschaft und menschliche Existenz" was written in German (2nd edition, 1970). The present text is based on a series of 15 lectures which the author delivered at the University of Massachusetts during the fall term of 1975. In the Prologue "Science and Responsibility", some basic problems are formulated in more detail. While the treatment of the "Scientific Method" can already claim a well-established tradition of scholarship, the responsibility of the scientist has up to now only rarely been used in the consideration of the phenomenon of science. The author does not equate philosophy of science with epistemology, nor does he follow the tendency of excluding anything from consideration which might raise moral problems. Rather, the lectures on "The Ethics of Science", "The Crisis of Science" and "Science and Values" are as essential for the book as the epistemological treatment of "The Scientific Approach". Another characteristic of the book is that some traditionally epistemological problems, such as empirism and rationalism, are investigated from the point of view of scientific knowledge.

Mammalian peripheral nervous system

The Peripheral Nerve. Edited by D. N. Landon. Pp. xii+836. (Chapman and Hall: London, 1976.) £25.

VARIOUS aspects of present knowledge about the mammalian peripheral nervous system are reviewed in this book, special emphasis being placed on fine structure, and on the nature of the relationships that exist between the neurone and its supporting cells, end-organs, and other surrounding tissues.

The first nine chapters deal with the functional morphology of the myelinated nerve fibre (D. N. Landon and S. Hall); unmyelinated nerve fibre (J. Ochoa); perineurium and connective tissue (F. N. Low); sensory ganglia (A. R. Lieberman); anterior horn motoneuron (S. Conradi); spinal and cranial nerve roots (H. J. Gamble); ganglia of the autonomic nervous system (G. Gabella); sensory terminals (L. H. Bannister); and motor end-plates (G. F. Gauthier). The remaining chapters review motor end-plate function (A. J. Buller); chemistry and structure of myelin (N. A. Gregson); histochemistry of peripheral nerves and nerve terminals (J. F. Hallpike); selected aspects of peripheral nerve pathology (G. Allt); and electrophysiological properties of peripheral nerve (J. J. B. Jack).

This comprehensive survey, with its extensive bibliographies and superb illustrations, will provide a valuable reference work for those engaged in research on the mammalian peripheral nervous system. Naturally, in a work of such length and scope and varied style some parts appeal more than others For me the authoritative reviews on myelinated and unmyelinated axons, and on the nerve sheaths, are among the most interesting and useful contributions. There is also an excellent account of Wallerian degeneration and subsequent regeneration (excluding re-innervation), and an admirably comprehensive review of receptors.

The editor is to be congratulated for embarking on such a worthwhile enterprise and bringing it to a successful conclusion. There are signs, however, that active and critical editorship was sometimes lacking. For example, the consecutive chapters on motor end-plate structure and function should have been edited so that one complements the other. As it is, no functional comment is made on much of the ultrastructural information; "tonic" and "slow" muscles in one are respectively "slow" and "slow-twitch" in the other; references to "Normanski" optics in the chapter on function remain uncorrected; and the use of the term *"en grappe"* is left in unnecessary confusion. Another contributor is allowed to depict a periaxial space in the Golgi tendon organ, and to present a bizarre account of muscle-spindle innervation in which, for example, the secondary sensory endings are supplied by "group IIa" afferents, and a collateral motor innervation is derived from axons belonging to "group IIb". The editor certainly knows better than this; perhaps it is his view that an editor should do little more than serve as the channel through which his sources flow freely and unfiltered from pen to print. At times that way can leave the reader floundering.

The book, over 800 pages long, is heavy (1.5 kg) to handle and at times heavy to digest. Paragraphs sometimes run on far too long and occasionally there is a rash of instructional italics. Publication evidently took three years, writing being mostly completed by 1973, although an effort has been made to update references to 1975. It might have been better to have published the work in two volumes; better still to have included other aspects and run to three. The value of a well-documented survey of this standard would certainly have warranted that.

David Barker

David Barker is Professor of Zoology at the University of Durham, UK.

Heat on the move

Thermal Conduction in Solids. (Oxford Studies in Physics.) By R. Berman. Pp. xi+193. (Clarendon: Oxford; Oxford University: London, December 1976.) £9.75.

EVERY now and again one happens gratefully on a monograph born purely of the author's desire to communicate, to distil the fruits of a lifetime's personal interest and research into a form which renders the topic accessible to a wider audience. This is just such a book. Our present relatively mature understanding of the mechanisms of thermal conduction in solids owes much to a steady succession of illuminating experiments carried out during the past thirty years by Dr Berman and his coworkers; so that, being a gifted expositor, he is particularly well fitted to convey to others some of his continuing fascination with this technologically important subject.

The book is aimed mainly at physics graduates (or, indeed, final-year undergraduates) who want to progress beyond the rather limited discussion of thermal conduction usually provided by general textbooks on solid-state physics, but who lack the stamina necessary to tackle the unusually abstruse symbolism of the monumental work by J. M. Ziman (*Electrons and Phonons*, Clarendon, 1960). Throughout, Dr Berman's emphasis is very much towards conveying an understanding of the topic in question, and he has eschewed the algebraic pendantries which, in the name of rigour, can so easily obscure the physics for most readers. The dustcover's description of his treatment as "detailed but uncomplicated" is entirely apt.

The book opens with an explanation of what the thermal conductivity coefficient is, how it is measured, and the general way in which it behaves for a variety of different materials. The next six chapters, dealing with conduction in non-metals, include discussions of phonons, phonon-phonon interactions, the scattering of phonons by defects, the Boltzmann equation and methods for solving it; and they explain how these concepts and techniques are able to account for the features of conduction observed in nearly perfect crystals, imperfect crystals, and amorphous materials. Of particular note are the sections which explain the subtle influence of normal (momentum-conserving) processes, Poiseuille flow of the phonon gas and a number of interesting resonant phonon-scattering mechanisms. These are topics which in most textbooks are dealt with either cursorily or not at all. The second half of the book deals lucidly with situations in which heat is transported by electrons, discussing the effect on the conductivity of various types of electron scattering in metals and alloys including superconductors, and in semiconducting materials.

The deliberate emphasis towards a description of work below room temperature is justified by the fact that such experiments usually provide a more sensitive test of the theory than is afforded by those carried out at higher temperatures. An extensive set of references to original papers is provided, and will enable readers to follow up particular aspects of earlier work which are of interest or of relevance to their own research. Books and review articles are also cited where they are likely to be helpful.

Dr Berman's well integrated and readable little monograph has filled what—with hindsight—was an obvious lacuna in the literature. It will continue to be of value for many years to come.

P. V. E. McClintock

P. V. E. McClintock is Lecturer in Physics at the University of Lancaster, UK.

obituary

Sir David Martin

SIR DAVID CHRISTIE MARTIN, the Executive Secretary of the Royal Society, died suddenly on Thursday 16 December 1976, after nearly thirty years' service as the principal executive officer of the Society. Born on 7 October 1914 in Kirkcaldy (where he did an early morning paper round which inured him to a lifelong regimen of early rising), and starting from a local primary school he proceeded to Kirkcaldy High School and thence in 1933 to Edinburgh University. After first class honours in chemistry in 1937, he took a Ph.D. in 1939 under the supervision of J. A. V. Butler on organic compounds containing deuterium. His flair for administration had already shown itself: he was the first President of the Science Students' Union at King's Buildings, and he was much concerned in the Students' Representative Council and the Athletic Club. Originally intending to become a school teacher, but having had his horizons broadened by research and by student activities, he became in September 1939 Assistant Secretary of the Royal Society of Arts, which immediately released him for service in the Research Department of the Ministry of Supply for the duration of the war.

© New Scientist 1960

This last experience convinced him of the contribution that science could make to human affairs, even though he noted that altruism and an ability in science were not always linked characteristics in human make-up. His success in administration brought him to the notice of senior scientists, and resulted in his appointment in 1945 as General Secretary of the Chemical Society and in 1947—at the age of 32—as Assistant Secretary of the Royal Society. In 1943 he had married Jean MacGaradh Wilson; and throughout his life their home, first at Stanmore and then in the new premises of the Royal Society, was a centre of warm hospitality.

As chief executive of the Society, he found himself administering an annual Parliamentary Grant-in-aid of £36,000 and a staff of 29. Some measure of the growth of his responsibilities (whilst he was not in the least an "empire builder") may be gained from the fact that the corresponding figures at his death were about £2,000,000 and 100. Following the Scientific Information Conference in 1948, which he organised between scientists of the Commonwealth and the U.S.A., he persuaded the Royal Society in the 1950s to become its own publisher, and he encouraged other learned societies to do likewise, a step which proved substantially to their benefit. In the years before 1957 he contributed greatly to the organisation of the International Geophysical Year, in which not only were Soviet scientists brought into co-operation, but the Antarctic Treaty was signed, recognising Antarctica as a scientific laboratory above military or commercial interests.

The years after 1957 were charged with the publication of the results of the International Geophysical Year, and with preparations for the celebration of the Society's Tercentenary in 1960. This started with a formal opening by Her Majesty The Queen before an audience of some four thousand in the Albert Hall on 19 July, which was followed by ten days of lectures and visits, including a Service with a congregation of fifteen hundred in St. Paul's Cathedral. The celebrations were a major national event, with many overseas guests who had to be looked after in a manner matching the occasion, and their success was largely due to the efforts of Martin and his relatively small staff.

For some years it had been evident that the activities of the Society were out-growing its premises in Burlington House, and the possibilities of a move were contemplated. There had been talk of a national science centre somewhere in London where all scientific societies could be brought together, but the proposal that eventually took shape was the move of the Royal Society into new premises in Carlton House Terrace. This was very largely achieved under the Presidency of Lord Florey by Martin, the move finally taking place in 1967 under the Presidency of Professor (later Lord) Blackett. In this way the Society was enabled to stay in most fitting premises in central London; and although these could not become the nucleus of a national science centre, the generous policy of the Society in making its accommodation available to other learned societies for symposia and conferences has helped to make it even more a forum of general scientific activity than it was previously.

The large post-war growth in the Society's activities coincided with Martin's appointment. It was primarily due to the greater national appreciation of the value of science and technology resulting from their effects in World War II. As the time of his appointment the number of Fellows elected annually had just been raised from 20 to 25, and it was increased to 30 in 1965 mainly to give increased recognition to engineering and technology, and to 40 in 1975, partly to recognise the growth of science and technology in the Commonwealth. Martin made a characteristic contribution in effecting all aspects of the expansion so smoothly that very few growing pains were encountered, and the staff that he recruited to support him have unfailingly reflected the courtesy, helpfulness and discretion of which he was a model.

In addition to the obvious landmarks in the evolution of the Royal Society in the past thirty years there have been many other new activities for which he provided enthusiastic support. Relations have been developed and maintained with a wide range of national academies overseas, including those in China, the Commonwealth, Japan, Latin America, the Middle East, the U.S.A., and the U.S.S.R. The International Council of Scientific Unions, too, owes much to Martin's support, as does the European Scientific Exchange Scheme, in which some 90 British scientists are exchanged annually with a corresponding number from the Continent; and in the 1960s he did much to save Aldabra and promote the foundation of the Royal Society research station there. These great peaks of administration, however, convey little idea of the continuous demands made of him in running the many activities of the Society. It has some 120 committees and he was Secretary of nearly all of them. He also attended many of the scientific lectures, for he always retained his interest in science for its own sake.

Ever since Babbage's celebrated attack on the Society in 1830 in his *Reflections on the Decline of Science in England*, the function of the Society has from time to time been questioned. I can remember Martin's chuckle when I drew his attention to the fact that his 1830 predecessor had come directly under Babbage's attack for taking a 10% commission from the keeper of the tavern in which he persuaded the Royal Society to hold its annual dinner. Martin's own quiet good humour contributed to that sense of proportion which he always maintained, both in dealing with the occasional challenges to the Society and with the idiosyncracies of some of its Fellows.

One result of Babbage's attack, incidentally, was that the British Association was formed in order to become the main forum for professional men of science, in contrast to the Society, to which laymen were often elected at that time. Over the years, the functions of the two bodies have tended to exchange, and one of Martin's further interests lay in the Association; he was a member of its Council almost continuously from 1959 onwards. Once again, he played a part in getting Government support for the British Association, with funds that have been channelled through the Society.

His abilities were very widely drawn upon. He was a member of the Councils of the Royal Society of Arts, the Society for the Protection of Science and Learning, and the Charities Aid Foundation; and he was on the Executive Council of the CIBA Foundation. The Royal Society of Edinburgh elected him a Fellow in 1956. Since 1967 he had been Chairman of the B.B.C. Science Consultative Group, and since 1950 a Commissioner of Income Tax. His work was recognised by the award of a C.B.E. in 1960, and a Knighthood in 1970, and Honorary Degrees of D.Sc. from the University of Edinburgh and of D.C.L. from Newcastle.

But with all his public service, the Royal Society—both for itself and what he believed it could do—was his absorbing interest. It recognised the increased responsibilities of his office when it re-designated him Executive Secretary in 1962. By a Statute of 1847 he could not be a Fellow, for in a sense his post is one in which the holder has to be a man apart from any of the sectional interests that constitute the full spectrum of science: "A means for the Fellows to express their policies" as he himself put it, adding "I have tried to organise affairs so that all the decisions on scientific matters are taken by the Fellows." To him, his part lay in securing all the information that they needed before taking a decision, and in smoothly implementing the decision once it was taken. He was careful not to volunteer guidance but members of Council, and many of its committee chairmen, gratefully found that he always had something helpful to say when he was asked for his opinion.

Although he could not be a Fellow, few Fellows have done more or had greater influence for good in the Society since World War II than David Martin. With his fervent belief in its cause, his valedictory words are a message for the future: "As the years have passed I have become more and more convinced that it is not enough to leave the advancement of science to scientists alone. The need to see it as making a contribution, and only one contribution, to the world's problems has caused me to recognise the desirability of seeking liaison with other bodies. . . . These bodies operate in different or wider canvasses and, in my belief, operate better in liaison with the scientific activities which the Royal Society represents. The ivory tower concept for scientists is now anachronistic and although I feel an elitist organisation for science has a vital and important role, the base of the pyramid of excellence must reside in the ordinary everyday life of the people."

As for a personal appreciation, what he said of Harold Hartley on the latter's 90th birthday might well have been said of himself: "I would not dissent from a eulogy that ascribed to him the philosophical powers of a Socrates, the strength of a Hercules and the decisive action of a Churchill, but above all he has a warm humanity, which secures a place of affection in the hearts of all those privileged to know him as a friend."

R. V. Jones

Leopold Ruzicka

LEOPOLD RUZICKA, one of the greatest and most influential organic chemists, died on September 26, 1976. His work exemplifies that combination of severely disciplined empiricism wtih intellectual fantasy and imagination, which is the hallmark of first class organic chemistry. Ruzicka moreover was a unique character with a personality which was perpetually interesting and stimulating to all who knew him. His life also could teach us a lesson sorely needed in the United Kingdom—how to make an effective combination of academic and industrial efforts in research—if only those in authority would pay heed.

Ruzicka was born on September 13, 1887, in Vukovar, a small town in Eastern Croatia where the river Drava joins the Danube. The family name is Czech, going back to his great-grandfather. Ruzicka's father, a cooper and timber merchant, died when the boy was four years old, and the family moved to the neighbouring town of Osijek, where the young Leopold attended the classical high school, learning much Latin and Greek but neither chemistry nor geometry. At an early age Ruzicka was determined to become a priest, but this ambition had to be abandoned and, after much thought, he decided that his life's work should be in the organic chemistry of natural products. The circumstances which influenced this decision, remarkable at such an early age, are obscure; but we have Ruzicka's own word for it.

At the age of 18 Ruzicka left the Austro-Hungarian domain and sought training in Switzerland or Germany. His first aim was to enter the Polytechnic in Zürich, but the entrance examination was forbidding in its requirement for geometry as well as chemistry. So Leopold went to the Technische Hochschule at Karlsruhe, where he was accepted without examinations. The choice was fortunate because he was free to select the lectures suited to his special interests, and he joined Hermann Staudinger. It is typical of Ruzicka's extraordinary energy and intellectual ability that in only four years he completed the course for both first and higher degrees, graduating in 1910 as Doctor Ingenieur. Staudinger invited his outstanding pupil to join him in investigating the then unknown constituents, poisonous to insects, of *Chrysanthemum cinerariifolium*, the pyrethrins now of such economic importance. And in 1912 Staudinger succeeded Richard Willstätter at the Eidgenössische Technische Hochschule, Zürich. So Ruzicka arrived eventually, without examination, at the institute which he was to serve so well for many years. In 1916 he ceased collaboration with Staudinger in order to work on his habilitation thesis, which in 1918 brought him the rank (unpaid) of Privat Dozent and in 1923 of titular Professor. His researches were in the field of alicyclic compounds, which always remained his chemical interest.

Finance was a great problem to the unpaid lecturer, and in 1921 he accepted an invitation to collaborate with the perfume factory in Geneva, then Naef et Cie and nowadays Firmenich et Cie. So began an academic-industrial collaboration, fruitful for both partners. Ruzicka's research proposal was 'synthesis of the sesquiterpene perfumes farnesol and nerolidol; clarification of the structure of the four important odorous ketones, civetone, muscone, irone, and jasmone'. Until 1925 the work was carried out in Zürich in a cellar, with eventually eight co-workers, but then it was transferred to better quarters in Geneva. It was one of the classical, seminal investigations in organic chemistry. Nowadays it is difficult to remember that accepted dogma precluded stability for macrocyclic carbon structures, such as were proved to be the basis of the commercially important perfumes of musk and civet. The structures of the natural products were elucidated, they were synthesised, and a simpler, cheaper synthetic musk perfume, 'exaltone', was produced. Ruzicka spent only 18 months in the industrial laboratory, but that cemented a lasting relationship between it and the ETH, Zürich.

In 1926 Ruzicka accepted a call to the Professorship in Utrecht, where he pursued the chemistry of the many membered rings and of the higher ketones. In addition he began to acquire that deep love and knowledge of Dutch painting, which was to become almost as important as his love for chemistry. The stay was, however, short because Staudinger's successor at the ETH, Richard Kuhn, returned to Germany, and the President of the ETH, Rohn, came to Utrecht to offer the post to Ruzicka. Thus Ruzicka, who had became a Swiss citizen in 1917, became the first non-German to occupy the chair, although in due course he continued their tradition, still maintained by his own successor, of becoming a Nobel Laureate.

At the ETH Ruzicka threw himself into the task of making it the leading organic chemical institute in the whole world. He built so well that this position has, in the perhaps prejudiced view of the writer, never been lost. Ruzicka had an oft-quoted saying, "academic freedom consists in being allowed to work far harder than is prescribed." He certainly followed his own precept —and made similar demands on his colleagues. From the Zürich laboratory poured many publications opening up the detailed chemistry of the higher terpenes, the steroids and especially the sex hormones. The series of papers *Ueber Steroide und Sexualhormone*, continued by former collaborators, has reached part 256 and another series *Ueber Triterpene* likewise reached part 196. Ruzicka took pride in the way in which these marathons were continued by relays of his pupils. The triterpene series, notable for the skill and exactitude shown in unravelling immensely difficult problems, was joint work with O. Jeger. Jeger went on to investigate the photochemistry of alicyclic compounds, and yet another long series of papers emerged and yet another first-class chemist, a "chemical grandson" of Ruzicka, K. Schaffner, now at the Max-Planck Institute, Mülheim.

Ruzicka had an instinct for the significance of apparently minor natural products. Few could have discerned that the constituents of wool fat, especially lanosterol, would turn out to have great importance as the precursor of the steroids.

In this work Ruzicka shrewdly enlisted financial support from both the CIBA company in Basle and the Rockefeller Foundation. The close contact with CIBA included supply of personnel for their laboratories and assignment of patents, which proved to be profitable. It is worth noting in passing that Ruzicka's successor, Vladimir Prelog, became a member of the board of CIBA, now CIBA–GEIGY.

While much of these researches comprised detailed experimental exploration of complex organic structures, the organic chemist's characteristic underlying interest in correlating experimental data was never neglected. The isoprenoid origin—in modern terms derived from mevalonate—of these natural products was always in Ruzicka's mind and eventually there emerged the biogenetic isoprene rule. Such interests naturally led Ruzicka towards biochemistry proper, and he was largely instrumental in the establishment of a biochemical institute in the ETH. Moreover his younger colleagues, notably V. Prelog and D. Arigoni, have extended the scope of organic chemical researches into enzymology and experimental, as distinct from merely speculative biosynthesis.

In his prime Ruzicka had a rather conservative view of organic chemical theory, but again it is noteworthy that another of his brilliant pupils, A. Eschenmoser, has transformed much of our outlook on organic chemical synthesis by thorough understanding of theoretical concepts.

Initially Ruzicka had a critical view of physical chemistry, but, as his interest in spectroscopic and other physical methods grew—and he ensured that his institute lacked nothing in instrumentation in that regard—his sympathy for physical chemistry increased. He helped the growth of young physical chemists and the development of a separate institute in the ETH.

The patents on partial synthesis of the male hormones, testosterone and methyltestosterone, generated substantial sums of money. Ruzicka used them to built up a superb collection of Dutch painting—works by Franz Hals, Rembrandt, Rubens, and many others—which was presented to the Zürich Kunsthaus. One example of the quality of this collection will suffice: a Dutch art expert considered that of all the views of Haarlem painted by Jacob van Ruisdael, the finest was in Ruzicka's collection. This collection was not assembled by merely following the advice of art dealers. On the contrary, Ruzicka was a very knowledgeable amateur, in the best sense of the word, and his Zürich endowment includes an important library. The former director of the Mauritshuis in the Hague has testified to Ruzicka's expertise and his characteristic cunning and energy in acquisition of the best pictures for his collection. The writer remembers Ruzicka's indignation when difficulties were raised about an export licence for the portrait *Philip the Fourth* (Rubens) bought in London. Various letters, one translated into "too polite Cambridge English", another in Ruzicka's own words, were ineffective. Eventually a successful arrangement was made through the diplomacy of the Swiss Ambassador in London.

No memorial to Leopold Ruzicka would be complete without reference to his wit and penchant for entertaining stories. Although a very loyal Swiss citizen, he loved to parade his left wing views, suitably exaggerated for the benefit of the conservative Swiss, while being proud of his membership of the Papal Academy of Sciences, not forgetting his simultaneous membership of the Soviet Academy. It is recorded that in a Leningrad hotel he announced loudly that "as we are all good Party members, we can speak freely". As his hosts blenched, he went on to compare unfavourably the contributions made by Stalin to the Hermitage collection with those derived from Catherine the Great. This outspokenness was evident in the laboratory. The writer well remembers a distinguished American author of a popular textbook on organic chemistry, being distinctly disconcerted by the interruption of his lecture in Zürich because Ruzicka would not tolerate a pentavalent carbon atom on the blackboard of his laboratory. But there was no malice in Leopold Ruzicka. He loved to see his younger colleagues develop and the superb institute at Zürich stands as a lasting memorial to his life and work.

Ruzicka detested Nazism, and he gave generous succour to victims of Nazi oppression.

He received, of course, numerous honours, among them the Nobel Prize (1939) and Foreign Membership of the Royal Society (1942).

The autobiographical memoir *In the borderland between bioorganic chemistry and biochemistry*[1] makes rewarding reading, as does Ruzicka's own obituary notice of Arthur Stoll[2], which reveals much of Ruzicka himself as well as the subject of the memoir.

The writer thanks Professor O. Jeger and V. Prelog for their help in providing information and advice.

G. W. Kenner

R. A. Morton

Richard Alan Morton, Emeritus Professor of Biochemistry in The University of Liverpool, an outstanding British biochemist of his generation, died peacefully at his home on January 21 after a short illness; he was seventy-seven. Born in Liverpool of Welsh parents, Professor Morton received his early education at Oulton School. After a short time in the Army he entered Liverpool University as an undergraduate in 1919 and, apart from a sabbatical year in the United States as Visiting Professor at Ohio State University in 1931, remained there until he retired in 1966. He graduated in chemistry and worked for his Ph.D. under Professor E. C. C. Baly, a pioneer in the application of spectroscopy to chemical problems; in 1924 he was appointed special lecturer in spectroscopy in the Chemistry Department where he remained until 1944, when, with great foresight, the University elected him Johnston Professor of Biochemistry. He held this chair, the first established chair of biochemistry in the UK, with great distinction for twenty-two years.

Professor Morton's early research work was concerned with relating the absorption spectra of chemical compounds to their structure and earned him the Royal Institute of Chemistry's Meldola Medal in 1930; later he pioneered the application of absorption spectroscopy to biology. This interest was first aroused in 1926 when he collaborated with Professor (later Sir Ian) Heilbron to show that an impurity in cholesterol isolated from cod liver oil and which exhibited absorption bands in the ultra violet region of the spectrum, was the compound which was converted by ultra violet irradiation into the anti-rachitic principle. These were the days before the structure of cholesterol was known, but the active compound eventually turned out to be 7-dehydrocholesterol. He then particularly concerned himself with vitamin A which had two spectroscopic 'labels', an ultra violet absorption band (λ_{max} 328nm) and the blue colour (λ_{max} 617nm) which it gave on treatment in chloroform with a saturated chloroformic solution of antimony trichloride. Critical examination of the colour test led to his discovery of vitamin A_2 which was found particularly in liver oils from fresh water fish. Again, thoughtful assessment of the absorption spectrum of 'retinene', the prosthetic group of the visual pigment rhodopsin, began work which led to his discovery in 1941–1942 that retinene was vitamin A aldehyde (retinal) and that the corresponding compound from porphyropsin from fresh water fish retinas was the aldehyde of vitamin A_2. These penetrating discoveries, which gave studies on the biochemistry of visual pigments a new impetus, resulted in Morton's election to the Fellowship of the Royal Society in 1950.

Other important investigations on vitamin A followed but the later stages of Professor Morton's research career saw two extremely important additional discoveries: the first was ubiquinone, discovered independently at the same time in the United States, and the second was the family of polyprenols. The impact of these discoveries on modern biochemistry was profound. The experts on electron transport could from then on carry out their experiments secure in the knowledge that in the case of ubiquinone they were dealing with a well characterised compound. Later work revealed the importance of polyprenols as carrier compounds particularly in cell wall biosynthesis. It gave Professor Morton great satisfaction in his retirement to follow the detailed elucidation of the biochemical significance of these compounds particularly when these developments were carried out by his old students.

During the second world war Morton was concerned with an investigation organised by The Accessory Food Factors Committee of the MRC to determine the vitamin A requirements of humans. The experiments were carried out on conscientious objectors who volunteered as experimental subjects. This stimulated a life-long interest in nutrition and although he never experimented further in nutrition he read deeply in the subject and made many thoughtful contributions to a number of nutritional working parties. In 1969 he was elected a member of The American Institute of Nutrition.

Under Professor Morton's sympathetic guidance the Department of Biochemistry at Liverpool prospered and his crowning achievement was to persuade the University to build the large new building in which the department is now housed. He developed an effective research school and a remarkably large number of his students now hold positions of high responsibility in places as far apart as India and Canada. Professor Morton's great gifts as a scientist and as a wise counsellor became well known outside the University early in his career and he was constantly in demand for professional committees; he served twice on the Council of the Royal Society, was Chairman of the Biochemical Society and was a member of many government committees. From 1963 to 1968, he held the important position of Chairman of the Committee on Food Additives. He enjoyed writing and editing and was a member of the Editorial Board of the Biochemical Journal for seven years and Chairman of the Publications Board of the Royal Society 1961–1962.

He received honorary degrees from the University of Wales, Trinity College Dublin and The University of Coimbra, where his first research student became Rector. When he retired he was elected an Honorary Member of the Biochemical Society.

In retirement he continued to be as active as ever and he retained his fresh and enthusiastic approach to biochemistry right to the end. Indeed he had only just returned from an international symposium in India and at the time of his death was busy editing the proceedings. He spent a great deal of time on the work of the Oceanography and Fisheries Committee of the Natural Environment Research Council and in 1969 was Royal Society Visiting Professor at The Royal University of Malta. In spite of all this extramural activity he found time to complete two projects close to his heart: one was the *History of the Biochemical Society* (1911–1969) and the other a mammoth two volume new edition of his book *Absorption spectra of Vitamins and Hormones* last published in 1942.

In spite of his great achievements and international renown Professor Morton remained unassuming, friendly and approachable. His life shows that shrewdness and devotion to the demanding career of a scientist need not be divorced from kindness, gentleness and sympathy. His many friends and colleagues will remember Alan Morton as a distinguished scientist, wise in his judgement, humane in his outlook, whose long career brought lustre to biochemistry and to the University of Liverpool.

Where is Federico Alvarez Rojas?

LAST year (*Nature* **263**, 452) we reported on the plight of Maximo Pedro Victoria, an Argentinian nuclear engineer imprisoned and brutally treated for no more obvious reason than that he, as a civilian engineer, had been in dispute several years previously with military scientists over the fuel for a new reactor. It seemed that now the military was all-powerful in Argentina, some old scores were being settled; Dr Victoria, who had been a member of the Board of Directors of the National Institute of Technology, had to be taught a lesson which included being beaten up and losing some of his teeth.

Late in October, Dr Victoria was freed; 'your husband must be a real angel to be let out of gaol', a military officer told his wife. He now lives in Belgium. Maybe, we naively thought, this is a turning point and the Argentinian authorities are beginning to let up on the extremely repressive way in which they have been dealing with subversives, real or imagined. Not so; a report just issued by Amnesty International of an international mission to Argentina (Amnesty Dept A, 55 Theobald's Road, London WC1; £1.00) makes it abundantly clear that despite President Videla's assertion that 'there are no Argentines detained for their political opinions', there could be several thousand political prisoners, most not tried or even charged, and some subjected to unspeakable brutalities.

A particularly alarming aspect of the present troubles is the number of people who disappear or are abducted. Estimates of numbers vary widely but since the military coup in March 1976, at least 2,000 have disappeared; in the last week of May 1976 relatives filed a total of 200 writs of *habeas corpus* in Buenos Aires alone. What happens to these people? Representatives of the Argentinian government pointed out to the mission that they might have chosen to go underground or to emigrate, or they may have been killed in a clash with security forces. This looks like only a part of the story; there seems hardly any doubt that many of those missing were taken into custody and that many of the remainder were killed by right-wing terrorist groups which seem to operate without much hindrance from the government. Indeed, recently the Minister of Foreign Affairs, in comparing left-wing guerrillas with microbes on the social body, described reprisals groups as antibodies which would disappear when the microbes were eliminated.

Among the several hundred whom Amnesty list as having disappeared are several scientists. These include Federico Alvarez Rojas, a physicist at the National Atomic Energy Commission (CNEA), and his wife Hilda Leikis, a computer programmer; Roberto Ardito, an electrical engineer at CNEA, and his wife and children; Ricardo Chidichimo, an Air Force metallurgist; and Antonio Misetich, a CNEA physicist with an international reputation. The case of Federico Alvarez Rojas will illustrate the problem.

Senor Alvarez Rojas, 33 years of age, has worked at CNEA since 1968, most recently as director of the X-ray diffraction laboratory; his wife worked as a programmer at Bairesco S.A. (Burroughs). His father, also Federico Alvarez Rojas, was in Britain for some time as a British Council Scholar and worked in the Soil Mechanics Division of the Building Research Station, Garston. Senor Alvarez Rojas Jr and his wife were abducted by an armed group in the early hours of 1 October 1976; their three children were left behind. Since then vigorous efforts to find them have been made by his father who has issued *habeas corpus* writs and appealed to the authorities, the church and the Red Cross without success. Efforts made through American and British diplomatic channels have been unsuccessful.

What can we do? We have a responsibility as scientists to be concerned about illegal actions against any member of the scientific community whether the person in question is known to us or not. As the recent Council for Science and Society report on scholarly freedom and human rights put it, science is particularly vulnerable to outside interference, and it is clear that there is outside interference of an exceedingly ugly kind in the national laboratories of Argentina. The rapid deterioration in conditions caused by the recent events is soon going to leave the country, in the words of one despairing correspondent, 'inhabited only by labourers and murderers'. Let us hope that this message gets through to the president, General Jorge Videla, to whom it is still worth writing at Balcarce 50, 1064 Buenos Aires, to enquire about the fate of fellow members of the scientific community. □

A fishy business

C. E. Purdom and **A. Preston** assess the state of fish farming and its future promise

FISH farming is arousing widespread interest on the basis of a variety of concepts, some of which are not valid. There is such confusion about the motives of fish farming research that it is necessary to define clearly the role that this form of animal husbandry has within the context of UK food supplies.

Throughout the world, fish farming takes many forms but there are three basic categories:

- sea ranching: fish are reared for release into the sea as juveniles, where they subsequently grow to marketable size;
- extensive production using natural productivity;
- intensive farming which relies on supplied feeds.

Sea ranching has strict limitations, being feasible only where the natural tendency of the fish is to return to the point of release when they are fully grown. Salmon and sturgeon in the United States and the Soviet Union respectively are farmed in this way. There seems little immediate prospect that private enterprise will be stimulated by the vision of a valuable investment swimming off to distant waters.

Extensive cultivation is carried out basically by warm water pond farming. It is by far the most widespread of fish farming systems on a global basis and is found in most areas where space, climate and a local market justify it. Carp (*Cyprinus carpio*) is the archetypal species in pond farming, but a quite spectacular growth occurred in catfish (*Ictalurus punctata*) farming in the southern states of the United States during the 1960s and there has been recent progress with several other species of fish in fresh and brackish waters in south-east Asia.

Pond fish farming depends upon natural productivity and, like any other form of extensive animal husbandry, benefits from pest control, the use of fertilisers and the supply of supplementary feeds. Its productivity is governed by management practices and, of course, by the natural features of the farm. Natural productivity alone is low, perhaps a few hundred kilograms per acre per year at best. Fertilisation and other water management practices can double this but big dividends come only from the use of supplementary feeds. Here is a snag: fish are not efficient users of food materials other than animal protein and fat. Occasional reference is made to the desirability, in a protein saving context, of rearing herbivorous fish. The fact that such species require over 100 kg of feed to make 1 kg of flesh, however, puts them way below the performance of farm ruminants.

Intensive farming is almost wholly artificial. Fish are held in small containers which are commonly circular tanks, linear raceways or net enclosures in tidal waters. Very high stock densities are maintained with a large flow-through of water. At fish densities up to 100 kg m^{-3} all the nutritional requirements must be met in prepared feeds which must contain high levels of animal protein, 40–45% dry weight, moderately high lipid content and vitamin supplements. Such feeds are expensive, but the rationale of intensive farming is to produce high quality protein from low quality protein (quality being defined in terms of acceptability for human consumption). Feed protein is converted into fish protein with an efficiency of about 30% and intensive farming is therefore a net user of protein. The fish most commonly farmed this way are salmon and trout, in fresh or salt water, but large quantities of yellow-tail, a fully marine species, are farmed intensively in Japan.

No cheap protein

It is abundantly clear that fish farming is not a means of producing cheap protein. Whenever fish are farmed, they are high quality, high priced foods. A further view of fish farming is that it is an alternative, or a meaningful supplement, to the yield from sea fisheries. This idea is also invalid on the grounds that the two spheres of activity are of widely differing scales. UK fish landing approach one million tonnes per year: currently, fish farming contributes 2,500 tonnes per year. Assuming a ten-fold increase during the next five years, which is both worthwhile and probable, the scale of fish farming will still be totally inadequate to accommodate the fluctuations in the yield from sea fisheries, which can follow from political or management decisions or from natural causes: these may be measured in hundreds of thousands of tonnes. However, for individual species of fish, for which landings are low, for example turbot (700 tonnes UK landings in 1975) or sole (1,300 tonnes UK landings in 1975), there is some prospect of significantly adding to supplies by farming.

Turbot: no pigment problem

Fish farming in the UK probably will be based on intensive systems for the supply of specific types of fish suitable for these systems and for which a current demand exists. The two species likely to fulfil these requirements are rainbow trout (*Salmo gairdnerii*), which constitutes the bulk of present farm production, and turbot (*Scophthalmus maximus*), which has been researched intensively over the past five years and is currently under pilot scale commercial production.

Research on plaice, sponsored by the Ministry of Agriculture, Fisheries and Food (MAFF) began in the 1950s. This species is no longer thought suitable for cultivation because it is relatively abundant around the UK, has a fairly stable population, and is not a good enough converter of food to sustain an economically viable industry. After much background research, therefore, attention was turned to sole and turbot which are prime fish of high value and in short supply. Mass rearing techniques were quickly established for sole along the lines developed for plaice. Little progress was made with on-growing (that is, rearing hatched fish to marketable size and sexual maturity), because the hatchery-reared juvenile fish were difficult to wean onto prepared diets. The sole is a quiet feeder with nocturnal, browsing habits—the introvert of the flatfish families. Further research in MAFF laboratories was restricted to the weaning phase. Turbot was assessed first in terms of its on-growing capabilities. It passed the test, being voracious, a good protein converter (achieving levels up to 50%), and robust and docile towards anything it could not swallow. Growth rate is then dependent on temperature.

Hatchery techniques

Following the satisfactory outcome of these trials, using small fish collected from the beaches, efforts were made to develop a hatchery technique to raise juveniles from eggs. Plaice and sole larvae were satisfactorily grown

---

C. E. Purdom and A. Preston are from the Ministry of Agriculture, Fisheries and Food's Fisheries Laboratory, Lowestoft.

on a diet of *Artemia* nauplii. Turbot, however, were too small initially to feed on nauplii but they could feed on natural plankton, mussel veligers and the rotifer *Brachionus plicatilis*, the latter being the most suitable. After a few days feeding on rotifers, turbot larvae accepted nauplii but the problems did not end there. Metamorphosed fish were reared for the first time in 1972; about 100 were produced from many thousands of eggs. Steady annual improvements in empirical techniques have since been made, and survival rates up to 25% are now feasible.

Solving the early feeding needs of the larvae, at least at an empirical level, did not remove all the obstacles to successful rearing of turbot. A number of minor problems, 'dropsy' in young larvae, a later lack of swimbladder development and atypical pigment formation at metamorphosis, mostly diminished with increasing experience. A major problem, however, was that, unlike plaice and sole, turbot larvae were not satisfied for long on a diet of *Artemia* nauplii. Progressively larger *Artemia*, grown on unicellular algae, were required by the fish as they grew larger themselves. A weaning process was developed whereby the larvae were switched to prepared foods by using specially designed weaning tanks which kept inanimate food particles moving but did not sweep the fish down the overflow. Rearing turbot larvae is now almost routine but it still requires sophisticated laboratory facilities and further research is needed to clarify scientific aspects and to simplify systems for commercial use.

Sole have similarly been weaned from *Artemia* to prepared diets but for rather different reasons. Earlier work with sole relied on a succession of live foods but these are not suitable for commercial use and they not only delay the problem of weaning but also intensify it: the luxury of live foods appeared to be habit forming. A clear demonstration that sole is suitable for domestication still remains to be made.

Coping with seasonal spawners

A problem with turbot, as with most fish, is that spawning is seasonal. This restricts management options in commercial farming and it also limits the pace at which research can proceed. Most seasonal spawners have light or temperature regulated hormonal clocks and in theory can be persuaded to spawn out of season by the correct manipulation of whatever parameter is appropriate. On the basis of successful work with dab, trials were set up to influence the spawning pattern of turbot, which normally spawns in midsummer. Spawning has been brought forward to March in one series and further trials are aimed at delaying spawning until early winter. The indoor work of hatching and larval rearing could then be completed by spring when the juvenile fish could make use of increasing temperatures outdoors.

Work with flatfish has been aimed at creating a new form of fish farming. Recent commercial investment in this area is a measure of its success and has introduced the provision of advice and assistance to industry through research and development programmes. The growth of trout farming led to a similar demand for R&D programmes and, after a recent review, it was planned that all the MAFF's fishing farming research, except work on infectious diseases, should be located at the Fisheries Laboratory, Lowestoft.

The trout research programme is divided into water management, genetics and feeding strategies. Water is clearly a limiting factor in trout farming and in simple systems about 20,000 gallons are used for each pound of fish produced. But the first limiting factor is oxygen. Water-saving systems employing oxygen or air are under development by industry. Removing the limitation of oxygen increases the levels of carbon dioxide, ammonia, nitrite and nitrate. Limited research on the effects of these and other water quality factors is planned but the principal MAFF investigation will be on the use of sea water for farming trout. This offers immediate scope for large scale increases in production.

Rainbow trout are not naturally anadromous but are successfully reared in sea water in some parts of the world. Smolting does not occur, as in salmon and migratory trout, but the ability of rainbow trout to withstand transfer to sea water increases with their size. Preliminary trials suggest that 30–90 g is the range over which fish may be acclimatised but there is evidence that age may be important and that domesticated strains vary in their tolerance of sea water. Clearly it is important to establish the earliest possible transfer to sea water where portion-sized fish of around 250 g are produced, but for larger fish, for which there is a growing market, the need is not so marked.

The genetic programme is based on the fact that several individual strains of rainbow trout already exist. A number of these strains have been imported with the objective of developing disease-free broodstock for subsequent trials both of the characteristics of the strains themselves and of cross-breeds. Electrophoretic analysis of enzyme polymorphisms suggests that some of the strains are inbred.

Strains differ in the time at which they spawn and it may be possible with trout to supply eggs throughout the year without recourse to environmental manipulation—more difficult for trout than for turbot on account of their relatively low fecundity and the need for large numbers of broodstock. Other genetic aims include selection for larger egg size and for late maturity.

Feeding is by far the most cost sensitive area of trout farming but despite a long history of domestication, there is little standardisation of feeding strategies. Current practice in the UK is to use pelleted feeds but in other countries, much reliance is placed on the use of cheap trash fish, particularly in sea water culture. Routine use is made of such materials within Ministry work but detailed nutritional and logistic assessment remains to be made.

Fish farming as a food producing industry has no other commitment but to operate in a cost-effective way. MAFF research has established a basis for turbot farming and continues to explore this and rainbow trout farming in order to supply industry with scientific advice. ☐

Cages of plaice and turbot in the North Channel

Start from the middle

The results of a year-long study of nuclear power by a distinguished panel were published last week. Colin Norman reports from Washington

In a report likely to have a significant impact on nuclear policy in the United States, and perhaps elsewhere, a panel of distinguished scientists and economists has urged the Carter Administration to bar domestic reprocessing of spent reactor fuel, and to curtail drastically the present crash effort to develop a commercial breeder reactor. The economic justifications advanced for those two programmes are dubious at best, the panel said, and to proceed apace with either of them would seriously hamper attempts to curb the proliferation of nuclear weapons.

With the Carter Administration now in the throes of putting together a comprehensive energy policy, to be unveiled on 20 April, the report* couldn't have come at a more opportune moment. In fact, the panel's conclusions are in harmony with some of President Carter's campaign statements, and it is generally expected that the recommendations will be reflected strongly in Carter's energy policy. In any case, the report is said to have gone down well in the White House, and Carter even took time last week to meet with all 21 panel members to discuss their recommendations.

The product of a year-long study sponsored by the Ford Foundation, the report is an attempt to examine and stitch together the economic, political and social arguments which have been raging over nuclear power in the past few years. The effort was initiated, according to the Ford Foundation's President, McGeorge Bundy, because of "a widespread feeling that this debate was suffering from a shortage of disinterested analysis", and the foundation therefore chose as members of the panel prestigious individuals who were not lined up on either side of the debate. Like the report of the Royal Commission on Environmental Pollution in Britain, the panel's conclusions have therefore gained some authority from the fact that the panel started from a middle-of-the-road position.

The panelists were mostly liberal academics many of whom have been active in arms control issues, and they include two top officials in the Carter Administration—the Secretary of Defense, Harold Brown, and Joseph Nye, deputy Under-Secretary of State (Brown was President of Caltech when he served on the panel and Nye was professor of government at Harvard). Other members included John Sawhill, former Administrator of the Federal Energy Agency, Wolfgang Panofsky, director of the Stanford Linear Accelerator Center, Kenneth Arrow, a Nobel prizewinner and professor of economics at Harvard, and Richard Garwin of IBM. The chairman of the panel was Spurgeon M. Keeny, a senior official of the MITRE Corporation, a think-tank which coordinated the effort.

With such an impressive list of authors, it's not surprising that the study has attracted considerable attention. It should be noted, however, that contrary to some interpretations, it is not an anti-nuclear document. Far from it. Though the panel challenges many of the chief arguments put forward by the nuclear industry, and opposes some programmes which the industry believes are crucial for its long-term prospects, the report nevertheless acknowledges that uranium is likely to be an important source of energy for several decades and it suggests that in some respects nuclear power may hold a slight edge over alternative energy sources.

The panel takes issue with conventional nuclear wisdom on two points fundamental to the nuclear debate, however. It argues that, in the United States at least, although nuclear power seems to hold a slight economic advantage over coal, "the choice is so close and the uncertainties sufficiently large that the balance could easily shift to increase or eliminate" that advantage. Similarly, adverse health and social effects associated with nuclear power are likely to be less than those associated with coal, but "the range of uncertainty in social costs is so great that the balance between coal and nuclear power could be tipped in either direction".

That is a far cry from the industry's contention that the atom would supply significantly cheaper and cleaner energy than alternative sources, but it leads the panel to suggest that the United States should maintain a mix between coal and nuclear power. The recommendation is really an acknowledgment of what is likely to happen anyway.

The panel is, however, much less equivocal in its conclusions concerning plutonium. Citing nuclear proliferation as "the most serious danger associated with nuclear power", the panel urges the Carter Administration to renounce domestic reprocessing of spent reactor fuel and recycling of plutonium. "If a decision to postpone this technology indefinitely is articulated and carried out effectively", the panel argues, "it can have a major influence on the assessment of costs and benefits of reprocessing and recycle by other countries that are, or soon will be, facing similar decisions. Conservsely, a US decision to go ahead with reprocessing . . . would accelerate worldwide interest in the plutonium fuel cycle and undercut efforts to limit nuclear weapons proliferation".

In any case, the panel argues that reprocessing is difficult to justify even on economic grounds. The nuclear industry has long argued that reprocessing and plutonium recycle will be needed to stretch out dwindling supplies of uranium and to pave the way for plutonium-producing breeder reactors, but the panel takes issue with the industry's chief assumptions. "Our review convinces us that current official estimates of uranium reserves and resources substantially underestimate the amounts of uranium that will be available at competitive costs", it notes, and suggests that "there will be enough uranium at costs of $40 (1976 dollars) per pound to fuel light water reactors through this century and, at costs of $40 to $70 per round, well into the next century". Moreover, the panel points out that the estimated costs of reprocessing have escalated rapidly, with the result that "any net economic benefit during this century is questionable".

The panel therefore urges Carter to short-circuit a major review by the Nuclear Regulatory Commission of whether reprocessing should be permitted by announcing that the United States will defer use of the technology indefinitely. In fact, Carter promised during his election campaign that he would "seek to withold authority for commercial reprocessing until the need for, the economics and safety of this technology is clearly demonstrated", and the panel is therefore essentially urging him to keep his campaign pledge.

As for the breeder reactor programme, the panel again takes issue with the industry's economic arguments, suggesting that "the early economic potential of the breeder has been significantly overstated". The report also notes that a breeder programme would involve full-scale commitment to the plutonium cycle with its attendant proliferation problems. In spite of those drawbacks, however, the panel doesn't recommend complete abandonment of the programme, but suggests instead that the effort should be sharply reduced in priority and be pursued only as "insurance" against the possibility of very high future energy costs or the failure of efforts to develop alternative energy sources.

---

*Nuclear Power Issues and Choices (Ballinger Publishing Co., Cambridge, Mass. $6.95.)

The effort to develop a commercial breeder reactor has long enjoyed pride of place as the federal government's most expensive and most controversial energy research and development programme. The expected cost of the programme has soared from $2,000 million to $12,000 million in the past few years, and the projected date for introduction of commercial breeder reactors has slipped from the late 1980s to the mid 1990s. A small test reactor, the Fast Flux Test Facility, is now nearing completion in Washington State and it is expected to start operations in 1980. The plan is to follow that with a 380 MW demonstration reactor, construction of which was expected to begin on the Clinch River in Tennessee this year, with operation scheduled for 1983. The next step would be a large prototype reactor, funded chiefly by electricity utilities, with construction scheduled to begin in 1981 and operation in 1988. A decision on whether to proceed from the prototype to a full-scale commercial programme would be made in 1986.

The Ford Foundation study suggests that the overlapping, crash programme leading to a decision on commercialisation as early as 1986 is unwarranted, and it recommends that the effort be completely revamped with more emphasis placed on technology development. In particular, the panel recommends that the Clinch River plant be abandoned, and it suggests that the decision on commercialisation can safely be postponed beyond the end of the century.

Again, that recommendation meshes neatly with Carter's campaign pledge to reduce the breeder programme to a "relatively low priority, possibly multinational effort". Last month, moreover, Carter recommended that nearly $200 million be cut from the Ford Administration's budget request for the breeder programme, and he ordered the Energy Research and Development Administration to undertake an intensive study of the need for and timing of the effort. That study is now under way, for ERDA established last month a committee containing some of the breeder programme's most vocal supporters and critics, and asked it to come up with recommendations before Carter's 20 April energy statement.

The Ford Foundation panel also urges the Carter Administration to take a number of other steps to reduce pressures leading to nuclear proliferation. In particular, it suggests that "the United States must have a clear policy on its long-term role in providing enriched fuel to both domestic and foreign nuclear power programs". The government should retain ownership of uranium enrichment facilities, the panel recommends, thereby reversing the Ford Administration's goal of turning enrichment plants over to private industry. The United States should also ensure that there is ample enrichment capacity in the 1980s and 1990s to meet international commitments, for the panel suggests that an assured fuel supply would reduce the incentive for other countries to develop their own enrichment and recycling facilities.

Finally, the panel recommends that the government should proceed promptly with plans to test the feasibility of disposing of nuclear wastes in salt beds and other stable geologic formations. Decisions on waste disposal have been continually deferred, pending introduction of reprocessing, a fact which has led to the widespread belief that reprocessing is an essential pre-requisite for permanent disposal (a belief which is written into legislation in Germany requiring that reactor wastes be reprocessed before disposal). The panel notes, however, that "spent fuel can be disposed of directly, and probably at costs comparable to those for reprocessed wastes". ☐

SERI site selected

The Energy Research and Development Administration (ERDA) last week conferred a much sought after plum on the State of Colorado. It selected a site in the Denver suburbs for the long-awaited Solar Energy Research Institute (SERI), a facility which could develop into the leading solar energy research centre in the United States.

Altogether nineteen organisations in 16 different states had been vying for SERI during the past year; the winner is the Midwest Research Institute, a St Louis-based research organsiation, which teamed with Colorado to offer a proposal.

To help soften the blow for some of the unlucky contenders, ERDA also announced last week that it will establish three regional solar energy research centres in New England, the Southeast, and the upper Midwest. The regional centres are expected to be run by consortia including representatives of several state governments, though their full role in the overall solar effort has yet to be determined.

SERI was called for in the Solar Energy Research, Development and Demonstration Act, a bill passed in 1974 which directed ERDA to establish a national facility and to seek the advice of the National Academy of Sciences on its role and scope. It was generally anticipated that SERI would be a large facility along the line of ERDA's nuclear laboratories.

The Academy furthered that expectation with a report recommending that SERI should be a major operation responsible for all phases of solar energy research including photovoltaics, fuels from biomass, wind power and so on. SERI should have a large budget, amounting to about $50 million by 1980, the Academy suggested. With very few large scientific projects up for grabs these days, such a big-league enterprise immediately generated a lot of attention and proposals came flooding into ERDA.

Early last year, however, ERDA, under pressure from the Office of Management and Budget, opted for something rather less grandiose. It announced that SERI would start small—a budget of about $5 million for its first year—and a decision would be made early in the 1980s on whether it should be expanded to the sort of facility the Academy had in mind. Even that scaled-down version attracted 20 separate bids, however, and ERDA shortlisted 19 of them for further study.

In announcing the selection of the Midwest Research Institute/Colorado proposal, ERDA Acting Administrator Robert Fri said last week that SERI will start with a budget of $4–6 million for its first year, and a staff of about 75 professionals. It will cover all aspects of solar energy, but initially its functions will be mostly concerned with assessments, analyses, information dissemination, education and consultation. Its research and development activities will build up more slowly, and ultimately it could be moved to its own 300-acre site nearby at the foot of the Rocky Mountains.

Colin Norman

BRITAIN

● When the UK Department of Energy (DEN) published the report of its Harwell-based Energy Technology Support Unit (ETSU) on solar energy in the United Kingdom last month, it simultaneously announced the launching of a £3.6 million programme of research and development over the next four years. Full details of how the money would be allocated were not published, but now the government has given a breakdown by department of the overall annual expenditure in the various fields of solar R&D (see table, below).

The details emerged last week at a solar energy workshop organised by the government's Inter-Departmental Steering Committee on Solar Energy R&D; it was attended by some 200 people from national and local government, public and private industry, research institutes and corporations, and universities and polytechnics.

Britain's solar energy effort involves expenditure of some £6 million over four years and stretches beyond the DEN programme, which mainly involves supporting commercial exploitation of solar water and space heating technologies and £600,000 of backing for biological conversion, in which NERC, ARC and MAFF have all shown interest. ETSU meanwhile is to establish this year a register of current R&D on new energy sources and energy conservation relevant to the DEN programmes, but to preserve confidentiality the register will not be published.

The Department of the Environment (DOE) work focuses principally on solar water and space heating too, mainly through its Building Research Establishment. The Department of Industry (DOI) is involved in photovoltaic conversion and supports a solar cell group at the Royal Aircraft Establishment's Space Department, a representative from which last week urged greater cooordination of support from the SRC and DOI.

The DOI now has an information officer attached to the Solar Energy Unit based at University College, Cardiff. As for the attachment of an Energy Research Support Unit to the SRC's Rutherford Laboratory, to provide assistance and support for energy research in universities and polytechnics, this was welcomed by the outgoing chairman of the UK section of the International Solar Energy Society (UK-ISES), who strongly urged devotion by universities to development now that scientific principles were known.

Britain's international involvement is mainly through the EEC, through which international collaboration is being sought in the particular field of thermal power generation, although last week one official from the DOE's Directorate of Research Requirements personally questioned whether UK efforts in this area ought to be concentrated on large-scale plants instead of "something smaller to meet export opportunities".

EEC expenditure amounts to some £320,000 a year in direct support of work at its Joint Research Centre, and £1.75 million in indirect partial support of projects elsewhere.

● Predictably, the first British response to the saccharin developments in North America was a parliamentary question in the House of Commons. The Ministry of Agriculture, Fisheries and Food sees no reason why Britain should ban the sweetener as well, but the data and results of the research are to be examined by expert committees before any action is taken.

The stir caused by the saccharin revelations added poignancy to the publication last week of *Why Additives? The Safety of Foods*, a booklet devised and edited by the British Nutrition Foundation, which is closely linked with the food industry. Many of the scientists who wrote it are also associated with the industry. Although meant to reassure the big public, the views expressed are not as suspect as many bromides which emanate from a nervous industry since, as the booklet explains, the use of additives in this country is strictly controlled, compounds are constantly tested, and use is based on a permitted list.

UK government involvement in solar R & D (£'000 p.a. on average)[1]

	Solar water and space heating	Insolation data	Photochemistry/ Photobiology	Photovoltaic conversion	**Total**
DEN	700	50	150		900
DOE	125				125
DOI	15[2]			215	230
Met. Office		50			50
SRC	35		90[3]	25	150
Total	875	100	240	240	**1,455**

[1] The figures are a rough indication of present allocations, and give an idea of annual average departmental expenditure on the programme over the next few years.

[2] Includes other aspects of solar R & D, not only heating.

[3] With Agricultural Research Council.

The booklet lists saccharin among additives requiring further evidence on safety and toxicology, but stresses that 80 years of widespread use is a good indication that it is "harmless", particularly as regular users include diabetics who see their doctors frequently. The main message is clear: additives make food safer, prolong storage life, allow bulk manufacture or are added for nutritional reasons.

Among additives meant to please, rather than prevent food poisoning or outrageous cost, are colourings. Man-made colourings have been more closely investigated than nature's chemical colours, but the benefits they offer are often purely aesthetic, though attempts to avoid colouring can be commercially disastrous. A former member of the Government's Food Additive and Contaminants Committee (FACC) suggested last week that colouring matter should not be added to infant foods or fresh fruit, meat or vegetables. The case of infant food is currently under review.

Anxiety also exists about the use of nitrites as antibacterial preservatives in bacon and other meat products. The authors of the booklet suggest that the risk of poisoning from botulism is a much greater hazard than any carcinogenic danger, but only experimental evidence can confirm this.

● The stark features about income and expenditure figures of the Imperial Cancer Research Fund (ICRF) —apart, that is, from their sheer size—are that the income all comes from legacies, subscriptions and donations, and the expenditure is channelled into research. Thus, according to the 1976 report published last week, just 3.3% of expenditure in 1975–76 went on administration, and 2.6% to appeals and publicity. Of the remainder—all £8 million of it—£3.9 million was spent directly on research, £2.8 million augmented the ICRF endowment and £1.3 million went on "extraordinary items".

The ICRF chairman, Professor Sir Eric Scowden, says in his report that "far-reaching changes are imminent" at the Lincoln's Inn Fields laboratories. Michael Stoker, the Director of Research, intends to retire in September 1979, and Renato Dulbecco, the Deputy Director, retires this September; the ICRF Scientific Advisory Committee is considering the future of "these vital appointments".

SWEDEN

Politics and power

Wendy Barnaby reports from Sweden on the latest discussion about energy policy

'PRIME Minister Fälldin is thought to be in difficulties', said a Swedish newspaper recently. Considering the energy situation, that is an understatement. Prime Minster Fälldin may well be in his political death-throes.

Only five months ago, after an election campaign in which he promised to rid the country of nuclear power, his appointment as the head of Sweden's three party non-socialist government was widely interpreted as the beginning of the end for nuclear power here. But his government has taken no concrete steps to stop the building—and, in one case, the loading—of reactors. His sympathisers are becoming disenchanted. Over the next few months, the decisions he will have to take will show where his real interest lies: in stopping nuclear power, or in remaining prime minister.

By 31 March the government must advise the Oskarshamn Power Company whether state credit guarantees will be given for the building of the Oskarshamn 3 reactor, now on the drawing board. The decision will also be significant for the owners of the Forsmark 3 reactor, which is at the same stage. The bill, specifying the conditions under which the building of reactors may continue, is expected to be made law in the middle of April. Under its provisions, the owners of any reactor being planned or under construction must present the government with concrete proposals for the 'completely safe' storage of unprocessed fuel or of highly-radioactive waste if the fuel is to be processed: reprocessing agreements must also have been concluded. If these conditions are not met, the government will stop work on the reactor(s) concerned at the end of the year and will compensate owners for costs incurred until the law comes into force in May. Compensation for money spent after May will be subject to special investigation by the government, which has said that it will not pay any bills incurred after it has become obvious that the conditions will not be met. Just exactly when this point is reached will be decided by the government and impartial advisers.

The conditions specified in the bill will have their first test this summer, when the government will have to decide whether or not to allow the loading of Ringhals 3 reactor which is scheduled for 15 July. It will probably be delayed, however, by a legal case brought by environmentalist Björn Gillberg and his lawyer, Gunnar Michelson, who are appealing to the Supreme Court to overrule a decision made last year allowing the release of $175 \text{ m}^3 \text{ s}^{-1}$ of cooling water from the Ringhals 3 and 4 reactors into the sea. There is at the moment neither a reprocessing agreement nor a storage plan for Ringhals 3. In October, the fate of Barsebäck 2, which is already loaded, must be decided—and the loading of Forsmark 1, due to begin next January, will provide the third test under the new law. The main findings of the government's Energy Commission—which is responsible for formulating an energy policy up to 1990 (including a plan for scrapping nuclear power in the mid 1980s)—are expected to be published next March. In the usual Swedish way they will be commented on by all interested parties before the government presents its proposals to parliament late in 1978.

None of these decisions will be easy. The three coalition parties are nowhere near agreed on energy. The Conservatives want 13 reactors by 1985, the Liberals, 11; and both want to retain the government's freedom of action until the Energy Commission's findings are known. The Centre Party would find it impossible to agree to this without finally damning itself as the party which compromised its anti-nuclear faith when faced with the temptations of power. But whatever decision Fälldin takes will bring him enormous problems. If he decides to stick to his election promises, he will be faced with unemployment in the nuclear companies and their sub-contractors, estimated to be as high as 40,000 man-years at a time when industrial unemployment is already worryingly high. If he calls a new election, it is by no means certain that he would win: the latest opinion polls show that the popularity of the Social Democratic opposition is rising. Another option would be to have an advisory referendum; but a special parliamentary bill would have to be passed by majority vote. As the Social Democrats are opposed to a referendum, the government parties would have to unite on the bill; and even that cooperation is in doubt.

Fälldin is confident that the nuclear power companies will not be able to meet the conditions of the new law. Jonas Norrby, Director of the State Power Board—which is building more reactors than anyone else—is just as confident that they will. The nuclear companies are cooperating in their attempts to find 'secure' solutions to the disposal problem, and expect to present a position paper on the subject next September. They are predicting that the political instability will finally put their reactors into operation.

The latest idea for disposal involves encapsulating the waste in ceramic material and then compressing it into a solid harder than granite. This suggestion has come from Asea-Atom, a company which is not building any reactors at all, but which is experienced with high pressure techniques in areas other than nuclear waste. It admits that only time and experimentation will tell whether the idea will work. One of those who doubts that it will is Gösta Wranglen, Professor of Cor-

rosion Science at the Royal Institute of Technology. He forsees problems arising from the radioactivity of the waste, which would cause the release of oxygen from the water surrounding it. The resulting oxidising environment would not only favour the spread of plutonium but would also oxidise the pyrites in the bedrock into sulphuric acid, making the water extremely corrosive.

Professor Wranglen is doubtful whether any man-made material could withstand such corrosion for thousands of years, but says that, if the waste must be buried, it should be encapsulated in fire-proof steel with a coating of gold about one-tenth of a millimetre thick: thick enough to ensure absolute impenetrability. To avoid the enormous expense of such a method, he suggests that high-level radioactive waste should not be buried at all, but should be stored under supervision in concrete bunkers or drained rock chambers above the ground water table. The heat from the waste would keep the steel cylinders hot and dry for centuries, and they would need no encapsulation at all. He argues that resistance to this solution is purely psychological: acceptance of nuclear reactors themselves implies acceptance that the fuel and waste within them might be used in wars or other catastrophes, and we ought therefore to accept a similar risk in connection with stored waste.

In the face of all these uncertainties, it is hardly surprising that gas as an energy source has become attractive. One of Sweden's ship-building companies, Kockums, recently presented a plan in which the need for nuclear power could be reduced from an estimated ten reactors to six by 1985 if liquified natural gas (LNG) were imported from Arab countries. By 1985, gas would provide 26% of the country's energy needs; dependence on oil would stand at 37% instead of the 47% now expected, and nuclear power would provide 11% instead of an expected 29%.

After the announcement of this proposal, a Swedish-American team, which has been doing research into ways of stopping leaks from underground gas storage chambers, declared that a large ship fully loaded with LNG would have an energy equivalent of a tactical nuclear weapon, and questioned the wisdom of letting such a potential disaster into the Baltic.

Looking further ahead, Sweden may be able to import natural gas from Norway through a pipeline off the projected Norway – Denmark – West Germany line whose parameters are being discussed in Oslo. According to the Norwegians' calculations, gas production would have to be 20 billion cubic metres a year to make the pipeline pay. Present production is only half of this and Norway's Prime Minister, Odvar Nordli, is reported to have refused to guess in which decade the project could begin. All of this can provide only cold comfort for Fälldin: he needs solutions right now. ☐

● Last week, Mr Alexei Kosygin, the Soviet Premier, opened Finland's first nuclear power station—a 440 MW pressurised water reactor—in Loviisa, a small town south of Helsinki. The order for the power station was placed with the Soviet Union in 1970 at a value of £25 million at the then rate of exchange. ☐

PAKISTAN

Bones of contention

Azim Kidwai looks at the place of science in the recent elections in Pakistan

AFTER an exceptionally emotional and at times hurtful election campaign, the ruling Pakistan People's Party led by Mr Zulfiqar Ali Bhutto swept the polls in the elections held for the National Assembly and the Provincial Assemblies on 7 and 10 March respectively. The main opposition, the Pakistan National Alliance, has challenged the results and has refused to accept them on the grounds that the elections were rigged. It boycotted the provincial elections of 10 March saying that the National Assembly elections had been unfair.

Without going into the polemics of the political scene, and accepting that the People's Party is to govern the country for the next five years, certain projections can be made on the emphasis which will be given to science and technology and the future shape of science policy in Pakistan. The policy kept in abeyance while everyone was preoccupied with the elections is now likely to be finalised, but the lessons learned from the elections might distort it to a certain extent; the first priority, one would expect, would be geared to meeting the practical needs of Pakistan as reflected during the campaign.

Science policy as such was not an election issue, and was not accorded any status as a separate issue in the manifesto of either of the major parties. The consequences of scientific and technological advance were nevertheless bones of contention. For example, the unprecedented price-spiralling during the past four years—an almost 100% rise—was the chief subject of debate in almost all election meetings. The National Alliance promised to slash prices by good management, by coming down heavily on the black-market and so on, and some of its leaders said they would bring them down to 1970–71 levels. The people's Party refuted the claim, saying that inflation was a complex international phenomenon and that a developing country, weak in basic science and mainly producing raw materials, had to pay through the nose for finished goods.

According to its manifesto, the People's Party is committed to making Pakistan self-sufficient in grain and oil within the next five years, and to a 50% increase in GNP without neglecting industry and defence. With its victory, therefore, agriculture and oil might take precedence; the polls reflected the greater popularity of the People's Party in the rural areas than in the urban centres (it lost heavily in Karachi, the largest city in Pakistan), probably because it is likely to fund the agricultural sector handsomely.

Agricultural research and inputs like fertilisers, pesticides, new varieties of seeds, and the Irrigation, Drainage and Flood Control Council are likely to be favoured in the development effort. The importance of agriculture in Pakistan is demonstrated by the fact that in 1975–76 it contributed no less than 39,000 million rupees (16 rupees=£1) to a total gross domestic product of 119,000 million rupees. It also happens to be a source of livelihood for almost three quarters of the rural population, which makes up about 70% of the people of Pakistan.

Farm mechanisation could be another priority area. In 1975–76, some 11,000 tractors were imported—a 100% rise over the 1969–70 figure; tillers are to be imported from China and Japan. Productivity in agriculture is still growing very slowly, and is likely to gain impetus through the use of the available scientific and technological techniques.

Luckly for Mr Bhutto, sizeable quantities of oil were found last December at Dhodak in the north. Although the site is primarily a large gas-field, it is estimated to hold about 200 million barrels of oil which can start flowing in the next two or three years. Oil exploration and refineries are foremost on the agenda of the People's Party government. ☐

IN BRIEF

SRC appointment

It is now widely believed that the next chairman of the Science Research Council will be Professor Geoffrey Allen, who will succeed Sir Sam Edwards in October. Professor Allen, 48, is at present at the Department of Chemical Technology, Imperial College, and was until 1975 Professor of Chemical Physics at Manchester University; his interests are largely in polymer science. He has done considerable committee work for SRC, where there seems to be general satisfaction at the prospect of his appointment.

Delaney Amendment review

The recently announced ban on the artificial sweetener saccharin in the United States and Canada has prompted a major review of an uncompromising provision in the food and drug law which forbids the use in food of any substance found to cause cancer in test animals. Known as the Delaney Amendment, the clause has long been a target of attacks by the food industry. It has been staunchly defended by many scientists and consumer groups as a prudent measure to keep carcinogens out of the food supply. Within days of the announcement of the proposed ban, a score of bills calling for repeal of the amendment was introduced into Congress, and last week the Secretary of Health, Education and Welfare, Joseph Califano, announced a review of the Amendment's workings.

RANN resignation

The Director of the National Science Foundation's major programme of Research Applied to National Needs (RANN), Alfred J. Eggers, has asked to be relieved of his duties at the end of June to devote more time to studying problems affecting the growth and health of society. Eggers, who has steered the $70 million RANN programme through a minefield of Congressional criticism in the past few years, offered his resignation in a lugubriously worded memorandum suggesting that "in the largest sense of our future activities with our natural resources in our environment, it may well be that in important respects we are entering a 'zero sum game' ".

Fast breeder wanted

The Highlands and Islands Development Board in Scotland would welcome with open arms the commercial fast breeder reactor (CFR) at Dounreay. At a one-day meeting in Glasgow last week that coincided with the closing-down ceremonies on the Dounreay Fast Reactor (DFR), Professor Kenneth Alexander, who chairs the development board, pointedly observed that the number of employees at Dounreay would rise to 4,500 if the CFR were built there but would sink to 500 if it were not.

Pas de Concorde

THOMAS H. JUKES

A DISPUTE is now raging over permission for landing the Concorde in New York Kennedy Airport. Some of my friends in England and in France tell me that they regard the American prohibition of Concorde landings as an insufferable discrimination. They point to numerous violations of environmental safeguards in the USA, to the concerted din of jetliners taking off in droves from American airports, and to the sonic booms of American military jets. The French say that the American objection to the Concorde is based on the 'PFI' doctrine (pas fait ici).

Against these protestations, I point out to them that the supersonic transport (SST) has become a dominant symbol (and a convenient three letter slogan) to American environmentalists; a tangible epitome of technology run wild beyond the bounds of necessity or justifiability. The noise made by Concorde is said to disturb the mating process of wild birds, a ritual that has taken on an almost sacred significance ever since Julian Huxley published his fascinating observations on the sexual foreplay of Great Northern Divers. Environmentalists point to the Concorde as being wasteful of fuel and as being used only by very wealthy people. The needle-like Concorde is said to threaten the delicate ozone layer, which we have come to regard as being like a fragile soap bubble that envelops our atmosphere, protecting us from skin cancer caused by ultraviolet rays from the sun.

In addition to this injurious effect, however, ultraviolet radiation has a needed role of preventing rickets by its nutritional action. To achieve normal calcium metabolism, most mammals and birds must expose their skins to the sunlight. It is possible to speculate that the spread of the human species to northern latitudes occurred because of a mutation that led to the loss of skin pigment. The pale-skinned mutants could utilise sunlight better for production of vitamin D in their skins than could their darker fellow-human beings. Sunlight was scarce and feeble during the long northern winters, but there was just enough for pale complexioned people and so, we speculate, the whites moved into the temperate and subarctic zones. Once there, they eventually found that the need for direct sunlight by their infants could be alleviated by eating fish liver oils.

But the long era of dependence on sunlight did not really come to an end until a tray of hog millet was pushed under a quartz mercury vapour lamp for ten minutes at the University of Wisconsin by Steenbock and Black. The irradiated millet prevented rickets when added to the diet of rats. In so doing, the millet had served as a 'way station' between ultraviolet radiation and the bodies of animals. From then on, it was no longer necessary to use direct irradiation for preventing rickets in babies. Preformed vitamin D now could be added to food at a trivial cost.

Another evolutionary development, probably a very ancient one, led to the appearance of a biochemical system for combating the carcinogenic effects of ultraviolet radiation: the complex system that removes thymine dimers from DNA, formed by such radiation. The dimers and some adjoining nucleotides in one of the strands are snipped out and removed by enzymes and other enzymes restore the DNA to its original state. Some individuals lack the repair system as a result of a genetic defect, and they are highly susceptible to skin cancer.

We have evolved in concord with our surroundings. Ultraviolet radiation is an example of a stimulus that has a beneficial role at low levels, but is harmful in excess. I am more optimistic for the future of the ozone layer than for the supply of jet fuel.

correspondence

Physical science in Chile

Sir,—My friend and former colleague Alwyn Eades, who recently spent three extremely busy weeks in Santiago, is reported (10 February, page 486) to have said that "it is very easy to be misleading about Chile and very easy to be misled". The truth of this statement is made patently clear by Eades' own article, "Three years after Allende", appearing in the same issue. The article is a mixture of factual information with some personal interpretations and political opinions; it also suffers from some important, and surely involuntary omissions. The unaware reader may find it difficult to distinguish between the first three of these and may not know about the latter; so he may easily be misled by an article which may easily be misleading, especially when the atypical front cover of the issue is politically leading.

Personal interpretations and political opinions are of course entirely subjective and Eades is entitled to make and have his own, but *Nature* is not the proper place to discuss them and I will not do so. I must, however, correct some of his most important omissions and errors lest it be thought that I and/or the Chilean Physical Society share all of his views about what has happened to the physical sciences in Chile.

Eades' account of the development of physical research in Chile is in general accurate. When he writes, however, about the talks for "developing a science policy for Chile" in the early 1970s—which did in fact take place but led to nothing definite—he fails to mention what had been done before and has been done since along these lines. He seems to ignore that the National Commission for Scientific and Technological Development (CONICYT), which was established before Allende in 1968 amongst other things to collaborate in developing such a policy, produced a draft for a National Plan for Scientific and Technological Development in 1974. This draft was carefully studied for several months by a committee in which an important role was played by a sizeable number of leading scientists (including several physicists) who were freely nominated by the universities and by the local Academy of Sciences. The outcome of the committee's work was a much improved version of the plan, which was officially approved by Chile's highest authorities early in 1976. These important omissions may leave the unaware reader of Eades' article under the wrong impression that the development of a science policy for Chile was completely abandoned after Allende and that no official steps had been taken before him.

When Eades writes about what has happened in the physics department of the Engineering School, where I work, he mentions "several waves of sackings for a mixture of political and economic reasons, as a result of which the number of academic staff has dropped from 45 to about 25"; he is wrong. So far there has been a reduction of only one member of staff (and this for economic reasons) and this affected four members of the department's academic staff: one of them had reached the minimum legal age to retire and had to do so and three of the youngest ones were transferred from full-time to half-time positions. The latter three preferred to resign and found jobs in other local institutions. Independently and at a later time, two other people left this department to work in the physics department in the Faculty of Sciences. Over the past three years, a few others have voluntarily taken posts abroad and some who were on study leave abroad chose not to come back. All this has taken the number of academic staff down to its present value of 32.

It is true that four laboratories in this department lie virtually abandoned; but Eades fails to mention that three of these were never in full operation because of the shortage of staff (one of them was a one-man job) and that the fourth was almost abandoned when the Argentinian physicists who formed it were asked to leave the country before Allende's time. Eades also says about one of the Chilean Physical Society's present preoccupations, that "since all elections are prohibited in Chile, it (the Chilean Physical Society) is unable (like many other organisations) to replace those committee members who leave the country or retire", so he thinks that "it may shortly find itself with no committee at all". Elections are forbidden and this was one of our preoccupations while he was here. We have since found, however, that there are legal ways for scientific bodies such as the Societies of Biology, Chemistry, Physics and Mathematics to renew their committees at their own free will and that some had in fact already done so. I am glad to inform him and your readers that we have now replaced one committee member who left the country and another who resigned, and that we are planning on renewing our committee early next year, when most of our membership will gather at the University of Concepción for the next scientific meeting.

Finally, I strongly disagree with Eades' statement that one side-effect of the coup was to set back physics research in Chile by nearly two decades. As his article rightly mentions, twenty years ago there was little or no research in physics in Chile: the first groups were just beginning to form, there was virtually no equipment, the Chilean Physical Society did not exist and the very idea of doing physics research in Chile was thought to be utopian by most. Whatever the results have been of the permanent brain drain from Chile over the past twenty years and the departure of scientists with every change of government, we are now much better off indeed than two decades ago. The large (by Chilean standards) number of scientific papers published in the last three years by Chilean physicists who are still working here is the best proof of this.

Yours faithfully,

Claudio Gonzalez

President,
Sociedad Chilena de Física,
Chile

Not rats, but mice

Sir,—We 'applied biologists' at the Pest Infestation Control Laboratory have been professionally associated with rats and mice for some thirty odd years, in all parts of the globe; I seem to have become our 'coprologer'.

Thomas Jukes (10 February, page 491) has made a slight error: it is not rat faeces that are unscreenable from wheat kernels but mouse faeces. The principle is the same however. I agree with his point about 'filth' in food—it is nearly always purely an aesthetic objection sustainable in the 'developed' world—provided the food has been cooked!

It is a pity therefore that he didn't get that point accurately stated.

Yours faithfully,

R. A. Davis

Pest Infestation Control Laboratory,
Surbiton, Surrey, UK

news and views

The inconstant Sun

from David W. Hughes

UNTIL recently astronomers were convinced that the Sun was a regular, well behaved star of considerable constancy. Its present day behaviour was taken to be typical of its activity over a much longer time span. This attitude is now rapidly changing thanks in no small part to the work of John Eddy of the High Altitude Observatory, Boulder, Colorado. He found (*Science* **192,** 1189; 1976) that there was little or no historical evidence to indicate that the 11-yr cycle of solar magnetic and sunspot activity existed before about AD 1700 and concluded (in *Physics of Solar Planetary Environments* (ed. Williams, D. J.) **2,** 958; 1976) that there seems to be a much more gross change occurring in the Sun's behaviour and especially in the solar constant (the energy flux received from the Sun at the Earth's orbit) over periods of hundreds and thousands of years. These changes do not seem to be periodic.

Maunder minimum

The inconstancy of the sunspot cycle was first noticed by F. W. G Spörer and E. W. Maunder in the 1890s. Spörer was studying the distribution of sunspots with latitude and found evidence that the number of spots in the northern and southern hemispheres of the Sun was not always balanced. To check this he consulted historical records of solar activity and found to his amazement that over a 70-yr period between 1645 and 1715 practically no sunspots were seen. This period has been named the Maunder minimum. The few spots that did occur were invariably at low solar latitudes and were single; only one group was seen between 1645 and 1705. Between 1672 and 1704 there were no northern hemisphere spots at all, in fact there were fewer spots between 1645 and 1715 than in a single active year under normal conditions. Eddy re-examined the historical data (*Science op. cit.*) bearing in mind that 'absence of evidence is not evidence of absence'. He also posed such questions as 'how good were the 17th century observers and their observing techniques' and 'how constant a watch was kept?'.

Most solar telescopes of those days had focal lengths of 2 to 4 m and apertures of 5 to 10 cm, the solar image being projected onto a white screen placed behind the eyepiece. The solar image was large enough to make spot umbrae and penumbrae easily discernable and observers recorded details of white-light faculae, penumbrae filaments, satellite sunspots and most of the observational details known of sunspots today. Several transits of Venus and Mercury were observed during the 17th century as well as some 53 solar eclipses. The fact that the first division in Saturn's rings was discovered in 1675 and that five of its satellites were discovered between 1655 and 1684 attest to the fact that a resolution of 1 arc s could be obtained and that 11th magnitude satellites less than 40 arc s from the limb of a bright planet could be observed. Eddy concluded that spots would have been seen if they were there, a conclusion supported by the fact that the few spots that did occur motivated the discoverers to report their observations immediately in the journals of the time.

Moving from sunspots to phenomena caused by and modified by solar activity Eddy verified Clerke's observation that 1645 to 1715 was a period characterised by a marked absence of aurorae and was also a time of profound magnetic calm. The number of aurorae reported increased dramatically after 1716. Even though the scientific renaissance came to auroral latitudes at that time and Halley's paper in 1716 put the auroral

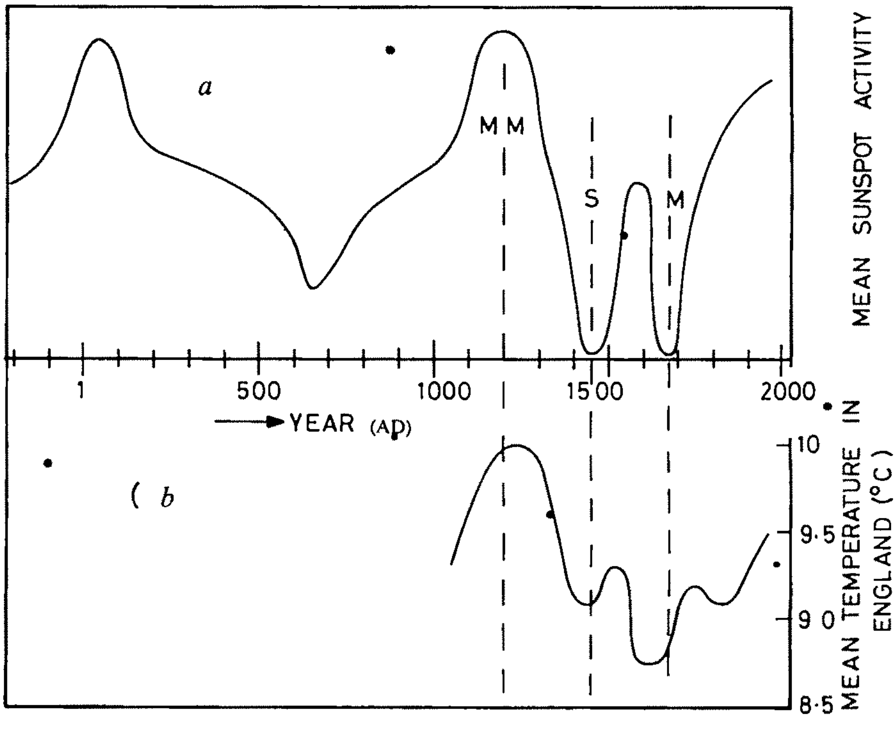

Fig. 1 *a,* A long term envelope over the solar sunspot activity using ^{14}C activity as a guide. MM is the Mediaeval maximum, S the Spörer minimum and M the Maunder minimum (after Eddy in *Physics of Solar Planetary Environments* (ed. Williams, D J.) **2,** 958; 1976). *b,* Estimate of the mean annual temperature in England (after Lamb, *Climate, Present and Past and Future* **1,** Methuen, 1972).

phenomenon on a firm scientific footing, both of these resulting in an upsurge of interest, the 'Maunder minimum' of sunspot activity is evident from auroral activity alone.

In addition it cannot just be a curious coincidence that the chromosphere was discovered in 1706 and that the first description of a structured corona was given in 1715. Coronal shape varies with solar activity. With many underlying spots the corona is large and made up of numerous long tapering streamers extending outwards like flower petals. At solar minimum, with very few sunspots, the corona becomes compressed and bland, the only unusual features being the long symmetrical extensions along the solar equator, this being the zodiacal light (or F corona). Between 1645 and 1715 the corona at eclipses was always described as being limited in extent (1 to 3 arc min above the limb) and as being dull or mournful, and reddish, typical of an extended minimum of solar activity.

Radiocarbon data

Now sunspot data only takes us back with any reliability to the early 17th century. Radiocarbon data on the other hand can extend our knowledge of solar activity back to about 5000 BC, almost half way to the last glaciation. ^{14}C is produced in the Earth's upper atmosphere by galactic cosmic ray bombardment. Through the intermediary of the interplanetary magnetic field the Earth can be shielded from these galactic cosmic rays, high solar activity increasing the field, reducing the cosmic ray flux and lowering the ^{14}C production rate. Trees assimilate ^{14}C as CO_2 in the photosynthesis process so individual tree rings preserve a record of the atmospheric ^{14}C/^{12}C ratio at the time of formation. Figure 1*a* shows the overall envelope of sunspot activity obtained when the ^{14}C concentration is used as an indicator. The Maunder minimum can be clearly seen as can the Spörer minimum (1400–1510) and the mediaeval maximum of activity which occurred between 1120 and 1280. At the present we are half way up an increasing branch of the curve moving towards a time of high solar activity. Figure 1 also shows how these massive solar changes affect terrestrial climate. The lower curve (Fig. 1*b*) shows mean annual temperature in England and it can be seen how the Maunder and Spörer minima correspond to the two coldest extremes of the Little Ice Age when global temperatures were depressed by 0.5 °C to 1 °C.

Solar variability

Eddy is convinced that the individual ups and downs of the 11-yr cycle and also shorter term solar variability are almost wholly unrelated to terrestrial meteorology, this in fact being governed by the total radiative output from the Sun (which is proportional to the solar constant). Öpik (*Irish Astr. J.* **8**, 153, 1968) found that the average value of the measured solar constant had increased steadily, by about 0.28% during the 30-yr period between 1921 and 1952. Figure 1*a* thus also represents the 1% peak-to-peak amplitude variation of the solar constant. Sunspot production is thought to be directly proportional to the rate of radiation flow through the solar photosphere.

In a recent paper in *Solar Physics* (**46**, 3; 1976) Eddy, Gilman and Trotter found that the equatorial rotation rate of the solar photosphere just before the Maunder minimum was 3 to 4% higher than its present value. The rate of change of rotation rate between 0 and ±20° solar latitude was also enhanced by a factor of 3. These results came from an analysis of a series of daily full-disk drawings of the Sun made by Johannes Hevelius between 1642 and 1644 and published in his book *Selenographia Sive Lunae Descriptio* This anomalous rotation may be just beyond the velocity range capable of producing sunspots by the solar dynamo action so the high velocity in the early 1640s could have caused the sunspot dearth that followed.

Dynamo theories of solar magnetic activity rely on the stretching of the general magnetic field of the Sun by a radial gradient of angular velocity in the subsurface convection zone. To explain the migration of sunspots towards the solar equator as the solar cycle progresses this angular velocity must increase with depth below the photosphere. Redistribution of angular momentum throughout the convection zone caused by a variation in the radiation flux and resulting in a decrease in angular velocity deep in the zone could reduce the strength of the dynamo action and switch off the spots.

Tidal influence unlikely

It has often been suggested that the 11, 78 and 179-yr cycles of solar activity are controlled by gravitational tides raised on the Sun by the planets, even though this tidal force is miniscule compared with the force of solar gravity (which is about 10^{11} times larger). Proponents of the tidal hypothesis tend to consider the tides as triggers but as Charles Smythe and John Eddy point out on page 434 of this issue of *Nature* trigger mechanisms have the disadvantage of being out of the reach of physical criticism and usually are beyond the grasp of observational tests. Tidal theories also produce regular sunspot periodicities so how can the Maunder minimum be produced? Planets surely did not stop exerting tidal influence when the spots disappeared.

Using a computer Smythe and Eddy calculate all the two, three and four planet conjunctions that occur between AD 1575 and 2000 and compare their occurrence times with solar activity cycles. There are no dissimilarities between the conjunction frequencies that occur within the Maunder minimum period (1645–1715) and the ones which occur at adjacent periods. They go on to calculate the daily tidal potential at the solar equator exerted by the planets. The power spectrum of this potential, over a 50-yr period, has principal peaks at *J*, *J*/2 and *J*/3 (*J* being the Jovian orbital period of 11.86 yr). The authors find that the power in each of these peaks has not changed perceptibly in the past 500 yr, the power spectra for 1925–1975 being indistinguishable from the Maunder minimum spectra. Tidal theories of sunspot formation thus become much more difficult to support.

So we are presented with an inconstant Sun with sunspots which can be switched on and off in about 10 yr and can stay off for around 70 to 160 yr. The spottiness seems to be tied directly to the total energy flux from the Sun and this seems to vary with time by about 1%. Why it varies and how it directly affects spot production are two questions still to be answered. ☐

H–2 and mating preferences

from J.C. Howard

It ill becomes an immunologist to draw attention to the work I want briefly to discuss. Unhappily, the paper appeared in a journal specialising at the moment in the advancing front of immunology, and was probably rather little read by most of the people best qualified to enjoy it. The paper, entitled 'Control of mating preferences in mice by genes of the major histocompatibility complex' (Yamazeki *et al. J. exp. Med.* **144**, 1324; 1976) reported that, given a choice, a male mouse will tend to pick a female mouse to impregnate on the basis of the alleles she carries in her major histocompatibility (H-2) system. Furthermore the preference shown by the male is itself a function of his H-2 alleles. The preference is not necessarily for the self H-2 type; in some matings it is, for instance BALB.B(H-2^b)♂ chose H-2^b♀

in 70% of trials, in preference to BALB (H-2^d)♀, but in another cross B6♂ (H-2^b) showed a preference for B6-H-2^k♀, and B6-H-2^k♂ for B6♀, rather than for the partner of their own H-2 type. The experimenters used H-2 congenic mice to avoid confusing influences from the genetic background.

This very strange and remarkable phenomenon was appropriately discovered at the Sloan-Kettering Memorial Cancer Center since it was the Sloan-Kettering's President, Lewis Thomas, who first suggested at the second International Congress of Immunology in Brighton in 1974, that the diversity of histocompatibility antigens might be used by animals to identify each other, presumably by smell, thus drawing together two of his persistent interests, immunology and pheromones.

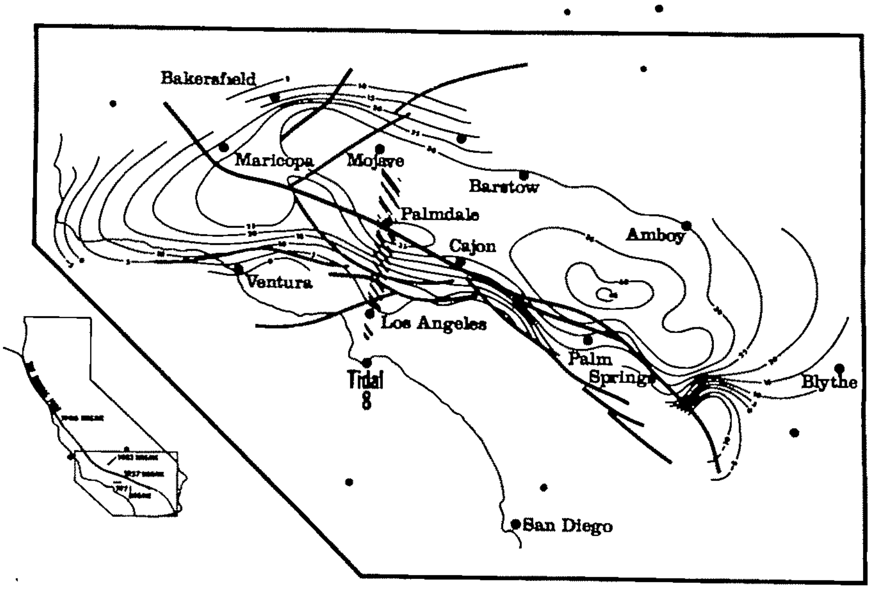
There are many aspects of these findings that need further clarification: do the females do any choosing, or do they merely wait to be chosen? Is the stimulus indeed a smell, and if so from where (the urine?), and precisely what is smelly? Histocompatibility antigens are not obvious candidates for airborne pheromones: perhaps the association with H-2 is indirect, through metabolites from characteristic bacterial flora infesting the skin, or intestinal and genitourinary tracts, the presence of particular organisms being under the control of H-2 linked Ir genes. In this context it was reported a few years ago that the bacterial flora of the human skin was indeed individual, as assessed by characteristic patterns of phage sensitivity, and of course the individuality of human odour has long been known, at least to dogs.

The biological significance of these complex phenomena is not clear. As Thomas and others have pointed out, the recognition of individuals is important for animals with a developed social structure. The H-2 associated mating preferences demonstrated by Lewis Thomas and his colleagues have two additional interesting consequences. In so far as the mating preferences are disassortative they will encourage the persistence of H-2 polymorphism. For a long time, evolutionarily inclined imunologists (and indeed immunologically inclined evolutionists such as J. B. S. Haldane) have been looking for possible 'external' reasons why H-2 polymorphism should be so extensive and so persistent. Until very recently there were no good clues. For a time the effect of H-2 incompatibility on placental weight in mice was offered as a mechanism for the maintenance of the polymorphism: foetuses H-2 incompatible with their mothers had larger placentas and a heavier birth weight than H-2 compatible foetuses in the same pregnancy. There were difficulties in repeating the work, and it has now dropped out of fashion. Furthermore its universal significance as a mechanism for maintaining polymorphism seemed doubtful when it was realised that it was hardly applicable to the birds!

More recently Doherty and Zinkernagel provided a simple mechanism for heterozygous advantage in H-2 when they showed that viral antigens on cell surfaces were recognised in association with H-2 specificities. The virus-infected H-2 heterozygote is thus able to display a more varied antigenic stimulus to itself than the homozygote, with a

Palmdale bulge changes shape

from Peter J. Smith



It is just about a year since Castle *et al.* (*Science* **192**, 251; 1976) reported their discovery of the crustal bulge centred near the town of Palmdale about 65 km north of Los Angeles. This uplift, which apparently began about 1960, had by 1974 reached more than 0.35 m at its highest point and was observable over an area of at least 12,000 km^2 of southern California. Interest in the bulge was enhanced by the fact that Palmdale lies almost on the San Andreas fault and by the discovery that the uplift contours were elongated along the fault over a distance of more than 150 km. Moreover, most of the area with an uplift greater than 0.15 m had remained virtually aseismic since at least 1932. The possibility that the bulge might herald a major earthquake therefore had to be taken seriously.

No such earthquake has yet occurred, but a new analysis of historical and recently acquired geodetic data, announced this month by the US Geological Survey, reveals that the uplift covers a much wider area than previously supposed and that part of it has collapsed since 1974 The zone originally studied by Castle and his colleagues lies between Maricopa and Cajon (see map), but it is now evident that uplift extends at least as far as Blythe in the southeast. The bulge thus stretches for at least 600 km along the San Andreas fault and covers an area of more than 90,000 km^2. Moreover, there is a second peak of uplift (between Palm Springs and Amboy) which is actually greater than the Palmdale peak in 1974.

Since 1974, however, the uplift in the vicinity of Palmdale itself has been reduced by about 0.18 m. The significance of this depression is unclear, although the area has seen similar behaviour before. A less well documented uplift of possibly as much as 0.30 m took place sometime between 1897 and 1914 but had almost disappeared by 1926, which has led Castle to speculate that "the recent deformation may be but a part of a generally cyclic process".

It may be significant that no major earthquake can be associated with the earlier episode of uplift and collapse, which would seem to imply that the present deformation does not necessarily indicate an imminent earthquake. On the other hand, uplift definitely preceded the 1961 Niigata (Japan), the 1971 San Fernando (California) and the 1975 Haicheng (China) earthquakes, among others. The 'Palmdale bulge' may or may not pose a problem to the residents of southern California, therefore. The only thing to do for the time being is to continue to observe it as closely as possible.

correspondingly larger protective immune response. This is the kind of effect that not only guarantees the persistence of H-2 polymorphism (though not necessarily its variety) but also may explain why the mouse, at least, goes to such lengths to increase H-2 heterozygotes in the population above the 'natural' equilibrium frequency, by using recombination inhibition from the neighbouring T system in combination with a high frequency of lethal recessive alleles. Disassortative mating preference by external identification of H-2 products or their effects will operate in the same direction.

Recognition of genetically endowed polymorphic pheromones may also play a part in maintaining the genetic integrity of incipient species in the face of a constant risk of interbreeding with the parent species. John Godfrey has shown for example, that subspecific variants of the bank vole *Clethrionomys glareolus* show a pheromone-dependent assortative mating preference for their own subspecies, given a choice. Some behavioural isolation is clearly a prerequisite for fixation of the subspecific gene complex: it would be interesting if the accumulation in a subspecies of polymorphic variants at genetic systems normally recognised as antigens were to play a part in this important phenomenon.

Clearly the Sloan-Kettering findings cannot be taken lightly. It is therefore a pity that the H-2 associated mating preferences shown by the use of congenic lines were not confirmed in breeding tests, since trivial and unrecognised differences between lines, for example in housing, handling and maintenance could possibly have caused the effects that were seen. I hope that the work is soon confirmed and extended, and that the study of major histocompatibility polymorphisms has just begun a new life far from the inward mysteries of the immune response. ☐

Landslides in sensitive soils

from I. J. Smalley

THE property of many sensitive clay soils in eastern Canada to transform suddenly and unexpectedly to material of virtually zero strength makes this region particularly prone to large landslides. Since the turn of the century, landslides in eastern Canada have cost more than 100 lives and involved the loss of more than 20,000 acres of upland. Another large landslide may threaten this spring on the calculation that these massive earthflows occur on average every four or five years and the last one, in which 31 people were killed, occurred at St Jean Vianney in 1971. 'Sensitive' soils have a very high ratio of undisturbed strength to remoulded strength but the nature of the transition and the factors which control it are not yet established despite the investigations which have followed in the wake of the St Jean Vianney disaster.

The Terrain Sciences Division of the Geological Survey of Canada has carried out extensive mapping in sensitive soil regions, and the geological setting of the problem in eastern Canada is becoming clearer (Gadd, *Proc. 4th Guelph Geomorphology Symp.* 137; 1975). Extensive studies of the pore water chemistry (Torrance *Can. Geotech. J.* **12,** 326; 1975) suggest that the leaching effect first described by I. T. Rosenqvist in the late 1940s should still be considered a significant factor in Canadian clays, although there appears to be no direct correlation between leaching and sensitivity. Another interesting lack of correlation is that between sensitivity and size of landslide; a conclusion reached by Mitchell and Markell after a study of 75 landslides (*Can. Geotech. J.* **11,** 11; 1974).

Interparticle cementation, by producing strong but brittle bonds, could be an important factor contributing to sensitivity Attention has been focused recently by R. N. Yong and his collaborators at McGill University on the presence and importance of amorphous matter as a cementing agent in these clays and it seems that some soils may have an amorphous matter content as high as 40%. Mineralogical studies on sensitive soils still present problems, mainly those of making quantitative estimates of constituents. Some initial thermogravimetric studies have been made on clay from the St Jean Vianney slide and further studies are in progress on material from the vicinity of another large 1971 event—that at South Nation River. The lack of clay minerals is notable; Gillott (*Can. Mineral.* **10,** 797; 1971) was one of the first to draw attention to the predominance of primary mineral particles (as distinct from clay mineral particles) in the Canadian sensitive soils. The soils, as a result, have a very low plasticity index and the low plasticity facilitates the solid–liquid transition. Cementation provides extra strength but once the interparticle bonds are broken there are insufficient clay minerals to influence the abrupt change in strength properties.

Mitchell and Klugman (*Engng Geol* in the press) in a survey of recent Canadian work report that regional differences in sensitive soils are becoming more apparent although the occurrence of landslides of the characteristic form may be more widespread than has been realised. Critical factors may be revealed when the scope of investigations can be enlarged to include the less accessible regions, in particular Labrador An improved classification of sensitive soils is also required and R. Soderblom at the Swedish Geotechnical Institute has recently taken a significant step in this direction (*SGI Prelim. Rept* **55,** 1974). He is concerned with soils of extreme sensitivity (often called quick-clays, after the Swedish term *kvicklera*) and has distinguished two distinct types. Those which require a considerable energy input to cause the solid–liquid transition he calls 'slow quick clays' and those which transform easily are 'rapid quick clays'. The new parameter of rapidity can be assessed using a standard Casagrande liquid limit device, and should prove very useful when sensitive soil comparisons are being made. ☐

Relapses in malaria

from F. E. G. Cox

RELAPSES, months or even years after an initial infection, are characteristic of malaria and in the quartan disease an individual may experience periodic fevers for the whole of his life. Until the discovery of the exoerythrocytic stages of malaria in the liver in 1948 it was widely assumed that during the remissions the parasites persisted in the blood at subpatant levels and that their spasmodic appearances in larger numbers represented recrudescences rather than true relapses. Relapses proper only occur when the blood is quite free from parasites during the intervals between periods of patency. The discovery of exoerythrocytic stages in the liver immediately suggested that it was there that they sojourned and from time to time flooded the blood with new erythrocytic forms. A number of observations, however, have indicated that this explanation is too simple (Garnham *Protozool. Abstr.* **1,** 1; 1977) and recent work in the Soviet Union and Romania suggests an alternative hypothesis.

It has been suspected for some time that the tertian malaria parasite, *Plasmodium vivax,* exists in two forms, one with a short prepatent period (13–16 d) before parasites appear in the blood following infection from a mosquito and the other with a less clearly defined longer period of 300 d or more (Sergiev & Tiburskaya *Arch. Roumaines Path. exp. Microbiol.* **26,** 475; 1967). The short prepatent form is characteristic of tropical strains and the other is typically found in more temperate regions such as the Soviet Union and North Korea Using a North Korean strain a team of nine coworkers, six British and three Romanian, (Shute *et al. Trans. R. Soc. trop. Med. Hyg.* **70**, 474; 1976) have demonstrated the coexistence of sporozoites capable of inducing long or short prepatent periods. They infected humans with 10, 1×10^2, 1×10^3 or 1×10^5 sporozoites and found that in those given 10 or 1×10^2 the prepatent periods ranged from 262–628 d, in those given 1×10^3 the prepatent period in one was 16 d and in four others between 257–386 d and in seven infected with 1×10^5 the prepatent periods were 13, 15 or 16 d. In parallel experiments using a tropical strain of *P. vivax* all the prepatent periods were short, 12–17 d (Ungureanu *et al. Trans. R. Soc. trop. Med. Hyg* **70**, 482; 1976). These experiments suggest that temperate strains of *P. vivax* consist of at least two genetic types, one with a long and one with a short prepatent period and that in any population of sporozoites there are more long prepatent period forms than short whereas in tropical strains the reverse is probably true. The selection of the two forms has presumably been due to differences in the seasonal availability of suitable mosquitoes for transmission.

It may well be that there are more than two forms of *P. vivax* within any one strain and Tiburskaya and Dukhanina (*Med. Parazit.* **45**, 218; 1976) believe that there may be as many as five in one Russian strain and that the expression of a particular form varies from month to month.

The life cycle of the malaria parasites must now be redescribed. Sporozoites are injected into the host and enter the liver where they may develop rapidly or slowly into multinucleate exoerythrocytic schizonts the products of which invade blood cells. There is no need to postulate a continuous series of exoerythrocytic cycles to account for relapses because these could result from initial infections with sporozoites having prepatent periods of up to several years. Differences in the time taken for different sporozoites to mature into exoerythrocytic stages could account for the irregular relapses characteristic of malaria.

Continuous exoerythrocytic cycles are now no longer thought to occur in any species of human malaria. In *P. vivax* and *P. ovale*, sporozoites with long but variable development are responsible for relapses whereas in *P. falciparum* and *P. malariae* small numbers of parasites persist in the blood after the initial infection and subsequent attacks of malaria result from recrudescences of these and are not true relapses It is now, more than ever before, important to know exactly what species is causing malaria because parasites that occur only in the blood respond to a number of antimalarial drugs whereas those that develop slowly somewhere else in the body do not. ☐

Telecommunications in the '80s

from John R. Forrest

A meeting entitled Telecommunications in the 1980s and After was held at the Royal Society on 10–11 March, 1977. A small exhibition also provided a demonstration of telecommunications hardware currently used or under development.

EXOTIC technology, system planning and social implications were all discussed in a balanced programme. Sir Edward Fennessy (British Post Office) saw an optimistic future for telecommunications on the global scale, with some 1,500 million telephones by the year 2000, this figure being dominated by the now-developing countries. He saw electronic letter and document overnight transmission as a very rich field for development in balancing the loading of telecommunications traffic. This optimism in regard to the almost limitless capabilities of technology was shared by K. Corfield (TEMA Ltd), but he showed concern that Britain should itself have a most modern and internationally-compatible telecommunications system as an incentive for a powerful export industry. By contrast,

Dimeric water molecules

from Graham Richards

IN the heady days when 'polywater' was thought to exist and even to represent a danger to life, theoretical chemists were quick to calculate the stability of water dimers and to risk their reputations by lending weight to credence in the new form of water The bursting of the polywater bubble has not, however, ended interest in the dimeric species $(H_2O)_2$. It was first postulated to exist in order to explain pressure, volume and temperature observations in water vapour and later observed directly in solid rare gas matrices and by mass spectrometric techniques. The dimer, trimer and other small polymers are of significance in the understanding of liquid water itself and in the study of the all-important hydrogen bond which must be involved in the stability of water polymers and indeed in most natural polymers.

The quality and reliability of the most recent theoretical predictions using *ab initio* molecular orbital methods is demonstrated by a new detailed experimental study of the water dimer by molecular beam electrical resonance spectroscopy (Dyke *et al J chem. Phys.* **66**, 498; 1977). Molecular beams of the hydrogen-bonded dimers were generated by expanding water vapour through a pinhole nozzle. The cooling so produced reduces the temperature of the beam so that the thermal energy is insufficient to break the relatively weak hydrogen bond. Radiofrequency and microwave transitions were observed arising from changes in the rotational energy of the rotating dimer. This gives structural information as does the dipole moment which can be interpreted to give the relative orientations of the two H_2O monomer subunits.

The resultant structure is the so-called "*trans*-linear" complex This consists of one water molecule joined to the other by means of a linear hydrogen bond. The covalently-bonded hydrogen of one partner points along a lone pair electron lobe of its mate with a plane of symmetry along the hydrogen bond bisecting the HOH angle of the proton acceptor. The non-hydrogen bonded protons are disposed *trans* to the long bond.

The distance between the two oxygens is longer in the dimer than it is in liquid water, a similar result also being known for $(HF)_2$. Apparently then, when a hydrogen bond is formed, charge transfer occurs in such a way as to enhance the formation of further hydrogen bonds which are strengthened, as is the case in liquid water.

Another striking point is that the geometry of the proton acceptor is nearly tetrahedral in conformity with simple ideas about the disposition of electron lone pairs, despite the fact that calculated electron density maps do not show prominent lone pairs on monomeric water. The results do, on the other hand, support the accepted view that hydrogen bonds have an important covalent component and are not merely electrostatic.

The detailed results of this work answer most of the questions about the water dimer, but many remain about the trimer. Is it an open structure with two hydrogen bonds, or is it a cyclic entity with three? No doubt theoreticians will now feel confident to answer this question long before the difficult experiments can be completed.

Mr. D. Elias (West German Ministry of Telecommunications) was more conservative towards exotic technology, with the exception of techniques like Viewdata, seeing as first priority the full development of conventional telephone service to all members of the public. He also stressed the need to take future system development decisions with careful regard to their effects on employment.

Speaking about integrated circuit technology, D. Roberts (Plessey Ltd) showed that although 1 Mbit of memory on a $1''\times\frac{1}{4}''$ chip was likely very soon, the progress to more and more logic elements on a semiconductor chip was likely to be checked by the low yields and higher failure rates as complexity increased, implying an optimum scale of integration. He pointed to the crucial need for very much greater contact between telecommunications equipment and semiconductor device manufacturers so that highly-structured logic devices such as telecommunications-dedicated microprocessors could be developed.

For telephone exchanges, digital switching and computer supervision through stored program control with its ease of modification to suit continued system development, was seen as essential by D. Leakey (GEC Ltd) and R. Ketchledge (Bell Laboratories, USA). Savings in cost and equipment size would also result, but advances in software were still much needed. Because of the diversity in population settlement size, hybrid systems involving local microprocessor control coupled to centralised computers were felt to be the optimum solution by K. Cattermole (University of Essex). Since optical techniques were likely to be used in transmission, he also saw optical switching as a very fruitful research area for future wide-band systems.

In transmission techniques, the most exciting development was undoubtedly optical fibre communication. Fibre attenuation was now down to a few dB km^{-1} in large volume production. Continued research was needed in fibre jointing, fibre reproducibility, laser characteristics and modulation bandwidth, but no fundamental barriers to progress were seen. The optical link for telephone traffic from Martlesham to Ipswich in the UK would eventually be upgraded to a modulation rate of 560 Mbit s^{-1} from the initial 8 Mbit s^{-1}, providing a full test of possible future systems. Although multi-mode, graded-index fibres had bandwidths up to 1 GHz, A. Gambling (Southampton University) was optimistic over the future for the higher bandwidth single-mode fibres.

The continued growth of submarine cable installation at around 16% each year was predicted by J. Tilley (STC Ltd). This was one area where it was felt that digital transmission would not replace analogue transmission for some time, a further generation of analogue submarine cables with bandwidths up to 150 MHz being likely. The optical fibre submarine cable was, however, suggested as an exciting possibility for the next century.

There was very similar traffic growth rate on mature satellite links, but here transmission would be overwhelmingly digital in future. The long-term development, in the opinion of B. Edelson (COMSAT, USA), was the construction in space, using the space shuttle, of large satellite platforms containing replaceable equipment modules. Antenna beams would be electronically shaped and steered

The lectures on planning for the future were almost entirely concerned with the social effects of a highly-developed telecommunication system, which can on one hand integrate nations and populations, or alternatively insulate them from personal contact. G. B. Thompson (Bell-Northern, Canada), in a highly entertaining lecture, felt that neither extreme would occur, but in his opinion our society did not know how to handle information and ran into trouble when too large a proportion of the population was involved in information processing as opposed to materials processing. The basic difference with information is that you can sell it many times over and you still have it, he commented. He felt that some very careful research was needed before our society could adjust to a highly-developed information transmission system.

The overall feeling of the meeting was that the novel technology required for future telecommunications systems posed little problem, the research and development areas being clearly defined. The real difficulties were in the financial resources required for systems of ever-increasing size and the difficulty of organisation and decision. In the words of R. Ketchledge: " . . . only politics and lack of vision stand in the way of the new era". ☐

A hundred years ago

In an article which lately appeared in Nature (vol. xv., p. 308), I gave an account of certain very remarkable discoveries made by Prof. Kühne, of Heidelberg, which added additional interest to the startling announcement contained in a recent communication made by Prof. Boll, of Rome, to the Berlin Academy, to wit, that the external layer of the retina is, during life, of a purple colour, which disappears at death, but which is, during life, continually being bleached by the action of light.

It is with great surprise that I have heard that the prominence given to Prof. Kühne's researches on the "Vision-purple" in my article in Nature has given some pain to Prof. Boll, who probably feels some disappointment in not having been allowed to remain in sole possession of the promising field of research upon which he had entered.

In the particular case in point it would appear that Prof. Boll re-discovered (and, what is more, *appreciated the full value* of) a fact which had really been observed by some others (Leydig in 1857, and Max Schultze in 1866), but which had certainly not become part and parcel of the common stock of scientific knowledge, viz., that the rods of the retina are red, he observed that under the circumstances of his own experiments the colour faded at death, and arrived at the false conclusion that the colour was a function of the vital condition of the retina. He, however, observed the remarkable action of light in modifying the colour. "During life", he announced in his paper, "the peculiar colour of the retina is continually being destroyed by the light which penetrates the eye. Diffuse daylight causes the purple tint of the retina to pale. The more prolonged, dazzling action of the direct rays of the sun entirely destroys the colour of the retina. In darkness the intense purple colour is again restored. This objective alteration of the peripheral structures of the retina brought about by the rays of light undoubtedly occurs in the act of vision". This was the great discovery which Boll made, and with which his name will ever remain honourably connected. Although, however, he had been in full possession of the facts in the month of June of last year, when he demonstrated them to Professors Du Bois-Reymond and Helmholtz, and only published his paper in November, he did not succeed in making the discoveries with which, justly, the name of Kühne is now associated. Kühne showed that if the retinal purple is usually destroyed at death, the result is attributable to the action of light, persistence of the colour being by no means necessarily connected with the living condition of the retina. In his beautiful and far-seeing discovery of the true function of the retinal epithelium cells as restorers of the vision purple, he was fortunate enough to make a discovery which it would be very bold for any one—even for Prof. Boll—to say he would have made, had time and opportunities been granted In saying that Boll had discovered everything referring to the vision purple, M. Warlemont shows that he has not appreciated the fact that two great discoveries have been made, the second supplementing the first, and actually needed in order that the significance of the first should be appreciated.

Temperature and duration of the shadow of a recently-arrived lunar boulder

S. A. Durrani, K. A. R. Khazal & A. Ali

Department of Physics, University of Birmingham, Birmingham, UK

Natural thermoluminescence retained by soil samples from the shadows of some Apollo 17 boulders and from an adjacent sunlit area has been used to derive the temperature in the shade and the length of time for which the shadow has been cast in one case. This has implications for soil mechanics on the lunar surface.

In the near-perfect lunar vacuum, the absence of gaseous convection, and the highly insulating nature of the powdery surface soil, ensure that there are steep temperature gradients across the boundary of a lunar shadow. It is therefore of interest, for example in studying the condensation of volatiles and even of any pristine water vapours, to try to determine the average temperature in the shade on the lunar surface. We have used the thermoluminescence (TL) properties of soil samples from inside the shadows of some Apollo 17 boulders and from an adjacent sunlit area to make such calculations. Some evidence, based on the freshness of boulder tracks observed by the astronauts, suggested that the boulders had not been in their present position for very long. We have therefore attempted to calculate the length of time for which one of the boulders had cast a shadow on our soil sample.

To preserve the natural TL of the shaded samples as much as possible it is important that they should be kept at low temperature after retrieval[1]. Some of the samples used in the present study were kept refrigerated by the staff of the Lunar Receiving Laboratory, at ~ −20 °C, starting about 3 weeks after the Apollo 17 splashdown on 17 December 1972. Since their receipt by us in England (on 22 March 1974), these samples have been kept in our laboratory at the temperature of either dry ice (−78.5 °C) or liquid nitrogen (−196 °C). This continuous refrigeration has proved beneficial. For comparison, a counterpart of each of the shadowed samples has been kept at room temperature from the beginning: the 'freezer counterpart samples'. The sample from an adjacent sunlit area has also, throughout, been stored at room remperature.

The samples concerned were collected from two locations at the Apollo 17 site. From Station 6 came the 'permanently shadowed' soil sample 76240, collected from about 1 m under the north overhang of boulder no. 4, which measured ~5 × 4 × 3 m. The boulder is believed to have been derived from the North Massif and seems to have been moving downhill on an 11° slope to the south. For comparison, a second sample (76260, the 'sunlit sample'), consisting of a 2 cm deep skim soil, was collected from just outside the shadow. From the second location, Station 2, only one sample (72320) was collected: a surface soil from about 20 cm under an east-west overhang of a 2-m boulder (no. 2) lying in a strewn boulder field at the lower slopes of South Massif. This sample seems, from our investigations, to have been only partially shaded. No sunlit sample from an adjacent area was available in this case. Details of the apparatus used by us for TL measurements may be found in ref. 2.

TL glow from shaded and sunlit samples

Figure 1 shows the striking difference observed in the natural TL glow emitted by the shaded and the sunlit samples. The shaded sample from ~1 m inside the shadow (76240, 22) has by far the most natural glow, followed by the one from ~20 cm inside the shade (72320, 4), with the least preserved glow being in the sunlit sample (76261,25). Moreover, the glow starts at successively and appreciably higher temperatures on going from the shaded to the unshaded samples in the above sequence (namely, ~55, ~110 and ~180 °C, respectively), resulting from thermal drainage of TL from the shallower traps under quite distinct lunar temperature environments.

To investigate the effect of room-temperature storage of the

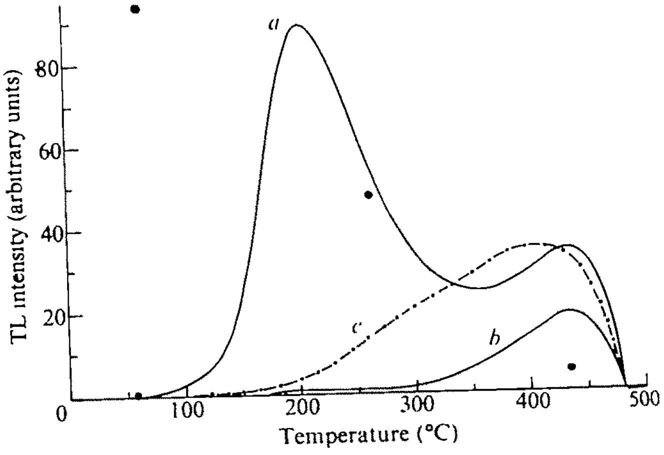

Fig. 1 Natural TL glow curves from the shaded and the unshaded samples. The 'permanently shadowed' sample (76240,22, curve *a*) and the 'partially shadowed' sample (72320,4, curve *c*) have been kept refrigerated (see legend to Fig. 2), while the sunlit sample (76261,25, curve *b*) has been stored at room temperature since receipt on the Earth. Sample weights: *a*, 1.6 mg; *b*, 2.2 mg; *c*, 1.8 mg. For Figs 1–3, the rate of heating in an oxygen-free nitrogen atmosphere is 3.6 °C s^{-1}; sample grain-size d is $45 < d < 106$ μm; the glow is seen by a quartz-window photomultiplier (EMI 6256 SQ) through an Ilford broad-band (375–530 nm) filter no. 622 and plotted an a chart recorder by a sensitive electrometer; black-body radiation has been subtracted from the glow curve.

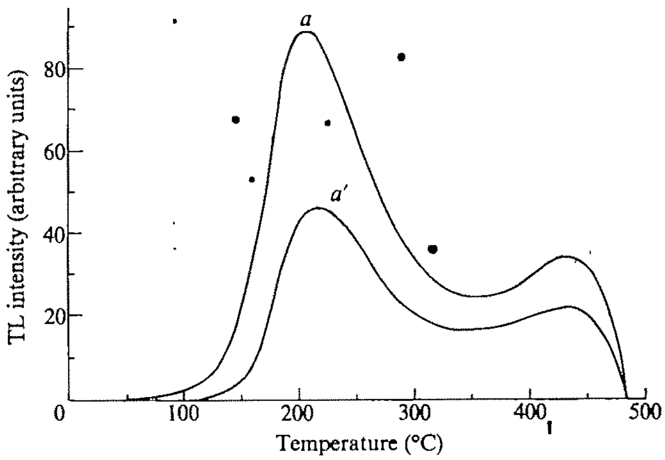

Fig. 2 Fading of the 'freezer counterpart' sample 76241,23 (curve *a'*), kept at room temperature for ~3 yr (date of readout, 26 January 1976), compared to the 'freezer sample' 76240,22 (curve *a*), kept at −20 °C from 11 January 1973–22 March 1974, and at CO_2-snow (−78.5 °C) or liquid-nitrogen (−196 °C) temperatures ever since. Most of the fading appears to be 'anomalous' (that is, not obeying the temperature-dependent equations). Sample weights: *a*, 1.6 mg; *a'*, 1.8 mg.

freezer counterpart samples over ~3 yr between sample retrieval and our experiments, natural-fading and isothermal-annealing studies have been carried out on the samples. Figure 2 shows the natural TL outputs at the beginning of 1976 from the freezer sample (76240) and its room-temperature counterpart (76241). The degree of fading, especially in the high-temperature region, is surprisingly high, suggesting anomalous fading[3]. In Table 1 we record the degree of fading observed in the two counterpart samples 76241 and 72321, after 3 yr of storage at room temperature, by comparing the natural TL surviving in three consecutive readout-temperature intervals of interest to us with the corresponding amounts in the freezer samples 76240 and 72320.

Dose response and inferred natural dose

For various calculations it is necessary to know the natural dose retained by each sample and the characteristics of the growth-to-saturation curves for them. In Fig. 3 we show a typical set of dose–response curves resulting from the artificial irradiation of a sample with ^{60}Co γ rays. The TL intensity from the sample (the shaded sample counterpart 76241, 23, 'sample *a'*') was integrated over three consecutive readout-temperature intervals, 216–306 °C (area I), 306–378 °C (area II), and 378–486 °C (area III), and the resulting 'TL glow areas' are separately plotted. By extrapolating such curves backward, we can infer the natural dose retained in each temperature interval by the sample. Similar curves have been obtained for the sunlit sample 76261, 25 ('sample *b*').

From the growth curves we can also graphically determine the 'half dose' $R_{\frac{1}{2}}$, so termed[2] from analogy with half life in a growth-to-saturation curve in radioactivity. This is the dose required to fill half the remaining traps at any stage of irradiation, assuming the growth law

$$n = N(1-\exp(-0.693\ R/R_{\frac{1}{2}})), \qquad (1)$$

where *n* is the number of filled traps for a total dose *R* (including the natural dose) and *N* is the total number of available traps of a given energy depth.

Theoretical framework

To determine the effective temperature and length of storage of the various samples in their lunar environment, we need to know the trapping parameters *E* ('trap depth', usually in eV) and *s* ('frequency factor', in s^{-1}) of the levels responsible for the observed TL. We have determined these parameters by using the 'initial rise method'[4], and record them and other data needed in our calculations in Table 2.

In our calculations, we have assumed the trap-filling process to obey the 'first-order kinetics' of Randall and Wilkins[5], and followed the general procedure of ref. 2. The following are the essential equations governing the radiation-filling and thermal-emptying of TL traps in generalised environmental conditions.

For a sample with a total of *N* traps, each of depth *E* and frequency factor *s*, irradiated with a dose rate *r* while being held at an absolute temperature *T*, the following differential equation holds

$$dn/dt = -\lambda n + (N-n)rp \qquad (2)$$

where *n* is the number of filled traps at time *t*, λ is the decay constant at temperature *T*, and *p* is the probability per unit dose of filling one of the above traps. For parameters λ and *p*

$$\lambda = \tau^{-1} = 0.693/\tau_{\frac{1}{2}} = s\exp(-E/kT) \qquad (3)$$

where τ and $\tau_{\frac{1}{2}}$ are the mean and the half lives, respectively, of the trapped electrons at temperature *T*, and

$$p = 0.693/R_{\frac{1}{2}} \qquad (4)$$

where $R_{\frac{1}{2}}$ has been defined by equation (1).

The general solution of equation (2) is given by

$$n = \frac{Nrp}{\lambda+rp}\{1-\exp(-(\lambda+rp)t)\} + n_0\exp(-(\lambda+rp)t) \qquad (5)$$

where n_0 is the number of filled traps at time $t = 0$.

There are two cases of special interest to us. First, if all traps are initially empty (for example, when trap-filling first starts in the sunlight), so that $n_0 = 0$, equation (5) is reduced to

$$n = \frac{Nrp}{\lambda+rp}\{1-\exp(-(\lambda+rp)t) \qquad (6)$$

Table 1 Fading of TL in the room-temperature 'counterparts' over a period of 3 yr by comparison with the 'freezer samples'

Sample	Area I (216–306 °C)		Area II (306–378 °C)		Area III (378–486 °C)	
	TL mg^{-1}*	Fading	TL mg^{-1}	Fading	TL mg^{-1}	Fading
76240,22 ('freezer sample')	37.5		15.0		22.5	
76241,23 ('counterpart')†	20.0	47%	7.8	48%	12.8	43%
72320,4 ('freezer sample')	7.2		11.7		18.9	
72321,3 ('counterpart')	4.45	38%	8.3	29%	14.5	24%
76261,25 (sunlit sample)‡	0.68		1.82		7.27	

* TL (integrated over the temperature interval shown in each case) is expressed in arbitrary units, but has been normalised for sample weight.

† Separate studies on the fading of freshly produced TL in sample 76241, kept at room temperature, were carried out to estimate the fading of TL in the 'freezer samples' themselves as a result of the first ~3 weeks of 20 °C storage of all samples at LRL in December 1972. This effect has been ignored in the above table (see ref. 6 for details).

‡ The values for the sunlit sample are recorded for completeness.

Table 2 Values of useful parameters for the shaded sample (*a*) and the sunlit sample (*b*) related to calculations for the temperature and duration of the boulder shadow

Parameter	Sample *a* (76241,23; 'freezer counterpart')			Sample *b* (76261,25)
	TL area I (216–306 °C)	TL area II (306–378 °C)	TL area III (378–486 °C)	TL area III (378–486 °C)
Trap depth E (eV)	1.046 ± 0.05	1.134 ± 0.07	1.439 ± 0.06	1.72 ± 0.06
Frequency factor s (s^{-1})	$\sim 5 \times 10^8$	$\sim 2 \times 10^8$	$\sim 1 \times 10^9$	$\sim 2 \times 10^{11}$
Peak temp. T_p (° C)	279	351	450	441
N/n_{eq} (or N/n)*	7.41	4.58	3.31	3.85
Half-dose $R_{\frac{1}{2}}$ (krad)	500	520	520	340
Storage temp. T_1 (K)	256 (calculated)	256 (from area I)	256 (from area I)	371 (calculated)
Length of storage t_1 (yr)†	—	3.98×10^4 (assuming 48% fading)	5.65×10^4 (assuming 43% fading)	∞
Mean life τ (T_1) (yr)	2.44×10^4	3.50×10^6	7.16×10^{11}	3.85×10^4 (at $T_1 = 371$K)
Mean life τ (20 °C) (yr)	62	5.90×10^3	1.49×10^6	6.48×10^{10}

* These are the values of N/n (uncorrected for fading) as calculated from the heights of the TL dose–response curves (compare Fig. 3) at saturation, and at 0 artificial dose, respectively. In the case of area I (sample *a*) and area III (sample *b*), $n \equiv n_{eq}$ (the corresponding traps having reached dynamic equilibrium in nature).

† These values of t_1 result from equation (11), with $r = 10$ rad yr^{-1}, after a fading correction for the relevant TL area for sample *a* (Table 1) has been applied to the measured N/n value shown in Table 2.

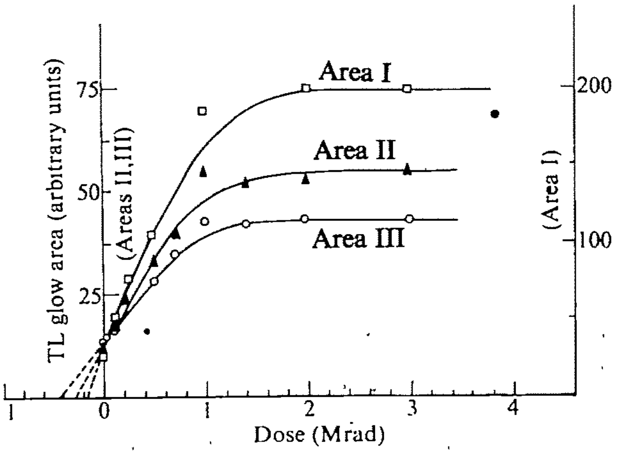
$$\equiv \frac{N}{(1+R_{\frac{1}{2}}/r\tau_{\frac{1}{2}})}\{1-\exp(-0.693rt/R_{\frac{1}{2}})\exp(-0.693t/\tau_{\frac{1}{2}})\} \qquad (6')$$

Second, when the radio-thermal environment changes at time t_0, say, (for example, the boulder arrives), such that the number of filled traps at time $t = t_0$ is n_0, equation (5) holds, except that the values of the relevant parameters are changed to r', p' and λ', and t may be replaced by t_1 such that $t^1 = t - t_0$. Our chief interest, however, is in the case where the time before the arrival of the boulder is very large, so that $t_0 \rightarrow \infty$. The value of n_0 to be used in the modified form of equation (5) is then reduced, by substituting t_0 for t in equation (6) and then setting $t_0 \rightarrow \infty$, to

$$n_0 = Nrp/(\lambda + rp) \qquad (7)$$

The modified form of equation (5), after the arrival of the boulder, thus becomes

Fig. 3 TL response of sample *a* ('freezer counterpart' 76241,23) to γ-ray dose from a ~3,500 Ci ^{60}Co source (dose uncertainty, ±3%). The TL has been integrated in each case over the three consecutive readout intervals termed area I (216–306 °C; □), area II (306–378 °C; ▲) and area III (378–486 °C; ○). Notice the higher scale (at right) for area I From each of the curves the corresponding values of n/N (ratio of the ordinates at artificial dose = 0, and at saturation), and half-dose $R_{\frac{1}{2}}$ (required to fill half the remaining traps at any stage) can be determined. Similar curves were obtained for sample *b* (the sunlit sample 76261,25); figure not shown.



$$n = \frac{N\,r'p'}{\lambda'+r'p'}\{1-\exp(-(\lambda'+r'p')t_1)\} + \frac{N\,rp}{\lambda+rp}\exp(-(\lambda'+r'p')t_1) \qquad (8)$$

A number of interesting limiting cases of equations (6, 6′) exist, details of which is given elsewhere[6]. Here we confine ourselves to two cases of immediate relevance. Thus

(i) for either $rt \gg R_{\frac{1}{2}}$, or $t - \tau_{\frac{1}{2}}$

$$n_{eq} \rightarrow \frac{N}{1+(R_{\frac{1}{2}}/r\tau_{\frac{1}{2}})} \equiv \frac{N}{1+(\lambda/rp)} \qquad (9)$$

and if, in addition $r\tau_{\frac{1}{2}} \gg R_{\frac{1}{2}}$

$$n_{eq} \rightarrow N \qquad (10)$$

where, in equations (9) and (10), n_{eq} represents the dynamic-equilibrium, or steady-state, value of n reached either as a result of giving a massive dose ($rt = R \gg R_{\frac{1}{2}}$) to a sample, or by filling the traps for a very long time t compared to $\tau_{\frac{1}{2}}$ at the temperature concerned; and

(ii) for $\lambda \ll rp$, that is, $r\tau_{\frac{1}{2}} \gg R_{\frac{1}{2}}$

$$n \rightarrow N(1-\exp(-rt\,p)) — N(1-\exp(-0.693rt/R_{\frac{1}{2}})) \qquad (11)$$

The values of N and $R_{\frac{1}{2}}$ in equation (11) are usually obtained by employing such a massive dose rate r in the laboratory that there is virtually no thermal drainage during the irradiation.

Determination of temperature and duration of the boulder shadow

We now determine the effective temperature of storage of the 'permanently shadowed' sample (76240 or 76241, 'sample *a*') and the length of its storage in the boulder shadow, by comparing the TL characteristics of that sample with those of the 'sunlit sample' (76261, 'sample *b*') and making use of the foregoing theoretical framework.

From equation (9), which applies to the case when dynamic equilibrium has been reached in nature (so that $rt \gg R_{\frac{1}{2}}$), we obtain, using equation (3), the value of the prevailing (or 'storage') temperature as

$$T = \frac{E/k}{\ln\left[\dfrac{sR_{\frac{1}{2}}}{0.693r\,(N/n_{eq}-1)}\right]} \qquad (12)$$

where N/n_{eq} is the ratio of the saturation TL (obtained from a separate experiment) to that found in the natural sample. If the natural dose-rate r is known, T can be calculated by determining the values of E, s and R_i for the relevant trapping level. We assume[7] a value of $r = 10$ rad yr^{-1} for unshaded lunar samples. As r occurs in the logarithmic term, even a substantial change (say reduction by a factor of 2) in its value after the arrival of the boulder has little effect on the calculated value of T. This also applies to the effects of fading corrections (discussed below) on N/n_{eq}.

In Table 2 we record the experimental values of all the parameters that are needed in our calculations. Our calculations involve the following steps:

(1) We assume in the case of the sunlit sample (*b*) that dynamic equilibrium has been reached in filling the traps corresponding to the TL readout area III (378–486 °C, with $E = 1.72$ eV), that is, $t_1 \gg \tau_i$ in sunlight. By using the values of the various parameters given in Table 2 (and after applying a 43% fading correction to N/n_{eq} by inference from the corresponding value for sample *a* in Table 1), we obtain from equation (12) the lunar storage temperature $T = 371$ K for the sunlit sample.

(2) We then calculate from equation (12) the storage temperature T_1 in the shade by assuming that equilibrium has been reached in TL area I of the shaded sample (216–306 °C; $E = 1.046$ eV), that is, $t_1 \gg \tau_i$ of the trap at temperature T_1 (compare Table 2). After applying a 47% fading correction to n_{eq} in the 'counterpart' sample, (compare Table 1), we find that the temperature in the boulder shadow is $T_1 = 256$ K.

(3) At $T_1 = 256$ K, the values of τ_i for the traps corresponding to TL area II (306–378 °C; $E = 1.134$ eV) and area III (378–486 °C; $E = 1.439$ eV) of the shaded sample are found to be such that the condition governing equation (11) is fulfilled ($r\tau_i \gg R_i$; compare Table 2). We can therefore solve that equation to obtain the length of storage t_1 in shade from either of these TL areas, using the known values of n/N. This implies that the natural TL in areas II and III of sample *a* is well below the corresponding saturation values.

Assuming the values for the amount of fading observed for TL areas II and III in the 'counterpart' sample *a* (namely 48 and 43%, respectively, compare Table 1), we obtain from equation (11) the following values for the length of storage, t_1, in the boulder shadow:

from area II (sample *a*): 3.98×10^4 yr; from area III: 5.65×10^4 yr.

These values are based on a dose-rate $r = 10$ rad yr^{-1}; if that rate is halved in the shadow of the boulder, the length of storage would be doubled, and so on.

Correction factor for 'anomalous' fading

The calculations based on the foregoing framework are found to be very sensitive to the values of the parameters for the various samples and TL areas that are fed into the equations. We mention in passing that the lengths of storage in the shade, as calculated from TL glow areas II and III of sample *a*, can be made to agree if one assumes an empirical relation for 'anomalous fading'[3], namely: fading $\propto 1/E$, where E is the trap depth. This leads to the following values of anomalous fading in areas I, II and III of sample *a*: 68, 62 and 49%, respectively (and for area III in sample *b*: 41%). If one assumes such fading to have taken place in the shadowed sample since retrieval, the duration of the boulder shadow is obtained (from both areas II and III of sample *a*) as $t_1 = 6.50 \times 10^4$ yr (for $r = 10$ rad yr^{-1}).

Conclusion

That we have been able to calculate the value of the duration of the shadow cast over our sample *a* (namely ~ 4.0–6.5×10^4 yr), and hence the time of the arrival of the boulder at its present location, has important implications for soil mechanics on the surface of the moon. Mitchell *et al.*[8] refer to over 300 tracks "made by boulders rolling, bouncing and skidding down lunar slopes". The Apollo 17 mission provided the first opportunity to study closely these interesting features which were very evident on the Taurus–Littrow hills. The mechanisms for setting the boulders in motion are not well understood, but could include cyclical thermal expansion and contraction, impact cratering and seismic events. Our estimation of the time-scale involved in at least one such event could be helpful in clarifying the picture.

In considering the duration of boulder shadow as calculated from the preserved natural TL in the shaded soil, it could be instructive to consider the role of dust movement on the lunar surface. Criswell[9] postulates the migration of electrically charged micrometre-sized grains from the sunlit areas towards dark or partially illuminated areas. From 'horizon glow' observations made at the time of lunar sunset, Criswell calculates a value of mass-flow rate of $\sim 10^{-8}$ g cm^{-2} yr^{-1} for the surface dust, corresponding to a layer turnover rate of ~ 6 μm yr^{-1}. Such a rate of inflow would deposit a layer ~ 30 cm thick in 50,000 yr under the boulder. That this is not the case is clear when one considers the top ~ 5 cm of the shadowed soil (the maximum depth of our scooped sample *a*). A thickness of 5 cm would, at the above rate, be deposited in $\sim 8{,}000$ yr, yielding an average age of only $\sim 4{,}000$ yr inside the shadow, whereas our calculated length of storage in the shade for sample *a* is 40,000–65,000 yr. Assuming the top 1 cm in the shade to be of external origin, the Criswell rate of inflow must be reduced by a factor of ~ 40. (This results in the duration of the boulder shadow being revised upwards from 6.0×10^4 yr to 6.67×10^4 yr to yield the observed amount of glow, assuming a homogeneous mixing of the top 5 cm of soil during and since its retrieval.)

The value of the storage temperature in the boulder shadow obtained by us (256 K) seems to be high when one considers the conductive processes on the Moon. Values as low as ~ 25–100 K can be obtained by using the lunar heat-flow data of Langseth *et al.*[10] or our own conductivity data[11], but such calculations are strongly model dependent. Our value in the shade is quite close to the mean equilibrium temperature on the lunar surface (~ 240 K). Imperfect shadowing of the sample (which came from only ~ 0.5–1 m inside the boundary of the shadow) and soil mixing could explain the rather high value of the effective storage temperature in the shadow of the boulder estimated by us. Our calculation depends critically on the value n_{eq}/N (the fraction of total traps filled at equilibrium) in the TL glow area I of sample *a*. If, as a result of possible exposure to sunlight during the retrieval procedure and/or the high-temperature ($\gtrsim 100$ °C) handling of the sample during EVA on the lunar surface, or because of a greater degree of anomalous fading than we have allowed for, the initial value n_{eq}/N was higher than that used in our calculations, the temperature in the shade would have to be revised downward. Similarly, if dynamic equilibrium had not as yet been reached in trap-filling for area I of sample *a* (owing, say, to a relatively short storage time in the shade), then equation (12) would not hold, and the value of storage temperature obtained by us would be an overestimate.

Our investigations have, however, been limited to the measurable effects in the context of information currently available, and the values obtained by us are the best estimates that can be made at present for the temperature and duration of the shadow of the lunar boulder concerned. Further refinement of the data may be possible in our future work which involves the simulation of the lunar irradiation conditions.

Climate periods in tree, ice and tides

Leona Marshall Libby
Environmental Science and Engineering,

Louis J. Pandolfi
Department of Chemistry and Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California 90024

Ten climate periods found in stable isotope ratios of oxygen and hydrogen, measured in 1,800 yr of Japanese cedar rings, agree with climate periods found in 800 yr of Greenland ice and with periods computed from the tidal stresses of the Sun–Moon–Earth system, and with periods found in the ^{14}*C record of the bristlecone pine sequence of southern California. The Greenland oxygen ratios have previously been found to have opposite phase to the* ^{14}*C ratios of the bristlecones, and we have found also an opposite phase between oxygen and hydrogen ratios in the Japanese cedar on the one hand and* ^{14}*C in bristlecones on the other hand.*

VARIATIONS of the oxygen and hydrogen isotope ratios have been measured in a Japanese cedar ring sequence of about 1,800 yr (see Fig. 1 and ref. 1). The Fourier transforms of these isotope ratios against age, into power against reciprocal periodicity, show the 10 periods enumerated in Table 1. Eight of these periods are evidenced in variations of the oxygen isotope ratio in Greenland ice[2]. Three of these 10 periods are evidenced in tidal stresses calculated for the Sun–Moon–Earth system[3]. The periodicities evaluated from these four sets of data agree with each other within statistical accuracy.

Why do the periods lie between 50 and 300 yr? The answer is to be found in the nature of sampling. Our cedar sequence was sampled integrating over 5 yr at a time and therefore cannot reliably show evidence for periods of less than about 50 yr. To look for periods of < 50 yr in a sequence of 5-yr samples or to look for periods of > 300 yr in a sequence of 1,800 yr is probably meaningless. Such periods may appear in Fourier transforms but they do not necessarily represent reality.

To understand this we generated random signals of values 0 or 1, and assigned them to 10-yr intervals in 1,000-yr hypothetical sequences, and made their Fourier transforms. In three such computer experiments we always obtained a period of about 20 yr as an artefact of the sampling interval. In part it occurs because short sequences of random numbers (say 100 numbers) are not really random, and in part because it

† Data from ref. 2.
(a) Denotes tidal[3] and (b) denotes ice core[2]. At about the 86-yr period the tidal data and ice core data are almost exactly 180° out of phase.

provides an alias of the sampling interval (see ref. 4 and consider the following example):

Let each sample integrate over $\Delta t = 10$ yr in a sequence of 100 samples corresponding to 1,000 yr. Such a short sequence, even if chosen randomly, produces artefactual signals at periods of 10, 20, 30, . . . yr in the power spectrum, as we have found in computer experiments with random numbers. Then the sampling frequency,

$$f_n = (1/2\ \Delta t) = 1/20\ y = 0.05 \text{ cycles per yr}$$

combines with the artefactual signal frequency,

$$f = 1/20\ y = 0.05 \text{ cycles per yr}$$

to produce the following alias signals,

$$f,\ 2f_n \pm f,\ 4f_n \pm f, \ldots$$

equivalent to

0.05 cycles per s, (0.1 ± 0.05) cycles per s, (0.2 ± 0.05) cycles per s, . . . so that the original signal at 20 y is reinforced by the alias signal at $1/(0.1 - 0.05) = 20\ y$.

If instead, the sampling period is 5 yr, corresponding to $f_N = 1/5 = 0.2$ cycles per yr the artefactual signals lie at $f^{-1} = 5, 10, 15, \ldots$ yr and the aliased signals are all at periods of $\leqslant 10$ yr.

Blackman and Tukey (ref. 4, pp. 31–32) warn us ". . . frequencies above f_N usually contribute some power. Each frequency, no matter how high, is indistinguishable from one in the band from 0 to f_N." Fortunately, there is little power in our D/H and $^{18}O/^{16}O$ spectra at high frequencies so we feel safe from aliasing at periods greater than about 20–30 yr. Thus we are in conformity with the remark (ref. 4, p. 52) that "It is likely that (power) decreases substantially as f goes from 0 to (the sampling frequency). If it does not, then aliasing is likely to have been serious, and satisfactory analysis at this spacing may be impossible." So we seem to be safe from aliasing for periods greater than 50 yr.

If we are guided by ref. 4, p. 11, the maximum oscillation which we should search for in a sequence of 1,800 yr is "a moderate fraction (perhaps 5–10%) of the length of the record" or 90–180 yr, but we shall stretch this to 300 yr because of the agreements among the four sets of periods shown in Table 1. Thus where we are cautioned[4] to study only periods which can oscillate more than 10–20 times in our data sequence, we have dared to take seriously periods which can oscillate 6 times or more in 1,800 yr.

With respect to a DC component, ref. 4, pp. 48–49 states, "All the DC power belongs in the very lowest frequency band . . .". We took the precaution, however, to subtract the DC component from both the D/H and $^{18}O/^{16}O$ data (as in ref. 4, p. 48). Thus as shown in our Fourier transforms[1] there is very little power in periods of more than 400 yr. Furthermore, we have excluded periods of >300 yr from our present considerations because they can oscillate less than 6 times in 1,800 yr.

The ratio of peak height to background in computer experiments on relatively short sequences of random numbers gives a way to assess what is the background caused by 'noisiness' of the isotope data. The peaks listed in Table 1 are significantly above background as shown in ref. 1, Fig. 7.

The validity of a 300-yr period in 1,800 yr of data can be tested by another computer experiment. Specifically one may generate a 300-yr periodic sine function for 1,800 yr, mix it with sine functions of shorter periodicities, and transform the mixture to show that the 300-yr signal is evidenced. Similar computer experiments were performed to see if short periods of 54, 57 and 59 yr are meaningfully separable. Our results indicate that they are. The measurements of Dansgaard *et al.*[2] were made on samples integrating over about 14 yr each, in an ice sequence of about 800 yr.

Thus, are periods between 50 and 300 yr in the ice cap, and even in the tree, representative of real climate variations? The remarkable agreement between the three sets of data suggests that they are. The agreement is expected, and explained, of course, because the ice cap is storing rain water and the tree is likewise storing rain water by changing it chemically to wood.

The evidence that the tree is storing a record of the climatically induced changes in rain water is that the least squares correlation of D/H against $^{18}O/^{16}O$ in the 1,800-yr sequence yields the relation[1]

$$\delta D/H = 8\delta^{18}O/^{16}O + \text{constant.}$$

The empirical slope of 8 is the same as in world-wide rain water within experimental error[5].

Thus the question of whether hydrogen and oxygen isotopes, bound in wood made in previous years, can be exchanging with sap of the current year, seems to be answered conclusively in the negative[1]; specifically, rings of previous years are sealed against exchange. If both O and H in OH groups of wood exchange with sap water, the slope cannot be 8, because there are twice as many H atoms bound to carbon, and these do not exchange.[6]

Fig. 2 Relative phases of ten climate periods evaluated for D/H, plotted against relative phases evaluated for $^{18}O/^{16}O$. Each point is marked by its respective period in yr. Phases are in radians. The dotted line is the best fit straight line, for which alpha $\delta\ ^{18}O = 1.13$ (alpha δ D) -0.771, and $r = 0.922$.

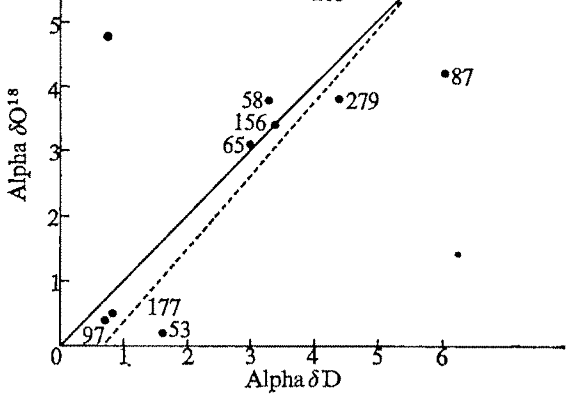

Table 2 Periods and their relative amplitudes and phases

T (period)	A (amplitude)	Alpha (α)	T (period)	A (amplitude)	Alpha (α)

53	2.63	1.56	54	1.84	0.21

Data based on Fourier transforms of our oxygen and hydrogen isotope ratios in a Japanese cedar AD 140–1950.

The remarkable agreement between our tree records of D/H and ^{18}O/^{16}O, and the ice record of ^{18}O/^{16}O, shows itself in yet another way. We have found the D and ^{18}O ratios for the Japanese cedar to be significantly correlated in opposite phase to the ^{14}C variations in the bristlecone pines of Southern California.[7]. Similarly Dansgaard *et al.*[2] found the ^{18}O record in Greenland ice to be significantly correlated in opposite phase with bristlecone ^{14}C.

We have also made a Fourier transform of the bristlecone pine ^{14}C record and find the following periods: 96, 183, 202 and 272 yr, in agreement with the longer periods in Table 1. Periods of <100 yr are probably not meaningful in Suess' measurements[8] because of his 30-yr sampling period.

The Fourier transform also evaluates amplitudes and phases of the periods evidenced in the measurements. For the isotope ratios measured in the Japanese cedar, these are listed in Table 2 for oxygen and hydrogen, and are in agreement with each other. A graph of the hydrogen phases versus the oxygen phases shows this agreement (Fig. 2).

We conclude from these observations—(1) The climate variations in Greenland, southern Japan, and southern California have had the same periodicities for the last 800 yr or more. Climate variability therefore seems to be a global phenomenon. (2) The calculation of Dansgaard *et al.*[2] of the age of ice against depth in the Greenland ice cap seems to be correct, with an error of not more than a couple of years, at least over the last 800 yr. The Japanese cedar rings have been dated by ring counting and by about 50 radiocarbon dates in the 1,800-yr sequence[9]; this serves to calibrate the calculated age of the ice by means of the present comparison of climate periodicities in the tree and in the ice[10].

Our conclusions depend on measurement of hydrogen and oxygen isotope ratios in a single tree: substantiation requires measurement of other tree sequences.

J. Witz
Institut de Biologie Moléculaire et Cellulaire du CNRS, 15, rue Descartes, 67000 Strasbourg, France

Small-angle neutron scattering from solutions of small RNA viruses has been used to study protein–nucleic acid organisation. In the five viruses investigated the RNA is confined to a sphere of about 100 Å radius, with a central hole (with one possible exception). The interpenetration of RNA and protein varies with viruses and seems to be related to the nature of the forces stabilising the virus.

THE basic principles of the architecture of viral protein shells are now well established[1], and the detailed assembly of protein subunits in the capsids of several small RNA viruses has been determined by electron microscopy and X-ray diffraction[2,3]. Very little is known, however, about the nucleic acid. Indeed, electron microscopy provides no information on the internal structure of small viruses, and low-resolution X-ray diffraction does not allow unambiguous location of the RNA, which represents, at most, 35% of the total mass. Klug *et al.*[4] compared low-resolution X-ray diffraction patterns of Turnip Yellow Mosaic Virus (TYMV) virions and the associated empty capsids, and attempted to modify the relative contributions of protein and RNA by increasing the solvent electron density by addition of salt. The contrast variation method has also been used by Harrison[5] and Zipper *et al.*[6]. It is limited, however, because high ionic strengths may dissociate virions or modify their structure, and it is practically impossible to raise the density of the solvent to the level at which it matches that of compact RNA.

Neutron scattering by virus solutions provides a straightforward alternative for obtaining low-resolution information about the viral nucleic acid, and utilises the fact that H_2O–D_2O mixtures can be made with scattering powers that match either RNA or protein[7,8], making it much easier to distinguish between protein and hydrated RNA at low resolution. The possibility that D_2O may affect the stability or the structure of the virus

Table 1

Name	Protein subunit MW	RNA content (MW) of the virion	Total MW
Turnip Yellow Mosaic Virus (TYMV)	20,130	1.9×10^6	5.53×10^6
Southern bean mottle virus (SBMV)	29,390	1.4×10^6	$6 69\times10^6$
Cucumber mosaic virus (CMV)	26,000	$\sim1.10\times10^6$ (multigenome)	5.78×10^6
Bromegrass mosaic virus (BMV)	20,300	$\sim1.05\times10^6$ (multigenome)	4.70×10^6
MS2	13,750	1.142×10^6	3.66×10^6

must be checked in each case, but D_2O is less likely to have an effect than high salt. The method is of general application and allows a simple systematic comparison between viruses. We report here the results of such a survey made on the five viruses, all with triangulation number[1] $T = 3$ (180 subunits), listed in Table 1.

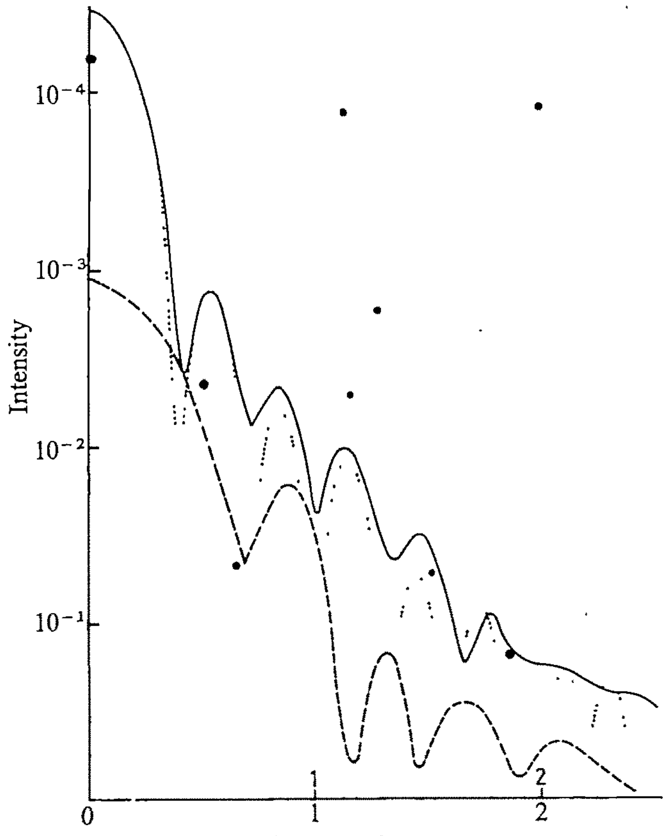

Fig. 1 Typical diffraction curves obtained for SBMV solutions, corrected for background (which is flat). ——, Buffer solution (20 mM phosphate, *p*H 7) in H_2O. ----, Buffer solution with 43% D_2O. The large shift of the first maximum in 43% D_2O shows that the RNA is spread over a much smaller volume than the virus. . . . . ., Curve calculated for the uniform spheres model (Fig. 2).

The viruses were selected to look for a possible correlation between stabilising forces[9] and morphology. TYMV is characterised by very strong protein–protein interactions[10], as shown by the existence *in vivo* of stable empty capsids. CMV, by contrast is stabilised mainly by RNA–protein interactions[11], being sensitive to ribonuclease and to high ionic strength. In bacteriophage MS2 both types of interactions are important[12]. BMV belongs to a special category: at acid *p*H it is insensitive to ribonuclease and high salt and empty shells can be formed *in vitro;* at *p*H 6.5 it swells, becomes ribonuclease sensitive and dissociates in high salt[13]. The physical chemistry of SBMV is not yet well documented, but this virus is under study by X-ray crystallography[14,15]. All viruses were dissolved in low molarity buffers ($\leqslant$ 0.02 M).

Data collection and analysis

The details of the method will be described elsewhere[16]. It consists in collecting the small-angle diffraction pattern of the virus solution at various levels of contrast between virus and solvent, that is, at various solvent D_2O contents. The contrast, $\bar{\rho}$, is defined as the difference between the average scattering density of the virus and the scattering density of the solvent. A typical diffraction curve is shown in Fig. 1. This intensity curve can be put on an absolute scale by comparison with scattering from water and from the intensity scattered at zero angle by a dilute solution of a well-known virus (here TYMV).

A complete analysis of this set of curves gives the following information.

(1) Radius of gyration

For small values of the scattering vector s ($s = \sin\theta/\lambda$ where θ is the scattering angle and λ the neutron wavelength), the scattered intensity varies as

$$I = I(0)\exp\left(-\frac{4}{3}\pi^2 s^2 R_G^2\right)$$

The radius of gyration R_G varies with the mean contrast, $\bar{\rho}$. The relation between R_G and $\bar{\rho}$ is[17]

$$R_G^2 = R_{GV}^2 + \frac{\alpha}{\bar{\rho}} - \frac{\beta}{\bar{\rho}^2}$$

Table 2

Virus	α_{exp}	R_{GV}	α_{cal}	Position of first subsidiary maximum in H_2O	in 43% D_2O	in 68% D_2O	Relative intensity of the first maximum $I(0)/I_1$ in H_2O	in 43% D_2O	in 68% D_2O
TYMV	3,450	111	3068	6.43	8.91	5.79	107	60	28
SBMV	2,840	123	2530	6.27	8.91	5.79	85	16	36
CMV	1,680	127	2160	6.30	8.75	5.79	60	20	34
BMV low *p*H	2,870	113	2455	6.92	9.55	6.16	65	not measured	30
BMV high *p*H	4,720	134	4400	6.06	7.16	5.44	40		26
MS2	4,710	117	5600	6.53	8.59	6.05	46		20

R_{GV} in Å; α is dimensionless, α_{cal} is calculated as explained in the text.
Positions of intensity maxima are given in $\sin\theta/\lambda$ and in units 10^{-3} Å^{-1}.
I_1, the intensity of the first maximum, is expressed by the ratio $I(0)/I_1$, where $I(0)$ is that of the central peak. For a solid sphere the ratio $I(0)/I_1$ is 135; it decreases for a hollow sphere with the size of the central hole, reaching 20 for a thin spherical shell.

Table 3 Results of our survey on five viruses

Capsid inside radius (a) From $I(0)/I_1$. (b) From Fourier transform.
*Data have also been collected on TYMV empty capsids, giving the same results as for TYMV protein shell[16].

A linear variation of R_G^2 with $1/\bar{\rho}$ has been obtained for all the viruses investigated. The values of R_{GV} and α are listed in Table 2; β is zero within experimental error in all cases. R_{GV} is in first approximation the radius of gyration of a homogeneous particle with the same morphology as the virus, but spatial inhomogeneities of H–D exchange also contribute to it[8,17]. A value of $R_{GV}^2 < 3/5\, R_{ext}^2$ (expected for a uniform sphere), where R_{ext} is the outside diameter of the virus (see below), suggests the presence of a central hole, because the radius of gyration of a hollow sphere is larger than that of a solid sphere of the same diameter. α is the second moment of the density fluctuations around their average, at zero contrast between solute and solvent. These fluctuations are determined by the internal structure of the virus. The values of α agree well with those calculated for very simple models consisting of a sphere of RNA surrounded by a protein shell, with dimensions taken from Table 3. β should be zero if the centre of gravity of the scattering mass does not vary with contrast, for example, if the protein shell and the RNA have the same centre of gravity. The experimental data show this to be the case. A separation of 10–20 Å between centres of mass of RNA and protein would not, however, be detectable in our experiments.

(2) The dimensions of the virion and its RNA

The simplest way to analyse small-angle scattering curves from 'spherical' viruses is to find the dimensions of the homogeneous sphere (or hollow sphere) which best fits the innermost part of the diffraction pattern, in particular the position and the intensity of the first subsidiary maximum (Table 2). The non-spherically-symmetric components of the structure do not contribute to that maximum[3] and a first set of values can be obtained by considering the virus to be composed of two spherical shells, each with uniform density, one for protein and one for RNA. Moreover, data have been obtained in 43% D_2O, where the diffraction pattern is dominated by the contribution of RNA, and 68% D_2O, where it is essentially due to protein. The radii obtained are self consistent. For instance the outside diameters deduced from the scattering in H_2O and 68% D_2O are the same, and the sizes of the central hole deduced from the data in H_2O and 43% D_2O. This first set of values can then be used to build models, which are refined using several subsidiary maxima. The values finally obtained (Table 3), are close to the first set. We have already seen that those values account well for the variation of the radii of gyration with contrast. The outside diameter is also confirmed by the Fourier transform of $I(s)$, which equals zero at the maximum diameter of the diffracting mass [18]. The values obtained for the outside diameter agree well with previous results for TYMV (ref. 4), BMV (ref. 20) and MS2 (ref. 6). The large intensities of the first subsidiary maxima (Table 2) strongly suggest the existence of large central holes in all of these viruses, with the possible exception of TYMV, where the hole (if any) is much smaller.

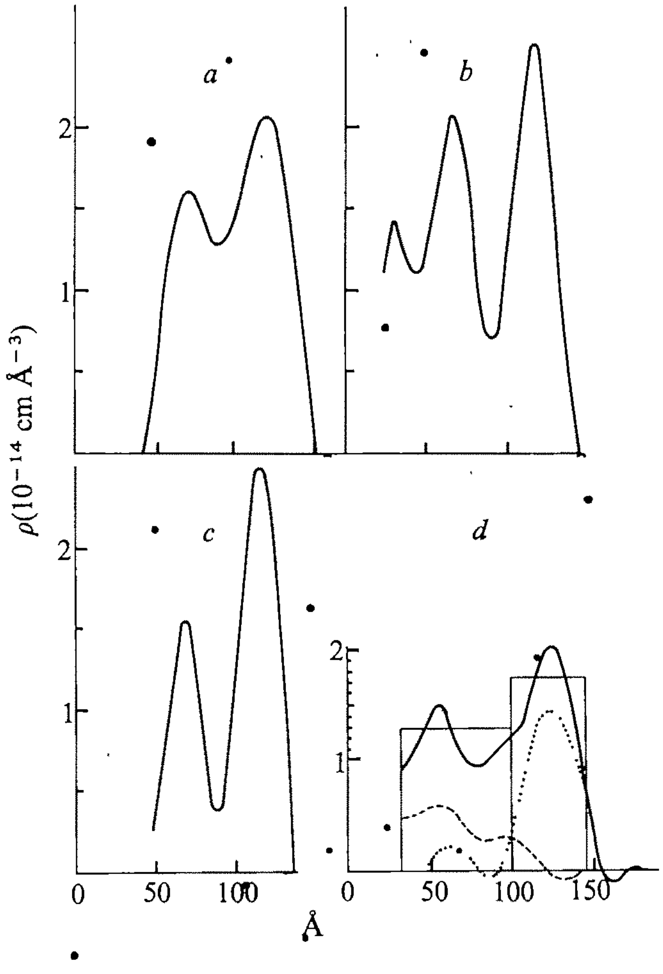
Another feature emerges from Table 2: with the exception of swollen BMV, at high *p*H, the first subsidiary maximum of the patterns dominated by the diffraction of RNA (in 43% D_2O) is at nearly the same positon for all of these viruses and, corresponds to an overall diameter of the RNA region of about 100 Å.

(3) The radial distribution of protein and RNA

The radial scattering density ρ(*r*) of the particles gives a more detailed picture. For an object with spherical symmetry,

$$\rho(r)-\rho_s=\frac{2}{r}\int_0^\infty sF(s)\,\sin 2\pi rs\,\mathrm{d}s$$

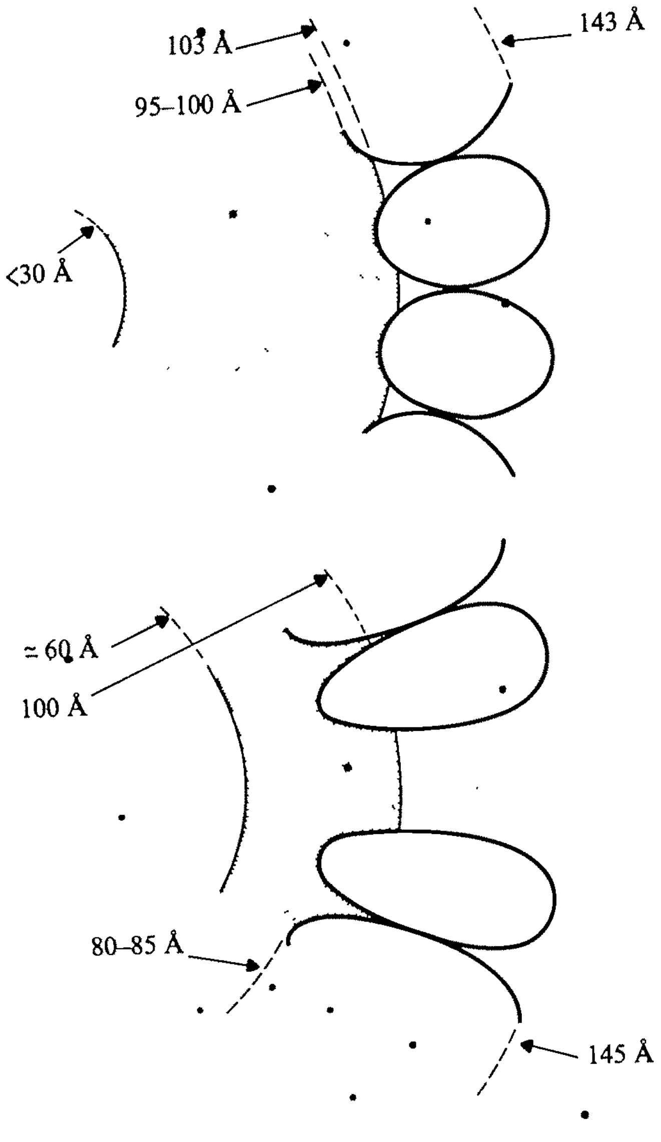
Fig. 2 Radial densities obtained by spherical Fourier transformation of structure factors deduced from scattered intensities: *a*, CMV in H_2O; *b*, TYMV in H_2O; *c*, MS_2 in H_2O; *d*, SBMV:——, in H_2O, – – – –, in 43% D_2O, ..., in 69% D_2O. The rectangles give the model used for the calculated curve (Fig. 1). All solvents were buffers of low molarity (0.02 M or below).



where ρ_s is the scattering density of the solvent. $F(s)$ is the square-root of $I(s)$, and its sign is assumed to change at each minimum of $I(s)$ as a consequence of the principle of minimum wavelength[19]. It is pertinent to compute $\rho(r)$ from data collected in H_2O and in buffers matching the contrasts of the protein and RNA moieties (that is, about 43 and 68% D_2O).

In Fig. 2 some of these radial densities are shown on an absolute scale. The variation with contrast of the protein part (the peaks at large radius), and of the RNA part (the more complex structure between the centre and the protein shell) confirms the attribution of the density to the corresponding moiety. These curves are deformed by cut-off effects in Fourier transforms and no reliable information can be obtained near the centre (r < 50 Å). The density at the maxima of the protein peaks, for instance in H_2O, is rather independent of the cut-off (Table 3). For TYMV and MS2 the experimental value of the density of this peak is that calculated for their coat protein, indicating a very tight packing of the subunits in the capsid. In contrast, for CMV and SBMV the experimental values are somewhat lower, suggesting the presence of channels between subunits in the capsid. The position and width of the protein peak is also very well determined, both by the radial density in H_2O and in 68% D_2O (Table 3). Except for SBMV they agree with those obtained from the analysis of the position and intensity of the first subsidiary maximum.

Fig. 3 Sketch of the organisation of protein and RNA in two viruses as deduced from neutron low-angle scattering data. The shaded area corresponds to RNA. *a*, TYMV. Protein molecules are represented in close contact. RNA does not penetrate deeply between subunits of the capsid *b*, CMV. The shape of the protein shell has been chosen to fit the data of Table 3. The size of the holes in the capsid has been calculated assuming 32 large holes (in the centres of hexamers and pentamers of the capsid). In this model the total volume accessible to RNA is about 2.5×10^6 Å^3; its average scattering density when this space is uniformly filled with CMV RNA is 1.60×10^{-14} cm Å^3, in excellent agreement with the experimental value.



For the RNA, which is located nearer the centre of the virus, the results are not so reliable. First, at contrast matching of the protein, the diffraction pattern has a fairly low intensity, and, except for SBMV, where a very concentrated sample was available, does not extend very far. Second, for a given resolution, Fourier transforms give less reliable results at smaller radii. The position of the RNA peak (Table 3) is correlated with the estimated size of a central hole as expected. The density of this RNA peak is also given in Table 3. Its accuracy is less than for the protein peak, but it is much lower than the density of pure RNA (4.04×10^{-6} Å^{-2}), indicating that 50–60% of the volume is occupied by water, even in the region where the RNA is the most closely packed.

Discussion

The analysis of the neutron diffraction at small angle by spherical viruses in solutions of buffer containing different amounts of D_2O provides a consistent set of data, from which low-resolution models can be built.

The comparison between values obtained for the dimensions and the density of the two moieties contributing to those viruses show the following features:

(1) All viruses studied in this work (with the possible exception of TYMV) possess a central hole, of increasing size in viruses containing relatively less RNA: Within 10% the difference between the overall RNA radius (Table 3) and the radius of the hole is proportional to the molecular weight of the RNA in the virion.

(2) The external diameter of the bulk of the RNA is much smaller than the virus diameter.

(3) The degree of interpenetration of RNA and protein is different in TYMV and CMV. In TYMV there is little (if any) penetration of the RNA into the protein capsid (about 5 Å), whereas in CMV this penetration must be about 20 Å. This difference in penetration is due to a difference in the internal diameters of the capsids. Our model for TYMV is different from that of Klug *et al.*[4], who suggested a strong imbedding of TYMV RNA into the capsid. The reason for this discrepancy will be discussed elsewhere[16]. We simply note here that our method gives in a fairly direct way the overall size of the RNA inside the virion, and that the high ionic strength used by Finch and Klug could induce a swelling of the RNA.

(4) We found that in TYMV (and MS2), the maximum of the scattering density of the protein shell suggests a very dense packing, whereas for CMV the packing is less dense, leaving room for holes representing about 15% of the surface at the radius of higher density (117 Å). The presence of such holes could explain the sensitivity of CMV to ribonuclease, even if its RNA is localised in a sphere much smaller than the overall size of the virus. These differences between TYMV and CMV organisation could account for the difference between their properties. The isomorphism of TYMV and TYMV empty capsids, the high stability of these capsids and virions, and the insensitivity of TYMV to ribonuclease, can be well understood from the structure we found for the virion (Fig. 4). Conversely, the absence of empty capsids, the sensitivity to ribonuclease and to magnesium ions can be easily understood from the model we propose here for CMV.

MS2 seems similar to TYMV, in agreement with the known properties of that virus, in particular the possibility of obtaining empty capsids by alkaline treatment. Our data for SBMV suggest that this virus may have some features in common with CMV, in particular, the presence of holes in its capsid: its sensitivity to ribonuclease is suggested by other experiments[21].

The case of BMV (ref. 25) is clearly intermediate between those of TYMV and CMV. In its low pH form it shows a small RNA penetration into the capsid (but larger than for TYMV or MS2). In its swollen, high pH form (which is likely to be an *in vitro* artefact), the RNA is strongly embedded between protein subunits. The fact that the BMV empty capsids, which can be formed at pH 4–5 (refs 22, 23), have a diameter intermediate between those of the two forms of the virion[24], suggests that both protein–protein and protein–RNA interactions contribute to the stability of that virus.

(5) If neutron low-angle scattering curves of virus solutions provide direct information on the protein–RNA interpenetration and on the density of the protein shell, very little can be said on the folding and the symmetry of the RNA at its contact with the protein shell. But it is clear that the RNA is, on average, loosely packed; the highest radial density measured corresponds to about 50% RNA, 50% solvent by volume.

In conclusion, neutron small-angle scattering of virus solutions allows a fairly clear correlation to be made for small RNA viruses between the packing of RNA and protein subunits, and the nature and importance of stabilisation forces. Deeper penetration of the RNA into the capsid seems to be correlated with the increasing importance of RNA–protein interactions. The technique, however cannot give data on the folding of the RNA. This could be achieved by neutron diffraction studies at low resolution of single crystals in various D_2O environments which will be undertaken soon.

We thank Drs M. G. Rossmann, M. S. Fiers P. Pfeiffer and H. Lot for providing samples.

Collagen–mineral axial relationship in calcified turkey leg tendon by X-ray and neutron diffraction

The axial relationship between the collagen and mineral components in calcified turkey leg tendon was investigated using low-angle X-ray and neutron diffraction. The results indicate that the mineral is arranged with the same axial periodicity as the collagen and occupies the gap region of the collagen structure.

MINERALISED connective tissue such as bone is a composite structure of protein, mineral and glycoproteins. The structural relationships between these components is still unclear although, individually, they are better understood.

In most hard tissues, the protein matrix is collagen which exists as long fibrils of diameter 200–1,000 Å and displays the 670 Å period of transverse bands seen in electron micrographs of normal tendon collagen[1,2].

The mineral is widely accepted as being calcium phosphate although there is disagreement as to the actual forms present. Crystalline hydroxyapatite seems to dominate[3] but there is clear evidence that an amorphous phase is also present[4]. X-ray[5] and electron microscope[6] studies show that the crystals have their unit cells oriented in a constant manner to the collagen fibril axis, suggesting a close structural relationship between these two ordered components. It is widely agreed that the crystals have one long side oriented parallel to the collagen fibrils, and the length of this long side is quoted variously between 300–1,000 Å. It is also agreed that one lateral dimension of the crystals is about 40 Å, although it is not known whether they exist as rods or plates. Many accept that the crystals are distributed along the collagen fibrils with the same 670 Å periodicity as collagen, but there is debate as to whether they are confined to the periphery or penetrate through the interior, and there is no certain knowledge about the axial location of the crystals with respect to the collagen period, although it has been suggested that they occur in the gap region[8].

We are investigating these questions using low-angle X-ray and neutron diffraction of mineralised turkey leg tendon. This tissue was chosen because the collagen is highly ordered in the axial direction, therefore giving well oriented diffraction patterns. Also, the system has been well studied using electron microscopy[8]. Although not strictly bone, the tissue does nevertheless represent a simple collagen–mineral interactive system, the results from which can be usefully applied to the whole problem of calcified tissues.

Principles of the method

X-ray and neutron diffraction patterns from tendons contain, at low angles, a set of meridional reflections which index as orders of 670 Å (D), the periodicity of the collagen fibrils when projected on to the fibril axis. The D period arises because, in projection, the 2,990 Å (L) long collagen molecules are staggered axially by D with respect to each other (Fig. 1). Since L is approximately $4.5D$, this molecular arrangement implies that each period has an overlap and gap region, each of approximately $0.5D$ in length.

The amino acid sequence of the collagen molecules is now known in some detail for rat and calf skin[10,11]. It is therefore possible to use the sequence and the Hodge–Petruska scheme

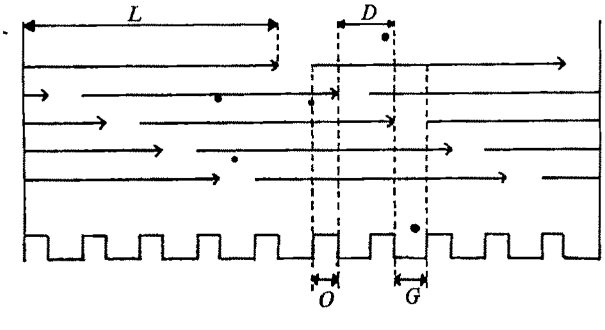

Fig. 1 Hodge–Petruska scheme for the molecular arrangement of collagen molecules[11]. *L* (2,990Å) is the length of each collagen molecule and adjacent molecules are staggered by *D* (670Å) with respect to each other. When projected on to the fibre axis, the arrangement produces a step function of period *D* containing an overlap region (O) and a gap region (*G*).

to construct the axially projected electron density (X-ray diffraction) and nuclear scattering density (neutron diffraction) profiles. From these models, the predicted intensities of the low angle X-ray and neutron meridional reflections may be calculated. It has been demonstrated[12,13] that a good correspondence can be obtained between the calculated and observed intensities in both diffraction techniques. Uncalcified turkey leg tendons from young birds show a meridional pattern very similar to that of rat tail tendon, the major differences occurring at a resolution in the order of 20 Å. This represents a much higher resolution than will be described here (74 Å) and, therefore, the scattering density models obtained for the rat tail can be confidently applied to this study of the turkey tendon. Thus, by comparing the X-ray and neutron diffraction patterns of calcified and uncalcified tendon an attempt can be made to locate the mineral with respect to the collagen axial structure.

The major problem when trying to compare the diffracted intensities from two similarly periodic structures containing different amounts of scattering material is one of scaling. In this case, it was overcome (in both diffraction techniques) by measuring the relative first-order intensities of a sample before and after decalcification. Allowance was made for the different absorption properties of the specimen with and without the mineral by normalising the intensities to the measured transmission of the undeviated beam. The important assumption that decalcified and uncalcified turkey tendon collagen are equivalent is substantiated by their X-ray diffraction patterns, which show no measureable differences to a resolution of 15 Å. Decalcification was carried out in phosphate-buffered EDTA (*p*H 8.0; 5%) followed by extensive washing in 0.15 M NaCl.

All experiments were carried out on leg tendons freshly dissected from turkeys killed in week 22 after birth. The tendons begin to calcify at week 16 and in the following 6 weeks calcify extensively to form stiff bone-like structures.

X-ray diffraction

Previous low-angle X-ray work[14] on calcified systems, including the turkey leg tendon, has shown the existence of an axial repeat of spacing 660 Å, and the intensities of the first six orders have been quantified. It was observed that these reflections have a much higher absolute intensity than those from uncalcified tendon. Furthermore, the reflections were obtained with mineralised tendon from which the collagen had been removed. It was concluded that these reflections come from the mineral component distributed with the *D* period and not the collagen which exhibits a spacing of 640 Å in the dry state.

We have extended these observations. Figure 2 shows the low-angle meridional patterns from calcified and uncalcified turkey leg tendon as well as that from rat tail tendon for comparison. Table 1 lists the measured intensities of the nine orders which are seen in the diffraction patterns. Several important preliminary observations can be made.

As observed by other workers[14], there is strong diffuse scatter from the mineralised tendon at low angles, which is confined to the equator. It is widely agreed that the origin of this scatter is the 'form factor' (or 'shape factor') of individual crystallites of mineral from which estimates of the crystal size can be made[7].

The absolute intensities of the reflections are indeed much higher for the tendon in the calcified state which must be due to the extra scattering by the mineral, although orders 1–5 in each pattern have relative intensities which are very similar.

Finally, the spacings of the reflections from the calcified and uncalcified tissues are exactly the same (orders of 670 Å). Because the mineral absorbs the X rays to such a large extent (approximately 90% attenuation for the thickness of sample used, see Fig. 2) and scatters much more strongly than collagen, it could be argued that the calcified tissue reflections are due solely to the mineral arranged *D* periodically, and that the collagen reflections which may exhibit a different *D* periodicity

Fig. 2 Low-angle X-ray diffraction patterns showing the first nine meridional reflections of rat tail tendon collagen (*a*), uncalcified turkey tendon collagen (*b*), calcified turkey tendon collagen (*c*). A mirror-monochromator focusing system was used linked to a rotating anode source (Elliot Automation GX6) with a specimen-to-film distance of 85 cm. Thin specimens, approximately 0.2 mm in diameter were suspended over 0.15 M NaCl in a sealed Perspex cell with Mylar windows. The rat tail tendon and the uncalcified turkey tendon clearly give very similar diffraction patterns. *d*, Calcified turkey tendon, taken at the Synchrotron Radiation Facility (EMBL) at DESY, Hamburg, in collaboration with A. Harmsen (specimen-to-film distance was 39 cm). The higher orders of the collagen are just visible above the intense low-angle diffuse scatter from the mineral crystallites.

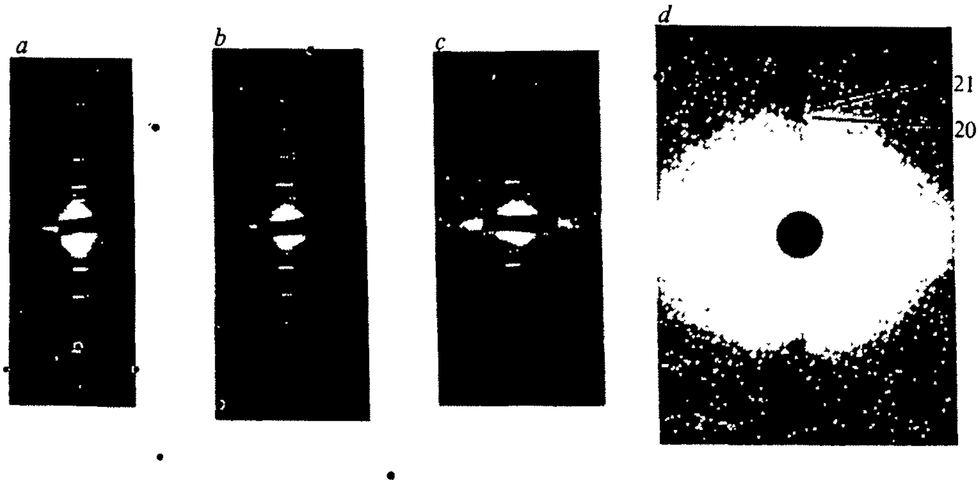

Table 1 Intensities of the first nine orders of the meridional X-ray diffraction patterns from rat tail tendon, uncalcified turkey tendon and calcified turkey tendon

Order	Rat tail tendon	Turkey tendon uncalcified	Turkey tendon calcified	Calcified collagen model
1	1,000	1,000	9,145	9,145
2	27	9	102	97
3	109	107	834	993
4	11	7	68	72
5	54	48	192	365
6	17	8	81	88
7	21	30	51	140
8	6	8	17	35
9	71	37	59	55

To measure intensities accurately, each diffraction pattern was digitised on an Optronics densitometer system, and the numerical data analysed with a computer program which integrates over each reflection and subtracts local background. Various corrections were applied to allow for the geometry of the X-ray camera, and other factors inherent in the measurement of fibre diffraction patterns. These are fully described elsewhere[15]. The arbitrary scale is 1,000 for the first order of uncalcified collagen. The final column lists the calculated intensities as obtained from the refined model of the calcified collagen.

are too weak to be seen. Very long exposures, however, fail to show up any other low-angle reflections. Furthermore. Fig. 2 also shows a diffraction pattern of mineralised turkey leg tendon obtained with Synchrotron Radiation at DESY in Hamburg. This very high-intensity X-ray source allows large specimen–film distances which reduces the diffuse scatter relative to the Bragg peaks whilst still retaining the ability to view the weak collagen reflections at higher angles. The higher orders of collagen, although still very weak, are clearly visible on the 670-Å spacing, especially the characteristically strong 20th and 21st.

Several important conclusions can be made. First, the mineral is arranged *D* periodically in the form of a step function along the collagen. The step width must be about 0.5*D* to give the strong, first, third and fifth orders. Second, the underlying collagen matrix retains its wet, native periodicity of 670 Å. At higher resolution, where the transform of the mineral component step quickly dies away, the collagen pattern can be seen.

The important question concerning the relationship between the two components, however, still remains unresolved. A specific interaction would mean that the amplitudes of the two individual transforms would add, whereas an incoherent arrangement would cause the intensities to add. The distinction cannot be readily made because the mineral scatter is so dominant. To help overcome this problem, the material was studied with neutrons.

Neutron diffraction

This is a particularly attractive technique to apply to calcified systems for two reasons. Unlike X rays, the nuclear scattering of neutrons by mineral and protein is comparable, and the former component does not dominate the resultant pattern. Second, we can use the fact that the background scattering by the water can be altered by introducing various amounts of D_2O into the system—the so-called contrast variation technique[16]. The average scattering length density of collagen at low resolution equals that of an aqueous background containing 47% D_2O, whereas that of the mineral is shown below to occur at a much higher value in the region of 80%. This large separation of 'matchpoints' between the two components means that we can effectively look at the scattering from one independently of the other. The behaviour of the rat tail collagen neutron diffraction pattern at different H_2O/D_2O ratios is well understood[17] and can be used to interpret the results from the calcified collagenous system.

The first six orders from calcified turkey tendon were collected on the D-11 instrument[18] at the Institut Laue-Langevin, Grenoble in a range of D_2O–H_2O mixtures from 0 to 100% in steps of 20% (Table 2). Several important features of the diffraction pattern and its variation with percentage D_2O are clear.

At all contrasts, except that in 100% H_2O, the intensities indicate that the structure in projection has a step function nature in having relatively strong first and third orders and a weaker second. Nowhere, however, is it as pronounced as with the X-ray data, and this reflects the fact that with neutrons the mineral is not dominating the diffraction pattern.

If the intensities are converted to amplitudes (by taking the square root), it is possible to plot their variation with percentage D_2O for each order and in all cases the relationship is non-linear. For any centrosymmetric structure, it can be shown that the amplitudes of its Fourier transform will vary linearly with percentage D_2O (ref. 16) and this is true for the low resolution rat tail tendon data (unpublished results). Clearly, the calcified collagen structure in projection is not centrosymmetric.

The large increase in the sixth order is entirely consistent with the collagen component and essentially results from its amino acid sequence[17].

Finally, the first-order intensity of calcified collagen is actually less than that of uncalcified collagen at 0% D_2O. If the intensities from each component were merely adding to produce the composite value, the first order for the calcified should be much higher than that of the uncalcified. The fact that this is not the case, strongly suggests that the amplitudes are adding with some phase relationship which in turn implies a specific interaction between the collagen and the mineral.

The results can be further analysed to give a low resolution picture of the relationship between the collagen and the mineral.

The X-ray results indicate that, at the resolution of the first order, both components can be considered as step functions. The first order of the composite diffraction pattern is a resultant of the two step function transforms at some phase angle Q. Therefore, determination of Q will give the axial relationship between each component. Contrast variation makes this possible using the neutron results.

Let A_M and A_C be the mineral and collagen first-order amplitudes in 100% H_2O, F_M and F_C the fractions of D_2O at which each amplitude falls to zero (the respective matchpoints), and A_{XM} and A_{XC} the amplitude values at a fraction X of D_2O. Each component, being a step function, is centrosymmetric and the amplitudes of their transforms will vary linearly with the D_2O composition. It follows that

$$A_{XM} = A_M - (A_M/F_M)\,X \tag{1}$$

$$A_{XC} = A_C - (A_C/F_C)\,X \tag{2}$$

Table 2 Variation of the first six orders of calcified turkey tendon meridional neutron diffraction pattern with percentage D_2O in the medium

Order	Calcified turkey tendon intensities					
	% D_2O					
	0	20	40	60	80	100
1	861	481	349	357	659	979
2	25	13	10	15	30	42
3	29	29	17	30	84	139
4	4	3	5	11	20	26
5	10	8	2	4	13	21
6	4	6	13	31	61	85

Specimens of calcified tendon were prepared by laying slices of tendon side by side to form a sheet approximately 0.1 cm thick and 2 cm square. Large specimens are required to use fully the 1-cm² neutron beam. After thorough equilibriation in the 0.15 M NaCl DO_2/H_2O mixture, the sheets were mounted in specially prepared sealed cells with quartz windows containing the same bathing medium. Six orders could be well resolved on the 64 × 64 cm² detector using a wavelength of 5.4 Å, and a specimen–detector distance of 5.53 m. As with the X-ray data, the numerical output from the detector was analysed by a program which calculates integrated intensities corrected for local background. All values are scaled relative to a first order value of 1,000 for rat tail tendon in 100% H_2O.

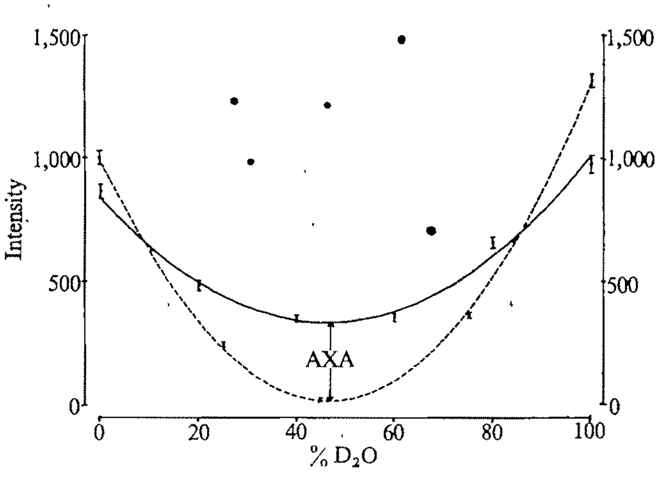

Fig. 3 Variation in first-order intensities of calcified turkey tendon (continuous line) and rat tail tendon (broken line) with percentage D_2O. The quadratic curves were fitted to the observed data using a least squares routine. The first cross-over point at 8% D_2O represents a point where the length of the two component amplitudes is such that their resultant is equal in length to the collagen amplitude alone. The second cross-over point at 86% D_2O represents the matchpoint of the mineral phase. At 47% D_2O where the collagen contribution is almost zero, one can estimate A_{XM} the mineral amplitude alone at this particular percentage D_2O.

Using the cosine rule, the resultant intensity variation of the composite first order with D_2O is

$$\begin{aligned}A^2{}_{MCX} = {} & X^2((A^2{}_C/F^2{}_C)+(A^2{}_M/F^2{}_M)+(2A_CA_M/F_CF_M)\cos Q)\\ & -X((2A^2{}_C/F_C)+(2A^2{}_M/F_M)+(2A_CA_M/F_M)\cos Q+\\ & +(2A_CA_M/F_C)\cos Q)+(A^2{}_C+A^2{}_M+2A_CA_M\cos Q)\end{aligned} \quad (3)$$

This equation predicts a quadratic variation in the first-order intensity with respect to fractional D_2O, and Fig. 3 shows a quadratic curve fitted to the results together with the rat tail tendon first-order intensity variation. The cross-over point provides a value for the mineral matchpoint F_M (0.86 D_2O). At 0.47 D_2O, the intensity of calcified system gives an estimate of A_{XM} (18.3) where the collagen contribution is at a minimum, and therefore A_M can be calculated from equation (1) as 40.4. A_C and F_C (31.42 and 0.47 D_2O) are known from the rat tail tendon data (unpublished results). Using equation (3), a value for Q can be found which gives maximum agreement with the quadratic curve fitted to the data shown in Fig. 3. The value resulting from such an analysis is 134°.

Refinement

Can this very crude model of two-step functions related by a phase angle of 134° be improved? The nine orders of the X-ray pattern of calcified tendon provides higher resolution information than the six orders observed using neutrons, and these can be used to refine the structure. Although the first few orders are dominated by the mineral, this is not true of the higher orders where the mineral transform is quickly dying away. The model structure for rat tail tendon collagen provides a reliable source of phases of the first nine orders of the X-ray pattern which can be combined with observed intensities to give a low resolution model of the uncalcified tendon. By adding a step function to represent the mineral, it is possible to calculate the expected X-ray intensities from the composite system and compare them with the observed. The length of the step function was varied between 0.45*D* and 0.55*D* (as indicated by the X-ray results), and its position varied between 120°→170° and −120°→−170° relative to the collagen step function (as indicated by the neutron results). Both angular regions need to be included because the centrosymmetric assumption used in the neutron diffraction data analysis cannot distinguish between these two possibilities. For convenience, observed and calculated first-order intensities were equalised by adjusting the height of the mineral block, and an R factor $\Sigma(|F_{obs}|-|F_{calc}|)/\Sigma|F_{obs}|$ was calculated on the amplitudes of the other eight orders to provide a measure of agreement.

The average R factor obtained within the refinement region was 0.49, but with a step width of 0.48*D* and a phase shift of +160°, a minimum value of 0.17 was obtained. This minimum is 2.8 s.d. units from the mean. For structures chosen randomly outside the refinement region nowhere was a value less than 0.6 observed. The calculated intensities from the best fit model are listed in Table 1 for comparison with the observed data.

Figure 4 is a Fourier synthesis of the composite structure using the model phases and observed X-ray amplitudes.

Discussion

The axially projected structure proposed for the calcified turkey tendon shown in Fig. 4 is based primarily on the results of X-ray diffraction, but it is consistent with the neutron diffraction. The observation that the first-order intensity with neutrons in 100% H_2O is higher for the uncalcified than for the calcified tendon is consistent with the component step functions being 160° out of phase, and the neutron scattering from each being comparable. In effect, the mineral scatter is cancelling that of the collagen and, therefore, removal of the former increases the first-order intensity. This also explains why the step function is enhanced at higher percentages of D_2O in the medium. In the middle range near the collagen matchpoint (30–60%) where its contribution is small, the mineral step dominates; the reverse is true in the higher range (70–100%) near the mineral matchpoint.

As predicted, the structure is not centrosymmetric, which would only be the case if the phase angle between the two first order components were close to 0° or 180°. The disparity between the phase angles obtained from the two diffraction techniques may seem rather large. The difference of 26° only represents, however, an axial distance of 48 Å which is less than the nine-order (74 Å) resolution of the model, and the value of 134° obtained from the neutron data analysis did provide a useful starting point for the refinement using the higher resolution X-ray data.

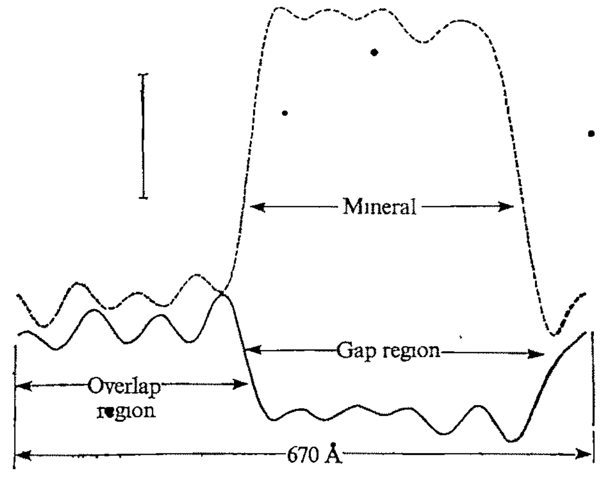

Fig. 4 Fourier syntheses of the uncalcified (continuous line) and calcified (broken line) turkey tendon with a *D* period Both were constructed using the observed intensities and calculated phases of the first nine orders—the uncalcified collagen phases from the rat tail tendon model, and the calcified collagen phases from the refined model described in the text. For clarity, the two curves are slightly offset, but the overlap region of the uncalcified collagen corresponds in electron density to the region of the calcified profile where there is no mineral contribution. Exact axial register between the minor peaks on each curve is not to be expected at this poor resolution where distortion due to termination errors is very high. It is clear, however, that the mineral is lying in precise axial alignment with the gap region. The vertical bar represents a height of 50 electrons per residue translation.

This work has shown that a definite axial relationship exists between mineral and collagen in calcified turkey leg tendon. The most attractive feature of the model is that the size of the mineral block and its position places it precisely in the gap region. Although these results provide no information concerning the lateral arrangement of the two components, it is difficult not to speculate that the mineral does penetrate the fibril and occupy the gap region. As indicated by others[8], this is the only way that penetration of the collagen by the mineral could occur without disrupting its fibrillar structure. The height and length of the artificial step, used to represent the inorganic phase in the model, corresponds to an actual volume of about 30,000 Å^3 per collagen molecule (using the apatite electron density). Taking the mineral block length as 0.48D (320 Å), this would correspond to a cross-sectional area of 94 Å^2. This may be considered rather low when compared with the crystal size estimates mentioned earlier, but it must be stressed that the tendons from 22-week-old birds are certainly not fully calcified, and that this value of 30,000 Å^3 only represents some kind of average over the tendon. A quantitative chemical analysis of the amount of mineral present in the tendons of birds at various ages should help to clarify this point.

Preliminary X-ray pictures of bat phalangeal bone indicate a similar low-angle diffraction pattern to that of calcified turkey tendon, and it is hoped that work on this and similarly well oriented hard tissues will bridge the gap between the calcified tendon system and true bone.

The initial X-ray work described was carried out in the Laboratory of Molecular Biophysics, University of Oxford, and we thank Professor D. C. Phillips, Dr C. Rodger and Dr B. Brodsky (Doyle) for their advice and assistance during this period. We thank the Arthritis and Rheumatism Council and the European Molecular Biology Organisation for support, and the ILL for neutron scattering and computing facilities.

letters to nature

The possible galactic origin of γ-ray bursts

FOLLOWING the discovery of non-solar γ-ray bursts[1], various models to account for their origin have been discussed. Extragalactic models include supernova bursts in remote galaxies[2], and the collapse of the cores in active stars[3], while galactic models are based on flare stars[4], thermonuclear explosions on neutron stars[5] and the sudden accretion of cometary gas on to neutron stars[6]. The acceptability of any of these models may be tested by the observed size spectrum of γ-ray bursts. The extragalactic models predict a power law spectrum with $\alpha = -1.5$ while for the galactic models the number index will be -1. The experimental data on γ-ray bursts is still meagre. So far, about 44 confirmed events have been recorded by satellite-borne instruments[7,8]. The number spectrum of the observed γ-ray bursts (Fig. 1) shows that the observed distribution for events with an energy less than 10^{-4} erg cm^{-2} is flat and thus makes the choice of any model completely arbitrary Carter *et al.*[9] presented an upper limit on the number of γ-ray bursts having an energy $> 2.10^{-7}$ erg cm^{-2} and suggested that the data are consistent with a power law spectrum in which $\alpha \sim 0.5$, or a modified galactic distribution. We present here an alternative analysis of the observed γ-ray events, which suggests very interesting possibilities for their origin.

In Table 1 we have listed the chronological catalogue of the observed γ-ray events. Inspection of the data relating to the estimated flux suggests that there is a preferred mean energy for γ-ray bursts. Some 90% of the events have an energy between 5×10^{-5} and 5×10^{-4} erg cm^{-2}, contrary to the predicted characteristics of the number spectrum of various models even if a detection bias of 10 is taken into account for low energy bursts.

We estimate in this analysis the relative distance of the origin of each burst by assuming a constant intrinsic luminosity of the source. The data were then divided into 10 bins. The number of bins is chosen to reflect the observed variations in energy by two orders of magnitude. In the histogram obtained from this analysis (Fig. 2*a*), the numbers are plotted using an arbitrary distance scale. In Fig. 2*b* we have plotted the galactic distribution of HII regions and clouds of molecular hydrogen[11]. The remarkable similarity between the distribution of γ-ray bursts, and that of supernova remnants, suggests a genetic relationship between the two and the galactic origin of the γ-ray bursts. A selection bias in binning the data to generate the γ-ray burst histogram can alter the shape slightly but the overall gaussian nature is preserved under all combinations.

If the apparent correlation shown in Fig 2*a* between γ-ray bursts and supernova remnants is genuine, then the burst source could be identified with 'cool', that is, completely run down neutron stars. Current theories of supernovae suggest that each supernova explosion results in the formation of a neutron star. This prediction has been further supported by the discovery of pulsars About 20% of these compact objects will be in close binary systems. Most of these neutron stars will lose their angular momentum in 10^4–10^6 yr, because $\Omega/\Omega = P/P = 10^{-12}$ s, is representative of the observed values of P in various pulsars. Thus, at any time, there exists a large population of 'cool' neutron stars in our Galaxy. We propose that γ-ray bursts originate from the disruption of these 'cool' neutron stars.

Lattimar and Schramm[12] investigated a mechanism whereby a neutron star falling towards a black hole is tidally disrupted, for example, in a binary system. This results in the decompression of the ejected neutron-star matter. As this material expands it follows a unique evolutionary path, like the r-process,

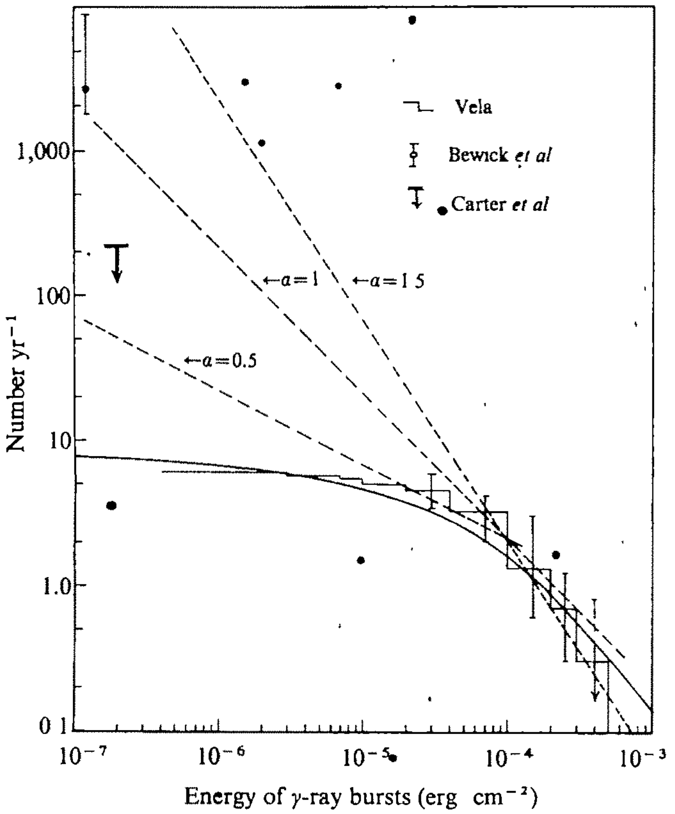

Fig. 1 The number spectrum of the observed γ-ray bursts. The three dotted lines labelled $\alpha = 1.5$, 1 and 0.5 represent the power law function $N \propto S^{-\alpha}$, predicted for sources distributed uniformly in 3, 2 and 1 dimensions, respectively. ——, Cumulative gaussian distribution normalised at 5×10^{-4} erg cm^{-2}.

towards the region of superheavy elements[13], and nuclei up to mass $A \sim 300$ are formed. Fission then sets in until such time that all the neutrons are used up. This process would result in a γ flash. The characteristic time scale for such a process is from 10 ms to a few seconds. If we take account of the comparatively long decay times of the various isotopes and the β-decay life time of the various intermediate nuclei, the observed time structure of γ-ray bursts can easily be accounted for. It is interesting, however, that some of the observed features will follow naturally from such a model.

(1) The spectral shape for all events will be similar. This is suggested by the spectra of the 14 events observed by the IMP satellite[8].
(2) The energy released during each disruption will be similar, as there is only a small range in the permitted mass of neutron stars.
(3) The expected rate of occurrence of γ-ray bursts in the entire energy range should remain constant within statistical limits.

The present model can also provide the required energy, which at a distance of 6 kpc and an average observed energy of 5×10^{-4} erg cm^{-2}, corresponds to 10^{42} erg s^{-1} emitted in γ rays during the burst. Assuming that 1% of the total energy is radiated as γ rays, the total energy released corresponds to 10^{44} erg s^{-1}. This value is well within the range of the energies associated with stellar explosions. As the energy is released in the disruption of the core, the restrictions observed in accreting models due to the Eddington limit ($\sim 10^{38}$ erg for the case of a neutron star having a mass of $1 M_\odot$) do not apply.

It is possible to predict the form of a number spectrum of the observed events if the association with supernova remnants is valid and neutron star disruption results in γ-ray bursts. The number spectrum predicted by such a model can be defined as a product of three distributions.

$$N(E) = N_C(t) N_L(E) N_R(r)$$

where N_C is the number distribution for star disruption, N_L the distribution of the luminosities of burst sources, and N_R the distribution of sources with distance.

All three distributions in the equation can be approximated by gaussian functions. The first two represent statistical phenomena, and the observed distribution of N_R seems to be gaussian as is indicated in Fig. 2*a* Therefore, the observed composite distribution will also be gaussian. The integral number-spectrum of burst events per yr will then be represented by a cumulative gaussian function Figure 1 shows that such a distribution fits the observed number distribution extremely well.

The present model predicts an anisotropy in the arrival directions of the bursts. The magnitude of this anisotropy will depend on the spatial distribution of the 'cool' neutron stars. Any analysis of this nature is limited by the very small number of observed burst (50) and the fact that the arrival directions

have large error boxes, except for a few cases. As most of the events were seen by the Vela satellites, the inferred positions have relatively larger errors in galactic longitude than in galactic latitude. Strong *et al.*[14] have analysed the latitude dependence of 16 γ-ray bursts. The resulting distribution deviates significantly from that expected on the basis of isotropic distribution, suggesting that γ-ray burst sources indeed cluster near the galactic equator. This conclusion is based on a small sample of observations, and therefore we do not yet regard this as firm supporting evidence.

The present apparent isotropic nature of γ-ray burst sources may be misleading due to poor statistics. More directional data are required to establish the form of the frequency distribution.

Possible detection of a radio event correlated with a γ-ray burst

COSMIC bursts of electromagnetic radiation, both isolated and in connection with other impulsive astrophysical phenomena, have been sought for many years[1], with only one suggestive positive result[2], until, in 1973, the discovery of γ-ray bursts[3] of cosmic origin prompted a new series of observations[4]. In 1975 we started a systematic search for electromagnetic bursts at v.h.f. and u.h.f. The system, based at Medicina (Bologna, Italy), is semi-automatic and assures highly efficient data collection. Simultaneous observations at different frequencies facilitate the evaluation of disturbances of local origin and, hopefully, their isolation. Regular observations started in July 1976, and we report here our detection of a radio burst, which seems to be correlated with a γ-ray burst.

On August 16 1976, a radio burst was detected at Medicina at four different frequencies[5]. About 60 s earlier, three satellites (1 Vela, 2 Solrads) (R. W. Klebesadel, personal communication) and one balloon-borne detector on its second transatlantic flight (M. Sommer, personal communication) detected an intense γ-ray burst.

Details of the radio and γ data are given in Table 1.

The 151- and 408-MHz signals were detected by north–south arrays of 10 dipoles (HPBW = 15°×75° and 12°×75°, respectively), used as transit instruments pointing along the meridian at an altitude of 16.5°. The 323.5- and 330.5-MHz data were obtained using two receivers connected to a 7° HPBW parabola (10-m diameter) tracking the Sun. The parabola operated in connection with the X-ray detector on its second transatlantic balloon flight. From the recordings (Fig. 1) it seems that the pulses have a duration of 30 s, which is long compared with the response recovering time of the pen recorders. On the same charts are several interference spikes whose width, much narrower than this, results from the finite thickness of the pen trace.

The similar duration and coarse structure of the radio pulses, evident at all frequencies, the coincidence within the resolution time between the signals detected by the arrays and the Medicina parabola (which are 700 m apart from each other), and the detection at four different frequencies make a man-made origin of the signal very improbable.

Strong evidence of a non-local origin of the phenomenon comes from the independent observation carried out at the Osservatorio Astronomico of Trieste (400 km away) (Table 1). At 237 MHz, with a 15° HPBW parabola (10-m diameter) monitoring the Sun, a structured event above the noise appears on the record in coincidence with our radio burst.

An atmospheric origin seems unlikely, first because the weather was clear and fine when the burst was detected, and second, because of the time coincident event at Trieste. From the rate of isolated pulses seen in coincidence within 10 s by the parabola and the arrays at Medicina, we expect a rate of fourfold random coincidence of 1 per 24 h. If we consider the Trieste dish, the rate of fivefold random coincidences drops to 1 per 432 h.

The γ-ray event occurs ~60 s earlier. Assuming a coincidence time of 2×60 s, the probability of a random correlation between the γ burst and the fivefold radio coincidence is 8×10^{-6}. This supports the hypothesis that the radio signals are the counterpart of the γ event, although a definite correlation can be given only when the location of the γ and radio event is found. To

Table 1 Radio and γ data for August 16 1976

Detector type	Array of dipoles		Medicina parabola		Trieste parabola	Balloon X-ray telescope

Peak intensity (W m^{-2} Hz^{-1})	8×10^{-22}	9×10^{-22}	3×10^{-23}	1.4×10^{-23}	2×10^{-22}	—

pinpoint the position of the radio burst source in the sky we could in principle convolve the heights of the signals measured at the various frequencies with the aerial beam patterns.

When the event occurred, the axes of the parabolae and of the arrays were roughly orthogonal. The relative peak intensities of the pulses cannot be reconciled with the source on the axis of any of the aerials. The Sun is then excluded, being on the axis of the two parabolae. A non-solar origin of the radio event is also supported by the available information on the Sun: on August 16 there was no evidence of activity in H (ref. 6), while at radio frequencies only a weak solar storm, not polarised, was present. Furthermore, a purely phenomenological analysis of the signals seen at the five different frequencies excludes the hypothesis of a typical solar radio burst.

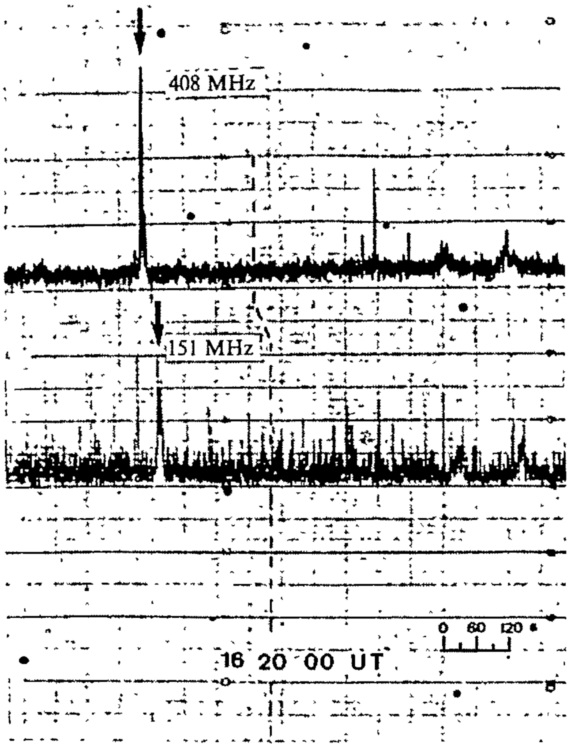

Fig. 1 Signals recorded on August 16 at 151 and 408 MHz. (Chart speed 60 cm h^{-1}.)

The decreasing peak intensities of the signal detected at 237, 323.5 and 330.5 MHz, respectively, and the frequency dependence of the parabola beam shape suggest that the source was at least 8° off the Sun position.

Analysis of the general trend of the power patterns of the aerials and their relative positions shows that the beam overlaps were only marginal. Here, the influence of side lobes is dominant and difficult to measure. Precise calculations of the beam pattern intersections are therefore useless and probably misleading Hence we limit ourselves to defining a region of sky (shaded area in Fig. 2) where the radio burst most probably originated. Some interesting objects exist in this region. Its area is so large, however, that any attempt to identify a precise object is meaningless.

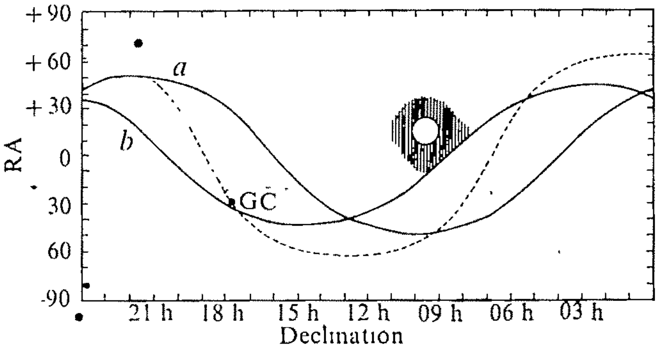

Fig. 2 *a*, Medicina horizon; *b*, balloon horizons, in equatorial coordinates The radio burst location is marked by the shaded area. — — —, Galactic equator, GC, Galactic centre.

We notice that all the possible positions of the source are at least 15° above the galactic plane and a delay between the 151- and 408-MHz radio signals produced by interstellar dispersion not greater than 10 s must be expected. It agrees with the upper limit we can assign to the delay between the extreme frequencies used in our experiment. The 1-min time difference between the onsets of γ and radio signals cannot be produced by dispersion. It implies a much higher delay between the radio signals. The γ–radio delay might then reflect the time evolution of the phenomenon which produced the electromagnetic burst.

Also, the duration δt of the radio burst, even in the case of the lowest frequency 151 MHz, cannot be attributed to dispersion across the bandwidth of the receiver. In fact, if the full 60-s delay between the γ-ray burst and a truly prompt radio burst were caused entirely by electron dispersion, δt would be only 0.8 s for a bandwidth $\Delta\nu = 1$ MHz.

Our radio data seem to be the radio counterpart of August 16, 1976, γ-ray burst. The probability of a random coincidence (8×10^{-5}) could have been drastically reduced by other independent observations. Unfortunately, this was not the case. We hope that more extended collaborations between various spaced stations will increase the efficiency in rejecting interference events and give further evidence of the existence of radio bursts of cosmic origin.

We thank Drs G. Cavallo, F. Fuligni and J V Jelley for helpful criticism and discussion, and Messrs G. P Cazzola, S. Cortiglioni, E Sbarbati and F. Tinti for technical assistance.

Observational test for the existence of a rotating black hole in Cyg X-1

X-RAY satellite experiments[1,13,14] are now investigating the degree and plane of linear polarisation of the radiation from Cyg X-1. This radiation can be explained as coming from an accretion disk around a black hole, the polarisation of the X rays being due to electron scattering in the hotter, inner regions of the disk. Novick reported[2] observing 3% linear polarisation (marginally significant at the 2.5σ level) at 2.6 keV from Cyg X-1. Existing predictions of the polarisation properties, as a function of energy, have been based on a Newtonian approximation[3-5], thus neglecting gravitational effects on the rays as they propagate from the disk's surface to an observer at infinity We present here preliminary results of a full general-relativistic calculation which show that gravitational effects completely alter the polarisation properties, and provide a sensitive test of the existence of a black hole.

Whereas in the Newtonian approximation the plane of polarisation as measured at infinity is the same for each point of origin on the disk (for the same initial polarisation), it varies considerably when we allow for general-relativistic effects. These rotational differences can amount to over 100°. Even the special-relativistic aberration contributions, in the regions of interest, are typically an order of magnitude smaller than those of a gravitational origin.

We use the general-relativistic parallel-transport equations[6] to propagate the polarisation vector from each point on the disk along the null geodesic linking it to an observer at infinity with polar angle θ_0. While a non-rotating, Schwarzschild, black hole can be treated analytically (R. F. Stark, unpublished work and ref 7), we report here numerical results for a Kerr black hole. For a rapidly rotating black hole the general-relativistic effects on the polarisation properties are an order of magnitude greater than for a slowly-rotating black hole or for a neutron star.

The degree of linear polarisation, δ, of the rays as they leave the disk will also differ from the Newtonian value. Gravitational bending of the light will alter the angle at which a ray leaves the disk's surface from the Newtonian value of θ_0. As δ depends on the initial direction of travel (varying, for an optically thick disk, from 0% for rays leaving the disk vertically, up to 12% for rays leaving parallel to the disk)[9], we can also expect gravitational effects to change the observed degree of polarisation.

We sum contributions from all parts of the disk to find the net observed polarisation properties, as a function of observed X-ray energy E_0, from the net Stokes parameters $\bar{I}(E_0), \bar{Q}(E_0), \bar{U}(E_0), \bar{V}(E_0)$ (ref. 8). Following Cunningham[9], we use a transfer function f to obtain the intensity, but also define a polarisation transfer function $h = fe^{2i\varphi}$ where φ is the observed angle of the plane of polarisation (measured from the unrotated direction). The net Stokes parameters can then be expressed as

$$\bar{I}(E_0) = \iint G(g)\, f\, I(E_0/g)\, r\, \mathrm{d}r\, \mathrm{d}g$$

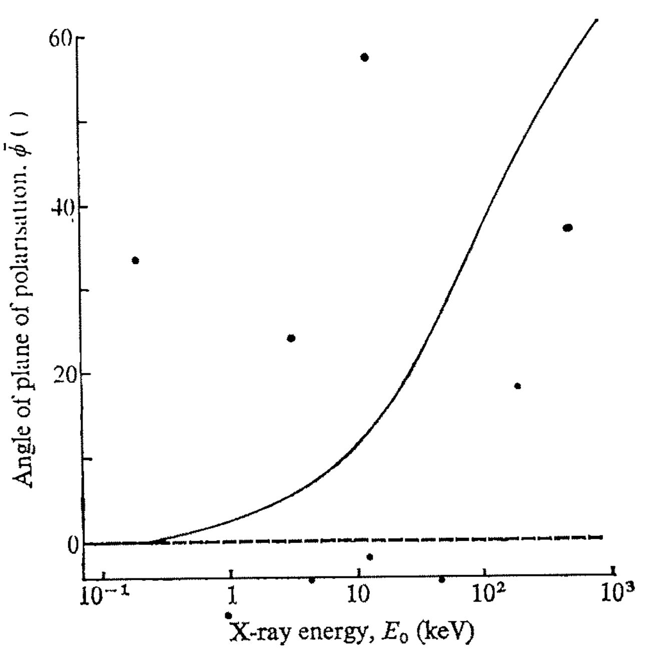
$$\bar{Q}(E_0)+\mathrm{i}\bar{U}(E_0) = \iint G(g)\, h\, \delta\, (E_0/g)\, I(E_0/g)\, r\, \mathrm{d}r\, \mathrm{d}g$$

where G is a function only of the redshift g, and I is the locally produced intensity. The assumption of a plane, homogeneous atmosphere for the disk implies that $\bar{V}(E_0) = 0$, that is, there is no circular polarisation. The net degree of polarisation, and net polarisation angle, $\bar{\delta}(E_0)$, $\bar{\varphi}(E_0)$, as observed at infinity are then given by:

$$\bar{\delta}(E_0) = \surd\, [\bar{Q}^2(E_0)+\bar{U}^2(E_0)]/\bar{I}(E_0),\ \tan 2\bar{\varphi} = \bar{U}(E_0)/\bar{Q}(E_0)$$

For illustration, we have used the Novikov–Thorne co-rotating, equatorial disk model[10], for a Kerr black hole with specific angular momentum $a/m = 0.9981$ (ref. 11) although, as we emphasise, and discuss below, we expect similar effects with most disk models centred on rapidly rotating black holes. For our chosen parameters the disk could always be considered to be optically thick throughout. We use Chandrasekhar's results[6] for the variation of δ with angle for such an atmosphere,

Fig. 1 Variation of plane of polarisation with energy for $\theta_0 = 75.5°$. The parameters used for the disk model were: viscosity parameter, $\alpha = 0.1$, mass of black hole, $M = 9M_\odot$; mass accretion rate $= 7\times10^{17}$ g s^{-1}. ———, General-relativistic curve; — — —, Newtonian curve.



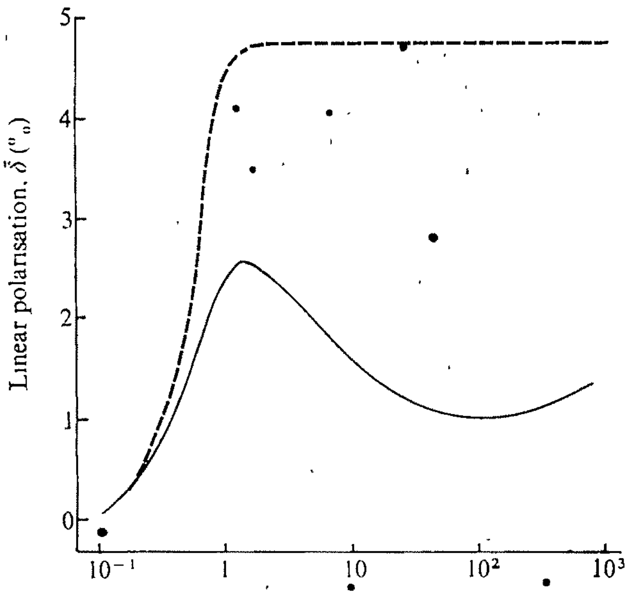


Fig. 2 Variation of linear polarisation with energy. Same parameters as in Fig. 1. ———, General relativistic curve; — — —, Newtonian curve.

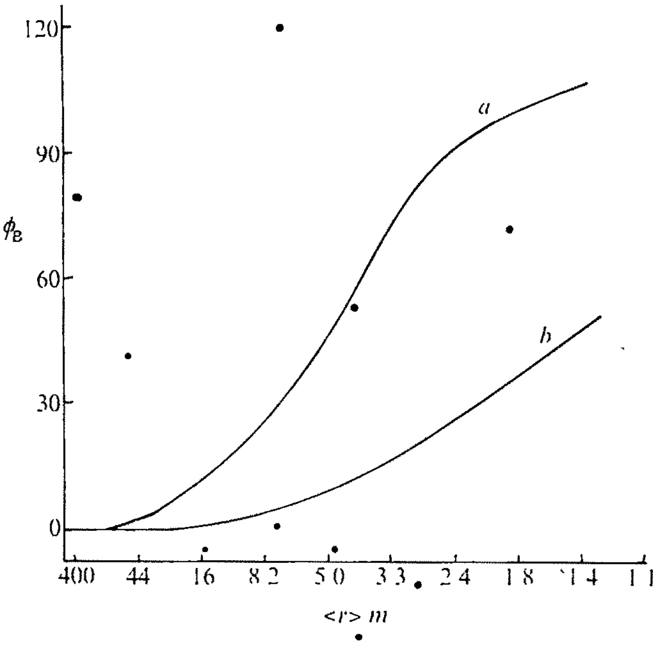
modified to include frequency-dependent effects due to free–free opacity.

Figure 1 shows the large general-relativistic variation of the polarisation plane with energy. An anti-clockwise rotation with increasing energy will be seen by an observer above the disk (that is, with $\theta_0 < 90°$), while observers below the disk will see a clockwise rotation. The effect of general relativity on the degree of polarisation (Fig. 2) is to cause a peak (below the predicted Newtonian value) and a fairly rapid fall-off at ~2 keV, and to cause a minimum and subsequent rise at higher energies. This behaviour is predominantly due to the gravitational bending of the rays previously mentioned, the depolarisation due to differential rotations in φ being smaller.

A large general-relativistic rotation in the plane of polarisation can be expected for most other disk models incorporating electron scattering, and a good estimate of the rotation for these models can be found by examining the peaking behaviour of the integrals with redshift and radius. For a chosen model, as E_0 increases, I peaks for an annulus of decreasing radius, on account of the radial temperature structure of the disk. Around this annulus the redshift factor G peaks where the rays leaving it are blueshifted the most into E_0. We thus find that the main contribution to the integrals comes from a small area of the disk. Figure 3 shows the variation of the observed polarisation plane φ_B of these maximum blueshifted rays with annular radius $\langle r \rangle$.

Fig. 3 Variation of the polarisation plane of the most blueshifted radiation with emission radius. $a/m = 0.9981$. a, $\theta_0 = 41.1°$, b, $\theta_0 = 75.5°$.



Once the variation of $\langle r \rangle$ with E_0 for a particular model has been found, the variation of φ_B with $\langle r \rangle$ can be used to obtain a good estimate for φ. If the disk has an optically thin inner region, $\bar{\varphi}$ will change by 90° as $\langle r \rangle$ passes through the transition region from thick to thin[12], and will then resume a general-relativistic variation. Large variations in $\bar{\varphi}$ with energy, of a gravitational origin, will occur whether the inner region is optically thick or thin (as in the two-temperature disk model)[15].

The very large general-relativistic rotations in the plane of polarisation provide an opportunity for testing the black hole hypothesis for Cyg X-1. To observe these effects, X-ray satellite experiments are required with more sensitive polarimetry across a wider energy range than is available at present. The results also indicate that the polarisation properties of radiation emitted from regions of strong gravitational fields can be both theoretically and experimentally important.

We thank Dr D. W. Sciama for guidance and Drs J. C. Miller, S. Pineault, T. Piran, G. Bath and Mr S. J. Rose for helpful suggestions.

X rays from radio binaries

THE properties of the radio binary systems, CC Cas, AR Lac, β Per (Algol), β Lyr, b Per and Cyg X-1 have been listed[1]. A thermal interpretation of the radiation from Algol[2] requires a much larger X-ray flux than the observed value of 3.8×10^{-11} erg cm^{-2} s^{-1} keV^{-1} in the 2–6-keV energy range[3]. The observation of some non-thermal flares, and the small size of the radio source in Algol indicate the non-thermal nature of the radio emission[1]. We interpret the radio emission as synchrotron radiation and suggest that the observed X-ray emission is inverse Compton scattering of the light of the primary star by the radio electrons. We calculate X-ray emission from other radio binaries using this model. The energy for the radio electrons can arise from annihilation of magnetic lines connecting the binary stars twisted by the rotation of the stars[4].

The energy of the synchrotron electrons of β Per (Algol) is fixed by the optical photon energy (about 0.8 eV) and the X-ray photon energy (4 keV); the relativistic factor for these electrons is about 75. The observed radio frequency (about 8×10^9 Hz) gives the strength of the magnetic field as 1.6 G in the radio-emitting region, using the usual sychrotron radiation formulae. The radio emission from the electrons, with the observed radio energy emission[1], gives the number of radio electrons as 2×10^{38}. The optical luminosity of

TABLE 1 X-ray flux from radio binaries

	CC Cas	AR Lac	β Per	β Lyr	b Per	Cyg X-1
Optical luminosity (erg s^{-1})	5×10^{36}	2×10^{34}	3×10^{35}	6×10^{36}	2×10^{35}	5×10^{36}
Maximum radio luminosity at 8085 MHz (erg s^{-1} MHz^{-1})	1.2×10^{19}	7.3×10^{17}	4.8×10^{17}	1.6×10^{18}	3.9×10^{16}	2.6×10^{20}
Distance (pc)	1000	71	25	260	52	2500
Calculated X-ray flux (erg cm^{-2} s^{-1} keV^{-1})	2×10^{-12}	10^{-12}	4×10^{-11}	3×10^{-11}	10^{-12}	10^{-11}
Observed X-ray flux (erg cm^{-2} s^{-1} keV^{-1})	?	?	3.8×10^{-11}	?	?	$\sim 4 \times 10^{-9}$

the primary B-star is calculated from the observed visual magnitude and an appropriate bolometric correction, and is about 10^{36} erg s^{-1} The optical photon density is obtained using a distance of 3×10^{11} cm from the star, which is a little less than half the semi-major axis of the close binary system Using a distance of 25 pc for Algol[1], the X-ray intensity at the Earth due to Compton scattering of the optical photons from radio electrons is about 4×10^{-11} erg cm^{-2} s^{-1} keV^{-1}, agreeing with the value of Schnopper *et al* [3]

The energy release, E, from the magnetic field twisting between the binary stars is given approximately for one turn as (see ref. 4)

$$E \sim B_S^2 a^6/R^3 P \text{ erg s}^{-1}$$

where B_S is the surface polar magnetic field of the star, a is the radius, $2R$ is the interstar distance and P is the period of rotation Using plausible values of $B_S \sim 30$ G, $P \sim 10^5$ s, $a \sim 2 \times 10^{11}$ cm, $R \sim 4 \times 10^{11}$ cm, we obtain $E \sim 10^{31}$ erg s^{-1}, which is approximately the energy in X-ray emission The value of B_S is compatible with the magnetic field in the radio-emitting region if we assume a dipole field.

Table 1 shows the X-ray flux expected from the other radio binaries listed in ref. 1 using the same model The X-ray flux observed from Cyg X-1 clearly shows that the X-ray-emitting process is different from the one considered here. Of the remaining radio binaries in the list, β Lyr seems the most promising candidate for observation

Transient structure in the high-energy X-ray light curve of NP 0532

ON 1974 June 21 we observed the Crab Nebula with a balloon-borne X-ray telescope (20–150 keV) with a sensitive area of ~ 700 cm^2. The observations took place between UT 54112 s and 78520 s. At times during this period a transitory third peak was observed in the light curve of NP0532, which we have reported earlier[10]. The peak comprised $2.0 \pm 0.5\%$ of the total emission from the Crab, and was detectable for ~ 5 min on two occasions (~ 40 min apart). We also report pulsed fractions in the primary and secondary peaks, and in the interpulse region.

Four light curves for the pulsar NP0532 are shown in Figs 1*a*–*d* (35–115 keV). The intervals over which data were superimposed are indicated. A fifth curve (Fig. 1*e*), is a superposition of background data, using the period for NP0532. The pulsar period was corrected for balloon location and drift, based on optical data and calculations provided by H. Helmken of the Center for Astrophysics. The data were binned in time bins of 1/85 of the pulsar period, that is, ~ 0.3901 ms. The actual time resolution of our data, however, is 2 ms.

Fig. 1 Light curves of NP0532 on 21 June 1974 (35–116 keV). The observation intervals (in UT; seconds from June 21.0) are indicated. Scans over the Crab Nebula were made with different exposures; thus, the amplitudes of the peaks are different for the four intervals: *a*, 54130–54800 s; *b*, 71880–72200 s; *c*, 73700–74200 s; *d*, 74450–74850 s. The primary and secondary peaks occupy bins 25–45 and 66–81, respectively. A third peak (bins 5–12) is apparent ~ 12 ms before the primary in *b* and *d*. A curve for background data (*e*, 81600–82600; folded at the NP0532 period) is also given.

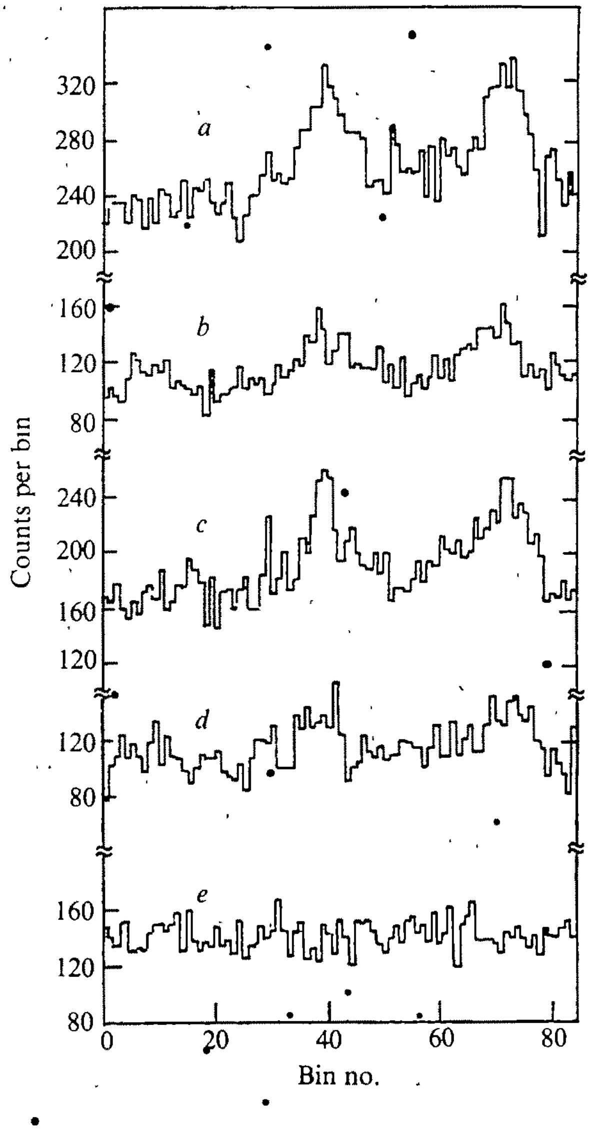

Table 1 Analysis of transient light-curve peaks

Bins per group	No. of groups	χ^2_{max}		Starting bin for χ^2_{max}		Null hypothesis probability	
		b	*d*	*b*	*d*	*b*	*d*
6	4	16.6	13.3	5	3	0.0036	0.0169
7	4	15.5	10.3	6	2	0.0063	0.0680
8	3	19.2	9.9	5	3	0.0002	0.0392
9	3	13.6	17.0	6	4	0.0093	0.0013
10	2	12.7	9.0	5	3	0.0020	0.0196
11	2	15.1	8.8	5	3	0.0010	0.0215
12	2	14.1	11.5	5	3	0.0020	0.0066
13	2	8.3	11.0	5	2	0.0306	0.0074
14	2	6.4	8.5	5	14	0.0775	0.0295

Bins 1–24 and 82–85 in the light curves of Figs. 1*b* and *d* were used. The first column gives the number of time bins combined into larger bins (called 'groups'). The second column gives the number of groups that could be composed from the data. The third and fourth columns give the maximum value of χ^2 obtained by forming groups from adjacent time bins from Figs 1*b* and *d*, respectively. This maximum occurred when the first of these groups began with the bin number given in the fifth column (Fig. 1*b*) or sixth column (Fig. 1*d*). The sixth and seventh columns give the probability that the given values for χ^2_{max} for the data of Figs 1*b* and *d*, respectively, would occur as statistical fluctuations in random data. These probabilities were determined by repeating the analysis procedure on 10,000 runs of computer-generated random data.

Figures 1*b* and *d* show the presence of a third pulse (bins 5–13) which leads the primary pulse by ~12 ms. To establish objectively a level of statistical significance for this peak, we used a Monte Carlo technique, that is, we tested for a feature of arbitrary location and width within the light curve. In applying this technique, we first calculated χ^2 for various combinations of adjacent data bins (which we called 'groups') from Figs 1*b* and *d*; a total of 28 bins (bins 1–24 and 82–85) were used in constructing the groups, covering the generally accepted 'unpulsed' portion of the light curve. Groups consisting of 6–14 bins were considered; the lowest-numbered bins were used and leftover bins disregarded when 28 was not divisible by the number of bins per group (for example, when considering groups of six bins, only bins 1–24 were used). χ^2 was evaluated for these groups, fitting the data to a constant count rate. The maximum value of χ^2 obtained in this manner is given in Table 1 for each group size used.

The same procedure was then followed on 10,000 runs of simulated data, generated assuming a constant counting rate equal to the mean observed rate and fluctuations dictated by Poisson statistics. The number of runs (divided by 10,000) which produced values of the maximum χ^2 in excess of that obtained with the actual data is noted in Table 1 for each group size. These numbers are, therefore, the probabilities for a constant source producing the values of χ^2_{max}. For a group size of eight bins, only two out of the 10,000 runs of simulated data produced as large a value of χ^2 as did the data from Fig. 1*b*. Consequently, we conclude that it would be very unlikely for the Crab pulsar, if truly constant over these bins, to produce the observed data. Note that this probability level does not directly give the statistical significance of any peak present; a 'valley', for example, could as easily produce high values of χ^2 in the simulated data. The significance of the feature in Fig. 1*d* is considerably less, as 13 runs (out of 10^4) yielded larger values of χ^2 (group size of nine bins).

The width of the apparent peak (eight or nine bins) is consistent with a much narrower feature, broadened by our time resolution; of course, it is not necessarily any narrower than eight or nine bins. We were able to rule out a single, brief burst (duration ~ a few ms) as the cause of the feature. We subdivided the 320 s of data used in Fig. 1*b* into two 160-s subintervals and established that each subinterval contributed approximately equal amounts to the feature. A duration somewhat greater than the ~5 min we report is also possible, as we did not observe the Crab during the ~4 h between the times when data for Figs 1*a* and *b* were taken. The feature was not evident ~20 min later, however, in a scan beginning at UT 73280 s.

We also established the pulsed fraction of the total Crab spectrum from our data, as a function of energy, by combining ~2 h of data taken between UT 54150 s and 78380 s on 21 June 1974 (assuming a photon number spectrum of $22E^{-2.29}$ photons cm^{-2} s^{-1} keV^{-1} for the total Crab flux[7]). Over such a long interval, the transient third peak washes out. Consequently, for this ~2-h interval, we report pulsed fractions only for the primary peak, the interpulse region, and the secondary peak (Table 2). The unpulsed portion of the light curve is comprised of the sum of 28 bins: 1–24 plus 82–85.

Table 2 Pulsed fractions in X-ray emission from Crab (nebula and pulsar) (21 June 1974, 2 h data taken between UT 54150 s and 78380 s)

Bins	Designation	% total flux over given energy range 20–28	28–35	35–47	47–64	64–80	80–115	115–146
25–45	Primary peak	4.5±0.8	5.6±0.9	5.5±0.6	5.6±0.5	6.8±0.6	5.9±0.8	6.7±1.7
46–65	Interpulse region	3.4±0.7	2.7±0.8	3.4±0.6	4.1±0.4	3.9±0.6	4.9±0.8	4.6±1.6
66–81	Secondary peak	5.9±0.7	7.0±0.8	6.0±0.5	6.6±0.4	6.9±0.6	9.0±0.7	7.2±1.4
Σ	Total pulsed	13.8±1.7	15.2±1.9	14.8±1.4	16.3±1.0	17.6±1.4	19.9±1.8	18.6±3.7

For the period of time during which the third peak was most evident (Fig. 1*b*), we calculated its contribution to the flux from the Crab by assigning only the sum of bins 1–4 plus 13–24 plus 82–85 to the 'unpulsed' portion of the light curve. We find that it comprised a fraction

$$f_t = 0.020 \pm 0.005$$

of the total Crab flux (35–115 keV).

The possibility of time variability in the NP0532 X-ray light curve was first suggested by Boldt *et al.*[1], based on a factor of 1.5–2 difference between their sounding rocket measurements of the pulsed fraction in 1968 (2–10 keV) and those of Bradt *et al.*[2] in 1969 (1.5–10 keV). Additional peaks in the NP0532 light curve at approximately the same location as the third peak in Figs 1*b* and *d* have been reported[3,12]. Large, infrequent variations on time scales of a few tenths of a second have been reported[4] in the 2–6 keV X-ray flux from the immediate vicinity of the Crab, based on *Uhuru* data. Helmken[6] has pointed out an apparent discontinuity in the light curve, obtained by subtracting the NP0532 optical light curve (normalised to the X-ray primary peak) from a composite X-ray light curve, at a point

~10 ms preceding the primary peak. He suggests a possible association with the third peak (Figs 1*b* and *d*) reported here.

For an assumed isotropic radiation pattern, the energy radiated in the third peak would be $\sim 4\times10^{37}$ ergs (at an assumed source distance of ~2 kpc) This is likely to be an overestimate, since the Earth probably lies near the plane of the pulsar rotational equator[9]. It is interesting to compare this number to the energy associated with pulsar spinups (and subsequent spindowns). For the September 1969 spinup, the fractional change in the pulsar rate has been given as $|\Delta\omega/\omega| \sim 3\text{–}9\times10^{-9}$ (refs 5, 8). Scargle and Pacini[11] argued that the accompanying total energy release from the pulsar magnetosphere was $\sim 10^{43}$ erg The associated rotational energy gain of the rotator would have been $\sim 10^{41}$ ergs If a similar scaling relationship were to apply for the transient third peak reported here, the resulting value for $|\Delta\omega/\omega|$ would be $\sim 10^{-14}$. Even if the pulsar spinup energy were comparable with the energy radiated as X rays, $|\Delta\omega/\omega|$ would still only be $\sim 10^{-12}$, far below the level of detectability.

In summary, the third peak is transient in nature; its duty cycle seems to be low ($\lesssim 10\%$). Further observations of this phenomenon will require extended measurements with detectors of even greater sensitivity than the ones we used.

Diffusion time scales and accretion in the Sun

SURFACE abundances in the Sun could have been essentially caused by accretion, either of comets or of grains[1–3]. It has been hypothesised that if surface convection zones could be smaller than is usually indicated by model calculations, then accretion could be especially important. Dust accretion by the Sun has also been suggested as the cause of ice ages on the earth[4]. Either the zone immediately below the surface convection zone is stable enough for diffusion to be important, however, or other transport processes (turbulence, meridional circulation) more efficient than diffusion, will tend to homogenise the star. Diffusion is the slowest of the transport processes and will become important when the other transport processes become inoperative. Using diffusion theory, we can determine the minimum mass of the convection zone, if transport processes at the bottom of the convection zone are not to influence the abundances in the convection zone. If diffusion time scales are shorter than the life of the star, diffusion will modify the abundances in the convection zone. The mass in the convection zone for which diffusion time scales are equal to the life of the star on the main sequence then determines the minimum mass in the convection zone to justify neglect of transport processes at the bottom of the convection zone. I determine here that, for the Sun, this mass is between 3×10^{-3} and $10^{-2}M_\odot$, and give a general expression for the diffusion time scale as a function of the mass of the convection zone.

Within the convection zone, the turbulent velocities are large enough to ensure homogeneous abundances[5]. The surface abundances are assumed to be the same as those in the convection zone. If the convection zone is considered to be mixed and emptied through its bottom then letting Y be the mass fraction, in the convection zone, of the element of interest

$$\frac{\mathrm{d}}{\mathrm{d}t}(Y\Delta M_c) = Yw_i\rho. \qquad (1)$$

ΔM_c is the mass of the convection zone in g cm^{-2}, w_i the diffusion velocity and ρ the density at the bottom of the convection zone (w_i negative towards the solar interior). Equation (1) integrates to give

$$Y = Y_0 \exp(-t/\theta) \qquad (2)$$

with

$$\theta = -\Delta M_c/\rho w_i \qquad (3)$$

Values of θ have been obtained[6] in seven models of main sequence stars of mass $1\text{–}2.6M_\odot$. In the Sun, most heavy elements will diffuse downwards, unless the mass in the convection zone is $< 10^{-6}M_\odot$. Gravitational settling dominates in solar type stars. Aller and Chapman[7] made similar calculations for the Sun, but neglected radiation pressure and used an incorrect thermal diffusion term (see ref. 8 for discussion). For helium in the Sun, one obtains, from equations (37), (8), and (10) of ref. 6

$$\theta = 3.6\times10^{5}\,\Delta M_c^{0.545}\ (\mathrm{yr}) \qquad (4)$$

or

$$\theta = 2.3\times10^{11}\,\Delta M^{0.545}\ (\mathrm{yr}) \qquad (4a)$$

In equation (4), ΔM_c is in g cm^{-2} and in equation (4a), ΔM is the total mass in the convection zone in solar mass units. For helium in the Sun, equation (4) is exact to within a few per cent. For $\Delta M = 3\times10^{-3}M_\odot$, $\theta \simeq 10^{10}$ yr, and $\theta \simeq 1.7\times10^{10}$ for $\Delta M = 10^{-2}M_\odot$. The diffusion time scales for manganese are, in the Sun, nearly equal to those of He (see Table IV of ref. 6), but those of Hg are approximately 40% smaller. For transport processes to have negligible effects on surface abundances in solar type stars, the mass in the convection zone must be at least 3×10^{-3} to $10^{-2}M_\odot$. In solar models with the mixing length equal to the pressure scale height, the mass in the convection zone is $2\times10^{-3}M_\odot$.

Use of equation (4) to estimate diffusion time scales for helium in main-sequence stars lighter than $2M_\odot$ is accurate to within a factor of 1.5, but leads to a factor of three overestimate in θ below the hydrogen convection zone of a $2.6M_\odot$ star.

Diffusion time scales in the Sun are very uncertain. The uncertainty arises from our poor knowledge of ΔM_c, that is from the hydrodynamics. Equation (4) is much better known than is ΔM_c. If we use this uncertainty on ΔM_c to increase the relative importance of the accreted mass, then if $\Delta M \leqslant 3\times10^{-3}M_\odot$, transport processes at the bottom of the convection zone must be taken into account, and the convection zone will lose the accreted matter, through its bottom. The calculations of ref. 3 suggest that $\Delta M \leqslant 5\times10^{-4}M_\odot$ for accretion to be important. For $\Delta M = 5\times10^{-4}M_\odot$, diffusion reduces Z, in the convection zone, from 0.02 to 0.01 A more generous estimate of the accreted mass is given by ref. 2, and for an upper limit of $5\times10^{-3}M_\odot$, diffusion would reduce Z by approximately a factor of 0.7. At the lower limit of ref. 3, ($\Delta M = 5\times10^{-5}M_\odot$), Z in the convection zone would be reduced from 0.02 to 0.002 or less. Transport processes at the bottom of the convection zone do not rule out completely the possibility that heavy elements in the convection zone, and so at the surface, were accreted by the Sun, but make it much less likely.

Planetary tides during the Maunder Sunspot Minimum

CONTROL of the 11-yr and longer cycles of solar activity tides raised on the Sun resulting from the gravitational pulls of the planets has often been suggested. Rudolf Wolf and R. C. Carrington were among the early astronomers who pointed out this possibility in the middle nineteenth century[1]. The close coincidence of the sidereal period of gravitationally important Jupiter (11.87 yr) with the mean period of the observed annual sunspot means (11.3 yr) raises the possibility of such a relationship; the range of possible configurations of the other planets allows a wide realm of other tidal periods and effects. In daily sunspot numbers, a small but consistent periodicity at the sidereal period of the planet Mercury has been found[2], and a possible 178.7-yr period in sunspots (about twice the Gleissberg cycle) has been linked with multi-planet tidal influences[3]. Wood and Wood[4] have applied a dynamical theory which includes all planets but Mars to reinforce their belief in a more than chance relationship. We reconstruct here Sun-centred planetary conjunctions and tidal potentials for the AD 1645–1715 period of sunspot absence (the Maunder Minimum). These are found to be effectively indistinguishable from patterns of conjunctions and power spectra of tidal potential in the modern era of a well-established 11-yr sunspot cycle. This places a new and difficult constraint on any tidal theory of sunspot formation.

The relative tide-raising forces of the planets are as follows: Mercury 0.91, Venus 2.15, Earth 1.0, Mars 0.03, Jupiter 2.26 and Saturn 0.11, with the three outer planets negligibly small. Problems arise in any direct gravitational theory because of the apparently insufficient forces and tidal heights that are involved: the tide-raising force of Jupiter on the solar photosphere is, for example, about 10^{12} times smaller than the force of solar gravity there, making planetary tides a miniscule force[1], even in the case of a rare, nine-planet conjunction. Thus proponents of the tidal hypothesis usually revert to trigger mechanisms, which is difficult to criticise or, apparently, to test by observation.

Any tidal theory rests on the evidence of continued sunspot periodicity, and the substantiation of a prolonged period of solar anomaly in the historical past[5,6] offers a possible *experimentum crucis* The Maunder Minimum was the most drastic change in the behaviour of solar activity in the last 300 yr, in that sunspots almost disappeared for a 70-yr period (1645–1715), and the 11-yr cycle was probably absent. During that time, however, the nine planets were all in their orbits, and planetary conjunctions and tidal potentials were indistinguishable from those of the modern era, in which the 11-yr cycle is well-established. This provides good evidence against the tidal theory

We have pressed the case further by reconstructing the pattern of planetary tidal forces during the Maunder Minimum to investigate the possibility that the multiple-planet forces somehow fortuitously cancelled at the time, that is, that the positions of the slower moving planets in the late seventeenth and early eighteenth centuries were such that conjunctions and tidal potentials were at the time reduced in number and force.

Historical planetary positions were determined using a computer code supplied by R. S. Harrington of the U.S. Naval Observatory and the mean elements of planetary orbits determined by Seidelmann *et al.*[7]. Only Mercury, Venus, Earth and Jupiter were considered in final analysis because the tidal forces generated by combinations with other planets are at least an order of magnitude less than these. A conjunction was defined as a Sun-centred alignment of planets within 0.15 rad, to assure that Mercury would remain in such an alignment for > 1 d.

Daily positions were calculated from J.E.D. 2296445 to 2451065 (about AD 1575–2000) and all two-, three-, and four-planet conjunctions noted. The results are shown in Fig. 1, with the history of the annual mean sunspot number. Binary conjunctions are omitted in the presentation. Higher order conjunctions exhibit subtle and beautiful symmetries and beat patterns, but there is no striking dissimilarity between the time of the Maunder Minimum and any other period shown.

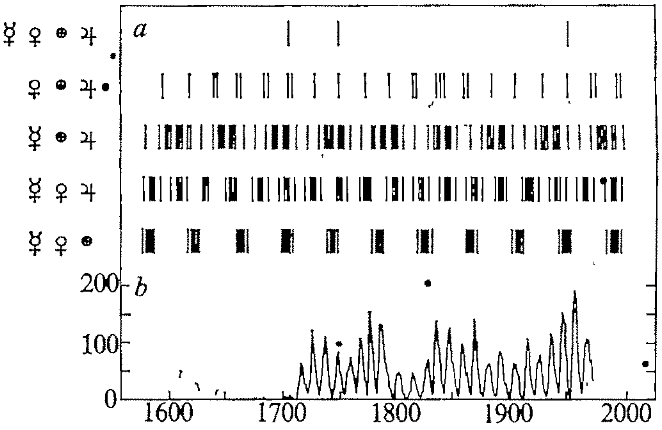

Fig. 1 *a*, Multiple planetary conjunctions (alignment within 0.15 rad) AD 1575–2000. *b*, Mean sunspot number[8].

The failure of planetary conjunction patterns to reflect the drastic drop in sunspots during the Maunder Minimum casts doubt on the tidal theory of solar activity. Yet this test is only a qualitative judgement of a pattern and not demonstrably conclusive. A more quantitative test comes from an examination of the tidal potentials, which are proportional to

$$P(\mathbf{x}) = \sum \frac{M_i}{R_i^3}\left(\cos^2\varphi_i - \frac{1}{3}\right) \qquad (1)$$

where M_i is the mass of planet i, R_i is its distance from the centre of the Sun, and φ_i the angle, seen from the centre of the Sun, between the planet and the point $\mathbf{x}$.

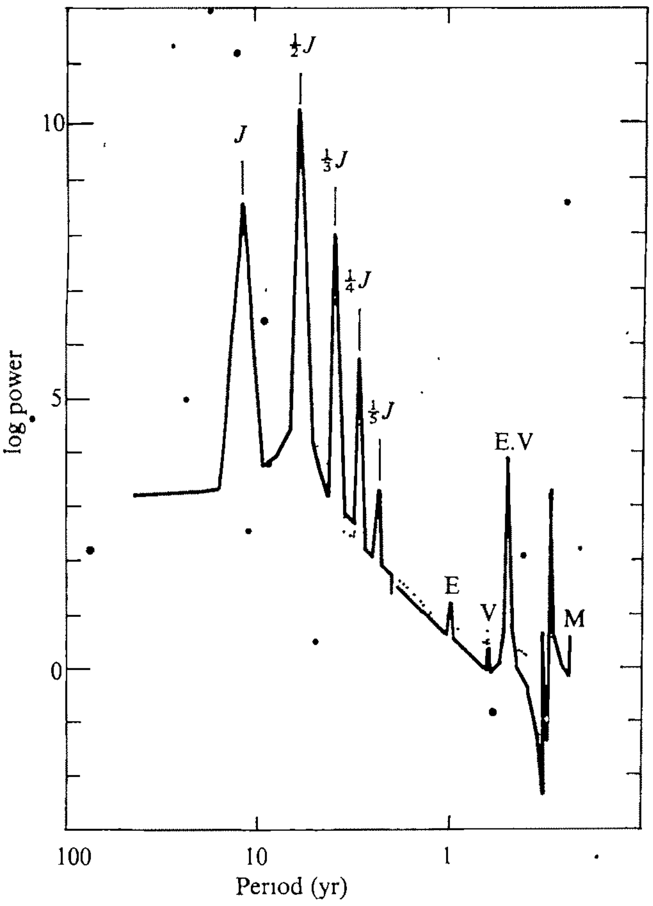

Fig. 2 Fifty-year power spectra of the tidal potential of planets on the rotating equator of the Sun (equation (1)), ———, AD 1925–1975; ....., which appears only where different from heavy line, AD 1650–1700. No differences appear in the major tidal peaks or in any other significant feature of the spectrum for these or any other epochs we examined. Major peaks correspond to fundamental and harmonic periods of the major tide-producing planets, identified by letter: J, Jupiter, E, Earth; V, Venus; M, Mercury.

We calculated a daily value of the tidal potential defined above at a point fixed on the rotating equator of the Sun, for AD 1450–2000. The period was then divided into sample intervals of about 50 yr, overlapped at 25-yr intervals, and the power spectrum of tidal potential calculated for each 50-yr sample using a fast Fourier transform. An example of the power spectrum of tidal potential is shown in Fig. 2. Principal peaks in the spectrum correspond to orbital periods of each planet and the harmonics thereof. (L. Auer has pointed out that each harmonic corresponds to the frequency of an epicycle in a Copernican decomposition of the orbit.) The usual means of dealing with the functional periodicity implied by Fourier techniques, such as tapering the end points to the mean, were inadequate in this case, since the longest periods of interest are a large fraction of the 50-yr sampling interval. This problem was avoided by adjusting the length of the sampling interval so that the potential function and its derivative were equal at the end points, hence the implied periodic function was continuous.

To compare the power spectra of tidal potential in different intervals we selected as a standard interval the modern period AD 1925–1975 (Fig. 2) and computed the ratio of the spectrum of this standard interval to all others from AD 1450 to 2000. We found that the power in each of the major peaks of tidal potential (notably the dominant first three harmonics of Jupiter) have not changed perceptibly in the last 500 yr. Also, there was no appreciable change in the power at any frequency during the years of the Maunder Minimum. In Fig. 2 we compare power spectra for the 1925–1975 period with that of the Maunder Minimum and find them effectively indistinguishable.

A few exploratory calculations showed possibly significant changes in the spectrum of tidal potentials over much longer periods (several millennia) which seem associated with known, secular changes in the orbital elements of the planets. For example, the eccentricity of Jupiter's orbit changes by about 0.1% per century[7]. There is no evidence, however, that these secular changes are associated with possible secular changes in solar activity.

Okal and Anderson[8] in examining the same problem computed a single power spectrum of the planetary tidal potential (or rather, its maximum value in longitude) for 10-d intervals from roughly AD 1800 to 3600. This sample, much longer than ours, defined the frequency of power peaks rather precisely. They found only one peak near that of the sunspot cycle, at the orbital period of Jupiter, 11.86 yr. They compared this with a power spectrum estimate on Wolf sunspot numbers[9] which showed peaks at 11.0 and 9.8 yr in this region, and reasoned that the discrepancy between 11.86 and 11.0 yr sufficed to rule out tides as a driving force for the solar cycle.

Peaks in the maximum entropy spectra derived by Cohen and Lintz[9] vary with the details of the input function: drastically in amplitude, and less in frequency. Their published examples suggest that the method of computation and data selected can shift the location of peaks near 11.0 yr period by at least ±0.1 yr, and amplitudes by a factor 3. This is consistent with the difficulties with spectral decomposition by the maximum entropy method[10,11]. Moreover, the period chosen by Cohen and Lintz includes all sunspot numbers from 1750 onward. Waldmeier[12] casts doubt on the quality of the early sunspot data as does Eddy[6], who points out that controlled observation of sunspots did not commence until about 1852. Thus, since the power peaks derived by Cohen and Lintz were based in part on questionable data, the significance of an apparent discrepancy between these sunspot power peaks and those of averaged tidal periods seems less than conclusive, and in need of the support presented here.

We thank Drs Robert S. Harrington, Raynor Duncombe and Robert Lackman for assistance, and Drs Larry Auer and Oran R. White for helpful discussions. The work of J.A.E. was supported wholly by NASA.

Order and disorder in weakly ionised plasmas

WE report the observation of novel radial structures for discharges in pure helium and argon gases in a magnetic field. The structure depends on the angle between the discharge tube axis and the magnetic field direction, a dependence which supports the idea, previously proposed, that gaseous plasma energised in specific conditions can have regions in which the electrons have an ordered spatial distribution.

The weakly ionised, high-frequency, electrodeless discharges were energised at powers between 500 W and 1 kW coupled to the discharge from an amplifier via a 143-cm long quarter-wavelength twin transmission line; this was connected to two copper bands, 14 cm apart, placed closely around the outside of the discharge tube. The discharge was maintained continuously between the bands and in a position centrally between a pair of Helmholtz coils in a horizontal, uniform magnetic field.

Optical flats sealed to each end of the hard glass tubes made it possible to view the discharges axially. The tubes were 70 cm long, and of internal radius 1.84 cm. A pattern of luminous and non-luminous plasma regions was observed, arranged in coaxial symmetry, the complexity of the pattern depending on the magnitude of **B**. At **B** = 0 (Fig. 1*a*) shows the simplest pattern for helium gas at 0.25 torr pressure. At **B** = 1,000 G, (Fig. 1*b*) besides the outer dark shell, a central non-luminous plasma was observed, the outer luminous region now being enclosed between the two dark regions. At **B** = 1750 G the inner dark region was larger in diameter, and a further plasma region, this time luminous and blue in colour was seen on the tube axis, inside and much shorter in length than the inner dark region (Fig. 1*c*).

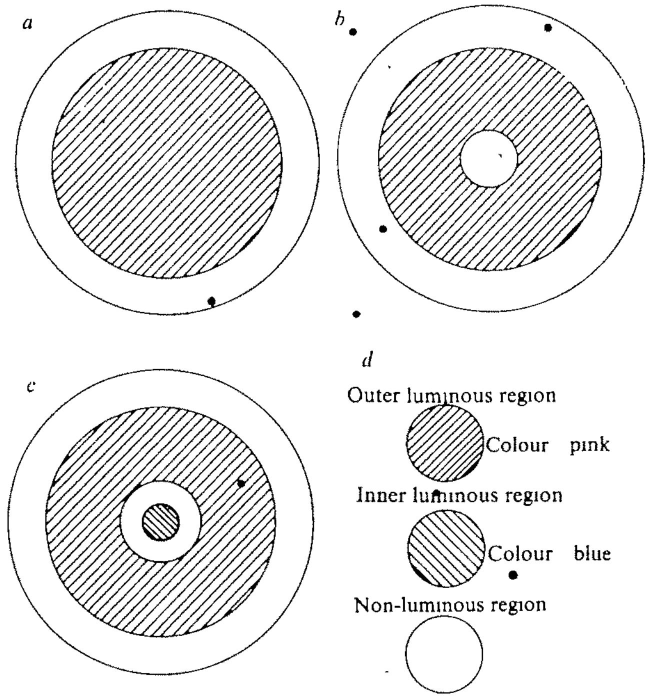

Fig. 1 Plasma regions: *a*, **B** = 0; *b*, **B** = 1,000 G; *c*, **B** = 1,750 G; *d*, spectral analysis of helium light and key to figures.

Figure 1*d* gives an analysis of the spectral emission from the outer visible region. The calculated electron temperature for this region is 85,000 K, and the measured average electron density for all regions was 7×10^{10} cm^{-3}.

Experiments in which the helium discharge tube was suspended from a spectrometer base and rotated in the horizontal plane showed that at given field strength, the diameters of the central regions were critically dependent on θ, the angle between the tube longitudinal axis and the direction of **B**; this is shown in Fig. 2*a*, in which the diameters are plotted against θ for **B** constant in magnitude (**B** = 1,750 G). Figure 2*b* shows how the diameters of both inner and outer regions vary with the field strength, keeping θ = 0. Given the results of Fig. 2*a*, it follows that there is a critical value for θ, θ_c, for which the central regions disappear or reappear as θ is increased or decreased, respectively, at fixed **B**. Figure 3 is a plot of θ_c against **B**.

In argon gas, for the range of field strengths of the experiment, the central regions differ from those for helium. In argon at 0.37 torr pressure, for example, no luminous central region is observed, and the dark central region is just beginning to appear at **B** = 1,650 G.

The central plasma structure (Fig. 1 *b* and *c*) and its dependence on θ, (Fig. 2*a*), are significant evidence for the presence of order in the non-luminous regions. These regions are believed to be occupied by oscillating electrons which have very little energy and are therefore not capable of exciting gas atoms, so that the regions are non-luminous. The basic theory of the interaction between low energy electrons and large numbers of gas atoms and molecules in which they are immersed, was given by Fermi[1]. According to his analysis, in which the electrons are treated as electron waves, stationary states form under certain conditions. For the present purpose we assume that the oscillators are formed from pairs of electrons, or aggregates of pairs of electrons, and the requisite conditions for stationary states relate the electron number density, *n*, the neutral atom

number density, N, and atomic constants[2]. When $\mathbf{B} = 0$ at low pressures the conditions occur near the tube walls, where n is smaller than on the tube axis; when **B** is raised to > 1000 G, however, the magnetic energy of the oscillators becomes significant and the conditions for stationary states are changed. In helium, the conditions are found not only near the tube walls but also at higher electron densities on the tube axis where the energies of oscillations are higher. A non-luminous region then appears on the tube axis. In argon, on the other hand, the potential energy of the interaction of the oscillating electrons and the gas atoms is negative rather than positive as in helium[1], a difference between the gases which results in the differences in the variation of the outer dark shell radius with **B** (Fig. 2*b*), and in the central structure. These are the lines on which an interpretation of the phenomena is believed to be possible.

Both the relatively sharp boundaries between the luminous and non-luminous regions, and the dependence of the central structure on θ are considered to show that the oscillators form a close-packed matrix, capable of reflecting fast-moving free electrons from the luminous regions, and of having anisotropic properties typical usually of crystalline substances.

The idea that ordered plasmas are sometimes formed in weakly ionised gases was prompted, not by the present visual studies, but from a prolonged study[3] of the properties of rare gas afterglow plasmas. From these studies we inferred a division of the afterglow plasma into two regions for $\mathbf{B} = 0$; at the start of electron density decay, we deduced that the junction of the two regions should be near the point on the tube radius where n has fallen to one half of its value on the axis. Assuming a simple Bessel function variation of n with radial position, this prediction from the afterglow work is that the junction between the two outer regions should occur near a diameter of 2 29, cm (in good agreement with Fig. 2*b* for $\theta = 0$).

Other measurements can be interpreted successfully using the model; for example, the measurement of forces of weak elastic constraint acting on plasma electrons[4], the very fast plasma decay rates observed at $\mathbf{B} = 0$, the anisotropic properties of afterglows in a magnetic field[5], and the resonances attributable to electron spin-flip in a magnetic field, can all be interpreted in terms of the ordered electron model. The anisotropic properties of afterglow plasmas are good evidence of correlation between the afterglow phenomena and the currently studied continuously excited plasmas. An examination of the value for θ required for the transition from slow to fast afterglow decay rates in helium at 0.25 torr pressure as a function of **B** reveals that when θ is just large enough for the fast decay rate to occur, the central dark plasma region in the excited plasma preceding the afterglow is just disappearing (Figs 2*a* and 3).

It is interesting to consider an extension of the idea of spatially ordered electron oscillators to some naturally occurring plasmas. Such an extension needs a change of emphasis in the theory, away from electrons as particles translating with random motion in the space between the other plasma particles, to electrons as waves occupying and propagating through the space containing the ionic, atomic and molecular fields.

We thank Dr M. Outred for advice on spectral analysis of helium light and its implications to the model.

Metal accumulation rates in sediments from Mid-Indian Ocean Ridge and Marie Celeste Fracture Zone

THE existence of metalliferous sediments on mid-ocean ridges is well documented[1] and the general conclusion is that they form by precipitation from submarine hydrothermal solutions. Pacific and Atlantic Ocean sediments have been studied in detail[2–6]. We describe here material from the Indian Ocean Ridge, collected during cruise 8/75 of RRS Shackleton, and compare metal accumulation rate data for ridge-crest and -flank sediments with those from other regions. The metalliferous sediments are present on the Mid-Indian Ocean Ridge, particularly near the Triple Junction[7,8], and Bostrom and Fisher[7] suggest that "there is a complete belt of iron-rich sediment along the entire length of the Indian Ocean–Pacific Ocean active-ridge system". We have found ferromanganese encrustations on basalts from the median-valley wall and have recognised what are probably sulphides in decorated vesicles of basalts. The metal accumulation rate data argue against a hydrothermal source of metals in the ridge sediments, however, and suggest that metalliferous sediment accumulations in the Indian Ocean may be more local phenomena than previously realised.

Sample locations and bathymetry of the study area are shown in Fig. 1. The Marie Celeste Fracture Zone is sharply defined by topography, seismicity and magnetics[9] and is one of the larger fracture zones offsetting the Mid-Indian Ocean Ridge. The half-spreading rate of the ridge is ~ 1.8 cm yr^{-1} and the

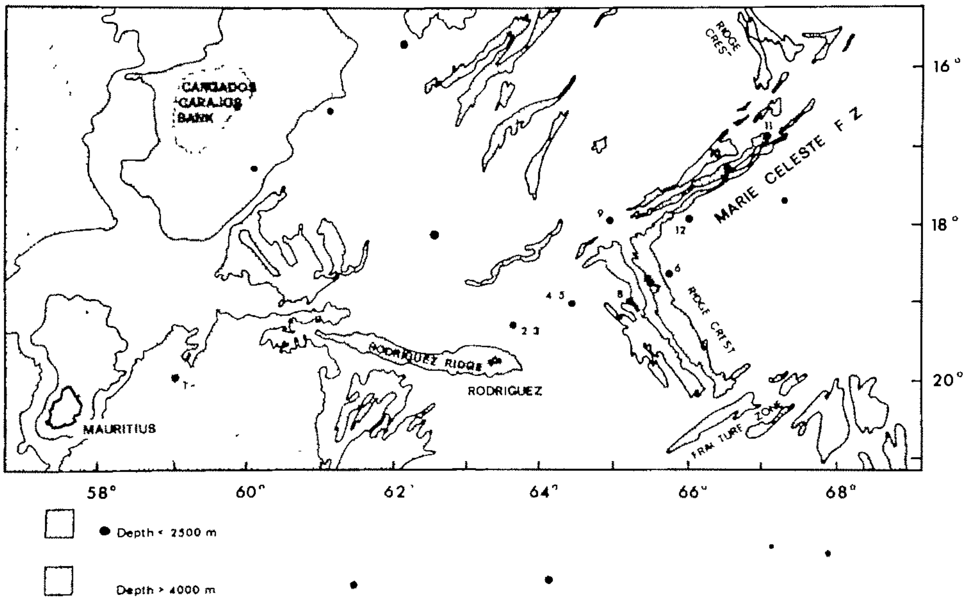

Fig. 1 Core location map showing bathymetry in region of Marie Celeste Fracture Zone. ●, Cores; ■, manganese crust.

ridge offset is 220 km (ref. 9). The maximum depth of the fracture zone is reported as 5836 m (ref. 10). The region shown in Fig. 1 seems to be a likely location for hydrothermal solutions and associated metal-rich sediments[5].

The sediment type ranges from siliceous lutite of low to moderate carbonate content, to calcareous lutite (~ 90% $CaCO_3$) in relation to the depth of deposition. Physical parameters (texture, colour, etc.) are very similar between and within the carbonate cores, suggesting that the three cores studies in detail are representative of the remainder. One core collected from the fracture-zone floor consists of siliceous lutite overlain by 110 cm of red clay. Chemical and microscopic comparisons with the carbonate sediments suggests that the fracture-zone core represents a condensed sequence deposited below the carbonate lysocline.

*From the fracture-zone floor. SO_4, Cl not determined.

There is no significant change in major-element chemistry with depth, except as a consequence of a 3–5-cm glass horizon which occurs between 37 and 62 cm in individual cores, and the compositions listed in Table 1 are typical of these sediments. The volcanic glass is acidic (refractive index ~ 1.50) and fine grained, and probably derives from Indonesia (G. Walker, personal communication, 1976). Also present are basalt fragments containing decorated vesicles of a type already reported[11–13]. Figure 2 shows a scanning-electron micrograph of a vesicle revealed by the fracture of a basalt fragment during sample preparation. Such decorations have been interpreted as sulphides[11–13] and their occurrence in the sediment is supported by evidence of sulphide mineralisation in Indian Ocean ridge basalts[14].

Mean sedimentation rate was obtained by radiocarbon dating of a section of core 12 at 18–20 cm which gave an age of approximately 20,000 yr. The rate of ~ 1 cm 10^{-3} yr^{-1} was confirmed by oxygen isotope stratigraphy (N. Shackleton, personal communication, 1976) and is in agreement with other estimates and measurements for this region [10,15,16] and with world averages for carbonate sedimentation[17]. Metal accumulation rates (Table 2) were calculated by age correlation using the acidic glass horizon. Comparison with accumulation rates in normal pelagic sediments and in hydrothermal sediments from the East Pacific Rise shows that metals are accumulating at these locations on the Mid-Indian Ridge at rates commen-

Fig. 2 Decorated vesicles in a basalt fragment from a carbonate core. The wall decorations are probably sulphides.

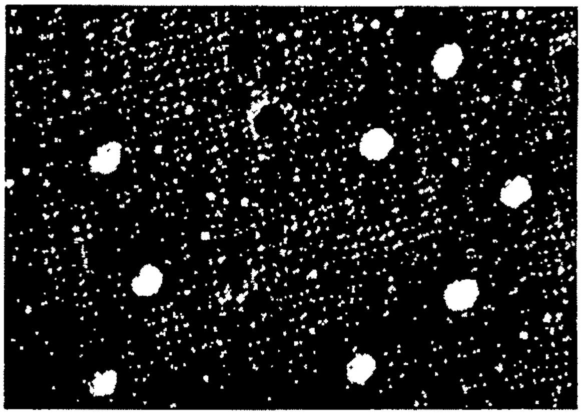

Table 2 Element accumulation rates (mg cm^{-2} 10^{-3} yr^{-1}) in Indian Ocean, normal pelagic, and East Pacific Rise sediments

	Indian Ocean Marie Celeste Fracture Zone	Ref. 23	Pelagic sediments Ref. 18	Ref. 24	East Pacific Rise sediments Ref. 1	Ref. 3
Ti	0.08–0.2	0.2–0.9	—	0.4	0.074	—
Al	1.5 –2.6	4–18	—	6	0.72	—
Si	4.2 –9.6	—	—	17	—	55
Fe	2.4 –5.2	3–9	—	4	63	110
Mn	0.4 –0.7	0.3–1.0	0.2–3.2	4	24	35

surate with the lower rates of pelagic sedimentation. Hence, no unusual processes are responsible for metal deposition in these sediments. The deposition rate for manganese (0.4–0.7 mg cm^{-2} 10^{-3} yr^{-1}) is similar to that in nodules (0.2–1.0 mg cm^{-2} 10^{-3} yr^{-1}) (ref. 18). A slow, uniform precipitation of Mn over the sea floor has been inferred from the similar rates of Mn accumulation in nodules and sediments from all oceans[18] and suggests that the metals accumulating on the Mid-Indian Ridge are authigenic in origin. The ratio Al/Al+Fe+Mn for these sediments (0.24–0.35) is, however, within the range used to classify Mid-Indian Ridge sediments as metal rich and of volcanogenic origin[1,7,8]. The sediments we examined are not of volcanogenic origin although they conform to this classification. It is clear that metal–aluminium ratios do not necessarily indicate regions of metalliferous sediment deposition and must be used with caution in this respect.

Despite the extensive nature of hydrothermal deposits on the East Pacific Rise many metal-rich deposits are of a very localised nature[2,5,6,19–21]. Our results do not disprove the existence of metal-rich exhalations and deposits within the area studied, but suggest that such deposits on the Mid-Indian Ridge are probably local and certainly less widespread than sometimes supposed. We made many attempts to sample sediment from within and on the flanks of the median valley in the hope of detecting hydrothermal material. No sediment was recovered, however, but, instead, the corer sampled a fragmented ~ 15 mm thick ferromanganese encrustration on basalt.

The encrustation contains 20.0% Fe, 12.5% Mn, 0.11% Cu, 0.081% Co, 0.14% Ni and 0.060% Zn. For manganese to be accumulating at a rate $\gg$ 1 mg cm^{-2} 10^{-3} yr^{-1} the oceanic crust at this point must be $\ll$ 120,000 yr old. As the encrustation was recovered from the median valley wall this is possible and it is just conceivable that this material may contain a component of local hydrothermal origin. Its overall composition, however, is unlike that of hydrothermal manganese crusts from the Mid-Atlantic Ridge median valley[6], The Galapagos Spreading axis[2] or the Romanche Trench[5], and is very similar to S.W. Indian Ocean nodules[22]. In the absence of other evidence, therefore, it must be regarded as a hydrogeneous deposit.

We thank A. Gray, D. Ninkovich, N Shackleton and G. Walker for their help, and the crew of RRS Shackleton for assistance with sampling operations. The research was supported by grant GR3/2180 from the NERC.

Estimation of gas-releasing efficiency of erupting magma from ^{226}Ra–^{222}Rn disequilibrium

VOLATILE components of volcanic magma have an important role in its explosive eruption[1]. The volatiles may be partially released from the erupting magma into the air, during eruptive events, and the ratio of the released to the original amount may be a possible determinant of the mode of explosive eruption. Direct measurements of these quantities, however, are extremely difficult; fresh ejecta are rarely obtained. The Sakurajima Volcano, Kyushu, Japan, erupted explosively on 30 October 1975, and discharged pumices and ash-like materials, some of which were later accessible. We report here a change in the measured radioactivity of pumice, possibly due to radon release.

Both types of ejecta were collected immediately after the eruption by the staff of the Sakurajima Volcano Observatory, Kyoto University. Within 48 h these samples were subjected to non-destructive γ-ray spectrometry, using a Ge(Li) semiconductor detector, at the Radioisotope Centre, University of Tokyo, to determine their contents of natural short-lived radionuclides (Table 1).

Gamma-ray spectrometric data so far obtained for some of the products from major eruptive episodes of the Sakurajima show no significant change in the U- to Th-series ratio of magma for the last few hundreds of years (Sato and Sato, in preparation). These data are included in Table 1 for comparison. Compared with the 'ash' sample and historical lavas, the 1975 pumice sample showed a marked deficiency in ^{214}Bi. A measurement performed on the same sample 1 month later showed that the specific activity of ^{214}Bi increased to a value similar to those for other materials listed in Table 1; the ascendant short-lived nuclides in the U-series which had been depleted through the eruptive event could have increased during the period. This observation agrees with the differing origins of the two types of ejecta: the pumice represents fragments of the erupting magma whereas the ash-like material could be composed of fragments of rocks pre-existing around the crater.

The significant degree of vesiculation of the pumices shows that a substantial amount of gases was discharged. The gaseous radioelement, radon, may have been expelled at this stage of eruption. One of radon's isotopes, ^{222}Rn (half life: 3.8 d), requires about 1 month to increase to an

Table 1 Th- and U-series radioactivity in some products of Sakurajima Volcano (10^{-13} Ci g^{-1})

Sample	Th-series (from ^{228}Ac and ^{208}Tl)	U-series (from ^{214}Bi)	U-series / Th-series
Pumice, 30 October 1975; andesite*	6.7±0.8	1.84±0.61	0.28±0.09
'Ash', 30 October 1975; andesite*	5.7±0.2	3.8±0.2	0.67±0.04
Lava, 1914; andesite	5.7±0.2	4.4±0.3	0.77±0.06
Lava, 1776; andesite	8.5±0.7	5.6±0.5	0.66±0.08
Pumice, Moeshima; dacite	5.7±0.2	3.8±0.2	0.67±0.04

*Measurements were made within a few days of their fall.

amount in equilibrium with the parent, ^{226}Ra, and is expected to show its transient deficiency for several days after the event. This could explain the lowering of the U- to Th-series ratio observed for the pumice (Table 1). The ratio is, therefore, regarded as being indicative of the ^{226}Ra–^{222}Rn disequilibrium.

In subsequent eruptive activities (a detailed account will be published later), the volcano ejected, on 13 May 1976, a considerable amount of pumice. Figure 1 shows U- to Th-series radioactivity ratios for this material, and shows that the U- to Th-series ratio of the 1976 pumice was again significantly lowered for several days after the eruption, then increased to a value close to those of earlier lavas (Table 1).

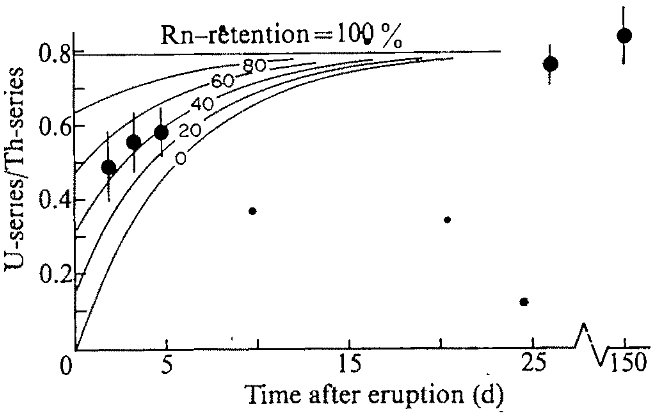

Fig. 1 Growth of U- to Th-series radioactivity ratio observed for the 1976 pumice from Sakurajima. Growth curves are based on the assumption that a ^{226}Ra–^{222}Rn equilibrium was established in the magma before the eruption. The values are plotted against the mid-points of counting times.

The disequilibrium observed above may also be due to radon release at the moment of eruption. If a ^{226}Ra–^{222}Rn equilibrium is assumed to have been established in the magma before the eruption, the growth of ^{222}Rn in the pumice should indicate its re-establishment. The data are expected to fit a growth curve derived from two parameters: (1) the observed U- to Th-series activity ratio of pumice at the equilibrium and (2) the percentage of unreleased radon in the erupting magma. In Fig. 1 are shown the growth curves for postulated values of (2), and, on this basis, the data correspond to a 50–60% release of radon.

The behaviour of radon in an erupting magma may be different from that of major volatiles. It would be possible, however, to characterise explosive eruptions by extending the method presented here to other fresh pyroclastic materials.

We thank K. Kamo, Disaster Prevention Research Institute, Kyoto University for the samples, and M. Takeda, Department of Chemistry, University of Tokyo for helpful discussions.

Effects of inbreeding on cognitive performance

THE few studies[1,2] in which the effects of inbreeding on cognitive performance have been examined revealed that offspring of first-cousin marriages had lower IQ scores than offspring of unrelated parents. These studies were, however, performed in societies where the population engaging in such marriages is a small (1%, 6%)[2,3] and unrepresentative proportion of the total population. Possible confounding of the effects of inbreeding with the effects of other intelligence-related variables such as socioeconomic status may lead the effects of inbreeding to be overestimated[2] Unfortunately statistical control may either over- or undercorrect for the correlates of the independent variables, leaving one in doubt about the true effect of inbreeding. I have now examined the effects of inbreeding on cognitive performance in an Arab population with a high rate of consanguinous marriage which minimised the distortions due to non-genetic variables. I show here that offspring of unrelated parents performed better than offspring of first-cousin marriages in intelligence and achievement tests administered at grades 4 and 6 The lowest level of performance and a higher variance were found for offspring of double-cousin marriages The inbreeding depression found in this study is consistent and cannot be explained by the effects of socioeconomic status. I drew a nationally representative sample of 3,203 children in grades four and six (approximate ages 10 and 12 yr) of the Arab educational system in Israel This sample constitutes about 10% of the total population in these grades and includes only normal (not retarded) children. Column 1 in Table 1 shows the division of the subjects according to grade level and consanguinity of the parents. A first-cousin marriage is between children of siblings. Children of first cousins have, on average, 1/16 pairs of genes by common descent. Double first cousins are children of siblings married to unrelated siblings. When they marry, their children have, on the average, 2/16 pairs of genes by common descent.

A study of Arab education in Israel revealed that the frequency of consanguinous marriages in the Arab population is about 34%. The Arab community encourages such marriages and therefore the group that intermarries should be a representative sample of the population Double first-cousin marriages are hardly known in Western Society but exist to a significant degree (about 4%) in my sample population. Their popularity is no doubt partly explained by economic considerations concerning the custom of 'bride price' When a brother and sister of one family marry a brother and sister of another, there is no need for the groom to pay the bridal price.

It is reasonable to assume that other consanguineous marriages—between, for example, second and third cousins —exist in our sample. However, only three alternatives were given to the question on blood relationships (unrelated, cousins and double cousins) and, consequently other consanguineous marriages were probably classified by the respondents as one of the two latter categories, especially first cousin marriages. This would tend to make the real inbreeding coefficients somewhat lower than the above coefficients (1/8, 1/16). We can also assume that, since prolonged inbreeding increases the coefficient of inbreeding[5], the inbreeding coefficient of the control group is not zero. But prolonged inbreeding has also occurred for the inbred groups, so it is safe to assume that there exists an increasing order of the degree of inbreeding, from the control group (of outbred children) to the first cousins' offspring and to the double cousins' offspring.

Table 1 Consanguinity and socioeconomic status of subjects

	Number of subjects	Father's education (mean yr)	Mean SES†
Grade 4			
First cousins	503	5.6	9.7
Double first cousins	71	5.1	9.1
Others (unrelated)*	1,054	5.2	9.4
Total sample	1,628	5.3	9.5
Grade 6			
First cousins	467	5.4	9.5
Double first cousins	54	5.0	9.1
Others (unrelated)*	1,054	5.0	9.4
Total sample	1,575	5.1	9.4

*In a population with a high rate of consanguinous marriages the so-called 'unrelated' group probably does not have a zero inbreeding coefficient (see text).

†Socioeconomic status.

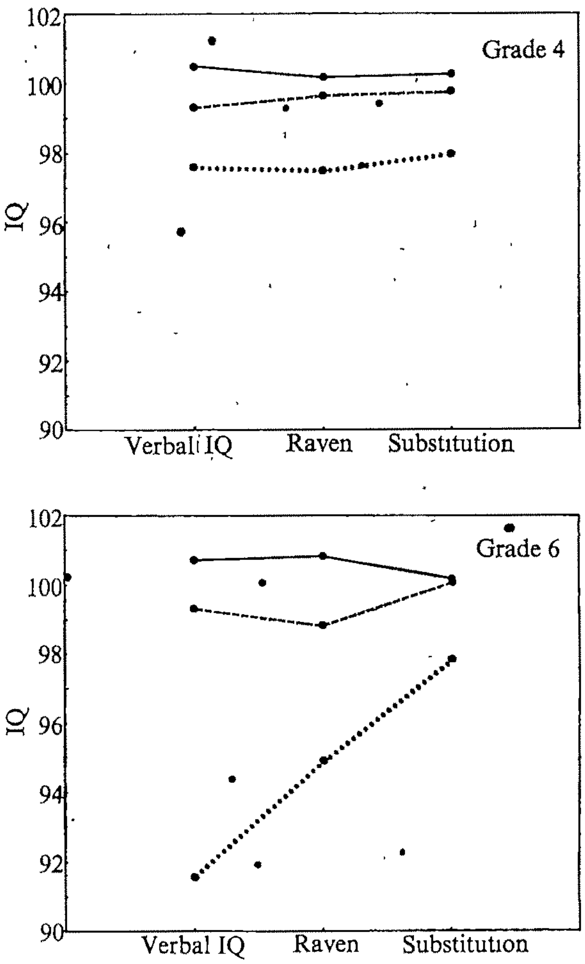

Fig. 1 Mean IQ scores on the three mental ability tests to parental consanguinity, for grades 4 and 6. ——Not related, - - - cousins, ... double cousins.

Socio-economic status (SES) of the groups was defined as an index of the following four components. (1) father's plus mother's level of education; (2) father's profession; (3) room density, and (4) physical home conditions. Each of the four components was divided into four graded categories. SES was defined as the sum of these four components, thus ranging from four to sixteen, with each of the four components being of equal weight. Table 1 shows that unrelated parents have somewhat lower SES than the first cousins. The double first cousins have lower SES than the unrelated group but the difference is less than 0.1 s.d. As the very small differences in SES favour the first cousins as compared with the other two groups, any reduction in performance found in the inbred groups cannot be explained by differences in SES.

Three mental ability tests and four achievement tests were used. As the genetic component is assumed to be larger in informal learning (ability tests) than in specific knowledge formally taught in the classroom (achievement tests) I expected inbreeding to have a smaller effect on performance in achievement tests than in ability tests. The mental ability tests included (1)*a*, a verbal general knowledge and comprehension test and *b*, a verbal test to find the 'odd one out'. Both tests were equally weighted to construct a single verbal IQ score (Alpha reliability coefficient is 0.93, correlations averaging 0.70 with achievement tests and teacher's evaluation) (2) A shortened version of Raven's Progressive Matrices[6] was used to measure nonverbal ability (3) A substitution test that, unlike the other two, was given under a strict time limit and was used to measure associative learning. The four achievement tests were constructed in accordance with the specific school curricula of each grade (Arabic, Hebrew, mathematics and science). The alpha reliability coefficients range from 0.80 to 0.91 and the correlations between the four tests average about 0.70. All tests were administered to groups of children and given simultaneously in all the sample classes.

Table 2 presents the mean scores and standard deviations for the mental ability and achievement tests, according to grade and parental consanguinity. Figure 1 shows the IQ scores on the three mental ability tests for the different consanguinity groups, separately for each grade. Figure 2 shows the *t* scores of achievement tests (with a mean of 50 and s d. of 10 for each test).

All the results follow the expected pattern and the order of performance level of the three groups is consistent. Outbred children achieved the highest level of performance and offspring of double cousin marriages achieved the lowest. Thus, an inbreeding depression is suggested in both grades and in all the tests.

The results in Table 2 show a tendency towards higher variance in the double cousin group. This is the case in 13 out of the 16 possible comparisons; the result is statistically significant in five of the comparisons, all of which are in grade 6 (general knowledge, finding the odd one out, Arabic, Hebrew and science).

The inbreeding depression shown in Table 2 and Figs 1 and 2 is too modest to warrant changes in educational policy, but the consistency of the effect for the different tests in both grades strengthens the argument that its cause is indeed genetic. Surprisingly, there was no difference between performance in achievement and ability tests: inbreeding

	First cousins	37.6	8.2	15.8	6.1	12.3	6.2	70.4	27.0	37.4	10.7	30.4	10.3	18.3	8.5	17.3	5.7
	Double first cousins	33.0	12.0	13.0	7.3	10.6	6.7	65.8	27.0	32.0	13.2	27.7	12.4	16.9	10.0	15.2	7.1

*Number of items in the test

†The left-hand numbers represent the number of items in the test for grade 4 and the right-hand numbers, number of items for grade 6.

depression seems clear and consistent in both. It is interesting that the effect is smaller for the mathematics and substitution tests, though the three groups fall into the same order here as for the other tests.

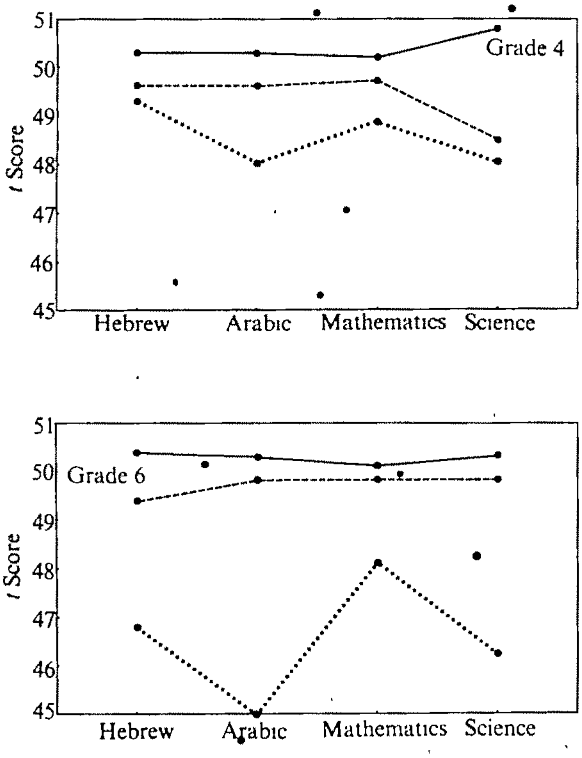

Fig. 2 Standardised means (t scores) of achievement tests according to parental consanguinity for grades 4 and 6 ——, Not related; – – –, cousins, ..., double cousins,

The inbreeding depression clearly demonstrates the importance of a genetic component in the variance of cognitive performance in this population This could result either from the general increase in homozygosity that results from inbreeding or from decrease in performance resulting from homozygosity for specific recessive alleles[7,8]. The higher variance of the double cousin group in some of the tests favours the second interpretation.

The significance of the nose for certain phenomena of visual perception

BOWER[1] draws attention to the fact that the majority of organisms have evolved in such a way that part of the body (almost invariably the nose) is permanently present in the visual field. This, as he points out, can hardly be accidental and indicates that the organ may have a function in visual perception; subjects lacking a nose may differ from normals on tests of visual capacity. Unfortunately this clinical condition is now rarely encountered and affected individuals may, in any case, develop compensatory techniques, for example, reliance on glimpses of some other part of the body. It may be more profitable to consider the effects of making the nose visible where this is not normally the case. The autokinetic phenomenon may, for example, be a consequence of the fact that in total darkness the nose is invisible and cannot play its customary role as a stable point of reference by which other objects in the visual field are judged stationary or in motion with respect to the observer. What would be the effect of making the nose visible? I report here two experiments in which the nose was visible in an otherwise dark visual field. Contrary to Bower, autokinetic movement seems to have persisted.

The autokinetic phenomenon occurs when a subject fixates a point source of light in an otherwise dark field. The light characteristically appears to move, though it is in fact stationary throughout. Recent experimental work has vastly increased our understanding of the parameters governing the extent of this phenomenon, but none of the proposed explanations has survived experimental test. Bower's proposal implicating the nose is prima facie appealing but has not been confirmed empirically. What is required is a means of making the nose visible to the subject in an otherwise dark visual field since movement should not then be reported. Two alternative methods suggest themselves. The subject may wear a luminous false nose, or small electric light bulbs may be inserted in his nostrils illuminating the nose from within Each method has disadvantages. The luminous false nose has a pale greenish-white appearance and does not correspond in size and conformation to the subject's own nose (being usually somewhat larger). The inserted light bulbs involve a degree of physical discomfort but the organ visible is the subject's own, even though translucent pink in colour. Both methods were used in the two experiments to be reported. The luminous false nose condition presented no special problems of method but in the inserted light bulb condition it was found that because the conformation of the nostril and the thickness of the nasal membrane differ from subject to subject, a greater or lesser area around the nose was sometimes illuminated To ensure that no additional visual cues were available, the subject was enveloped from the neck down in a voluminous cloth of black, non-reflective material similar (except in colour) to those used by hairdressers.

In Experiment 1 each subject spent three 2-min periods in total darkness fixating the point source and reported the onset and offset of apparent movement if any occurred. Ear-muffs were worn to avoid interference from irrelevant auditory stimuli The subject was allowed 5 min to adapt to the darkness before beginning his first observation period and rested for 3 min in dim illumination between periods

Each subject did one period wearing a luminous false nose, one with light bulbs inserted in his nostrils and one control period. A standard moulded rubber artificial nose was used, coated with non-toxic luminous paint The nostril illuminator consisted of a pair of 6-V, 0.36-W L.E.S bulbs partially embedded in plastic. These were disinfected between subjects using 5% cetrimide solution. Twelve subjects were tested (all female, average age 18.56 yr). In order to equalise the effects of practice and fatigue the three experimental conditions were presented to two subjects in each of the six possible orders of presentation

The results obtained are shown in Table 1. Three subjects did not report movement in any condition, results are therefore tabulated for nine subjects only

Table 1 Incidence of autokinetic movement in Experiment 1

	Illuminated nostril	Control	Luminous nose
Time of onset (s)	38.22	47.44	28.11
Duration (s)	41.67	38.44	55.78

There is no significant difference between the illuminated nostril condition and the control condition, either in time of first onset measured from the beginning of the period ($t=0.25$, not significant), or in duration—that is, total time during which the point of light was in (apparent) motion ($t=0.28$, n s.) The luminous false nose condition seems to have enhanced the effect (onset, $t=1.65$, n.s., duration, $t=2.32$, $P<0.05$).

It might be argued that the control condition in Experiment 1 was inadequate, since although the subject was unable to see his nose he was also free of the physical sensations and possible discomfort associated with the experimental conditions (particularly the illuminated nostril condition). In a second experiment each experimental condition was compared directly with a control condition in which the subject wore an ordinary (non-luminous) false nose or in which light bulbs were inserted in the nostrils but were not illuminated. Twenty-four subjects were tested in all four conditions (12 male, 12 female, average age 18.67 yr) The four experimental conditions were presented once each in the 24 possible orders of presentation. Procedure was otherwise as in Experiment 1.

The results obtained are shown in Table 2. No effects of sex were observed All subjects reported movement in at least two conditions

Table 2 Incidence of autokinetic movement in Experiment 2

	Illuminated nostril	Non-illuminated nostril	Luminous nose	Non-luminous nose
Time of onset (s)	41.33	27.37	25.71	24.58
Duration (s)	49.50	61.50	59.00	61.92

The luminous false nose condition did not affect the phenomenon, but the illuminated nostril condition seems to have been associated both with later onset and with shorter duration of apparent movement. Unfortunately, these differences (which would have supported Bower's hypothesis) fail to reach significance by the t test (onset, $t=1.71$, n.s.; duration, $t=1.53$, n.s.).

It may be that the techniques employed were not sufficiently refined. (We experienced some difficulty in persuading subjects unfamiliar with the requirements of strict experimental method to sit in total darkness, wearing ear-muffs, with electric light bulbs inserted in their nostrils —particularly when the bulbs were not actually illuminated). But the project is at an early stage. The results so far obtained while not positively refuting Bower's hypothesis, cannot be said to support it.

Sampling theory for alleles in a random environment

A MAJOR effort in theoretical population genetics has been aimed at developing statistical tests to distinguish between various explanations of observed patterns of enzyme variation[1]. Perhaps the most useful result to emerge from this effort is Ewens' sampling theory of neutral alleles[2]. This theory allows one to use the number and configuration of alleles in a sample to test for departures from neutrality. Watterson[3] has derived the analogous sampling distribution for a finite population subject to the joint effects of mutation and symmetric heterotic selection. It differs from the neutral sampling theory, providing a stronger hypothesis-testing situation than has previously been available. In this note I present a third sampling distribution. It applies to an infinite population in which the selective coefficients fluctuate at random through time and space. Quite unexpectedly, the sampling distribution turns out to be identical to that for the neutral model, indicating that agreement of data with Ewens' sampling distribution does not rule out the possibility that natural selection is responsible for the genetic variation in the sample. Furthermore, the properties of random-selection populations at equilibrium are indistinguishable from neutral-allele populations for observations made at a single time point. This result calls into question the claim that agreement of data with predictions of the neutral model argues against natural selection as an important factor for the maintenance of genetic variation.

Work on biologically-motivated models for natural selection in a random environment has shown that, under a wide variety of assumptions, two allele models yield diffusion processes with drift and diffusion coefficients of the form

$$\mu(x) = x(1-x)\,[a+b(1/2-x)] \qquad (1)$$
$$\sigma^2(x) = x^2(1-x)^2$$

For symmetric models, which will be the only ones considered here, $a = 0$, and

$$\mu(x) = bx(1-x)(1/2-x) \qquad (2)$$
$$\sigma^2(x) = x^2(1-x)^2$$

For example, for a diploid species with additive alleles in a subdivided environment

$$b = 2/[1-\pi(1-k)] \qquad (3)$$

where π is a measure of the patch structure and k is a measure of the correlation between patches[4]. Biological considerations suggest that $b \geq 2$, with larger b values associated with greater environmental heterogeneity. As another example, if the environments are autocorrelated, we can still obtain a diffusion process for the additive, diploid case, with

$$b = \frac{2}{1+\lambda} \qquad (4)$$

where λ is a measure of the autocorrelation of the encironment[5]. In this instance $1 < b < \infty$, with smaller values of b associated with more positively autocorrelated environments. Other models incorporating dominance and various population structures also give models of the same form as (2), with, in general, $1 < b < \infty$ (ref. 6). The asymptotic density for (2) is a β distribution

$$\Phi_2(x) = \frac{\Gamma(2b-2)}{\Gamma(b-1)^2}[x(1-x)]^{b-2} \qquad (5)$$

which always exists since $b > 1$. Two neutral alleles with equal mutation rates also yield a beta distribution of this form which hints of the reason why random environment models behave, asymptotically, like neutral allele models.

The K-allele extension to (2) may be written, using techniques, similar to those in Gillespie[7], as

$$\begin{aligned} \mu_i(\tilde{X}) &= bx_i(F-x_i) \\ \sigma_i^2(\tilde{X}) &= x_i^2(1+F-2x_i) \qquad i = 1, 2, \ldots, K-1 \qquad (6) \\ \sigma_{ij}(\tilde{X}) &= x_i x_j(F-x_i-x_j) \end{aligned}$$

where $X = (x_1, x_2, \ldots x_{K-1})$, $F = \sum^{K} x_i^2$, and $x_K = 1-x_1-x_2-\ldots x_{K-1}$. We can solve the three allele case by using the zero probability flux condition given in Kimura[8] and following the techniques given in his equations (9.5) to (9.7). If we write the asymptotic density as

$$\Phi_3(x_1, x_2) = \exp(\psi(x_1, x_2)) \qquad (7)$$

we are led to the system

$$\begin{bmatrix} \sigma_1^2 & \sigma_{12} \\ \sigma_{12} & \sigma_2^2 \end{bmatrix} \begin{bmatrix} \frac{\partial\psi}{\partial x_1} \\ \frac{\partial\psi}{\partial x_2} \end{bmatrix} = \begin{bmatrix} -2\mu_1 - \frac{\partial}{\partial x_1}\sigma_1^2 - \frac{\partial}{\partial x_2}\sigma_{12} \\ -2\mu_2 + \frac{\partial}{\partial x_1}\sigma_{12} + \frac{\partial}{\partial x_2}\sigma_2^2 \end{bmatrix} \qquad (8)$$

which yields, after considerable manipulations

$$\begin{aligned} \frac{\partial\psi}{\partial x_1} &= \frac{2b-5}{3}\left[\frac{1}{x_1} - \frac{1}{1-x_1-x_2}\right] \\ \frac{\partial\psi}{\partial x_2} &= \frac{2b-5}{3}\left[\frac{1}{x_2} - \frac{1}{1-x_1-x_2}\right] \end{aligned} \qquad (9)$$

Integrating this system gives

$$\Phi_3(x_1,x_2) = \frac{\Gamma(2b-2)}{\Gamma((2b-2)/3)^3}[x_1x_2(1-x_1-x_2)]^{(2b-5)/3} \qquad (10)$$

This is a Dirichlet distribution and suggests immediately that the form of the asymptotic density for K alleles will be

$$\Phi_K = C\left[\prod_{i=1}^{K} x_i\right]^{\beta} \quad x_K = 1-x_1-x_2\ldots-x_{K-1} \qquad (11)$$

If we substitute (11) into the equation giving the zero probability flux condition:

$$-\mu_i\Phi_K - \frac{1}{2}\frac{\partial}{\partial x_i}[\sigma_i^2\Phi_K] - \frac{1}{2}\sum\frac{\partial}{\partial x_j}[\sigma_{ij}\Phi_K] = 0 \qquad (12)$$

we discover that the appropriate value of β is

$$\beta = \frac{2(b-1)}{K} - 1 \qquad (13)$$

Thus the asymptotic density for the system (6) is the Dirichlet distribution

$$\Phi_K(X) = \frac{\Gamma(2b-2)}{\Gamma((2b-2)/K^{K})}\left[\prod_{i=1}^{K} x_i\right]^{\frac{2b-2}{K}-1} \qquad (14)$$

This is the same form as the asymptotic density for the K-allele neutral model (see refs 7, 9, 14).

The tractability of the sampling distribution of neutral alleles rests on the assumption that the underlying process has an infinite number of possible allelic states. The natural analogue in our case would be to consider the behaviour of Φ_K as $K \to \infty$. By this procedure we do not mean to imply that there are, in any real population, an infinite number of alleles, rather we view the $K = \infty$ case as an approximation to the behaviour of a large number of alleles. The behaviour of both Φ_K and samples from Φ_K are well known, the most powerful results coming from recent work by Kingman[10].

As $K \to \infty$, the limiting form of Φ_K degenerates, but the distribution of the order statistics

$$x_{(1)} \geq x_{(2)} \geq x_{(3)} \geq \ldots \qquad (15)$$

converges to the Poisson–Dirichlet limit. Kingman[11] has recently proved the remarkable theorem—"a sequence of populations has the Ewens sampling property if and only if it has the Poisson–Dirichlet limit."

Thus the sampling distribution for alleles subjecting to selection in a fluctuating environment according to equation (6) has the same sampling distribution as the neutral allele model. The fact that the Dirichlet distribution yields Ewens' sampling distribution as $K \to \infty$ was apparently shown first by Frank Stewart (unpublished results). Watterson[12] showed independently, that the order statistics of the Dirichlet distribution converge to a limit, and obtained the joint density for the first r order statistics.

For our parameterisation we can write down certain sampling properties immediately using the results of Ewens[3]. The probability that a sample of size $2n$ contains k alleles is

$$Pr[k\,|\,2n] = 1_k\frac{(2b-2)^k}{L(2b-2)} \qquad (16)$$

The probability that a sample of size $2n$ with k allelic types contains n_i alleles of type i is

$$Pr[n_1, n_2, \ldots, n_k\,|\,k, 2n] = \frac{2n!}{k!\,1_k n_1 \ldots . n_k} \qquad (17)$$

where, in (16) and (17)

$$L(y) = y(y+1)(y+2)\dots(y+2n-1)$$
$$= l_1 y + l_2 y^2 + \dots l_{2n} y^{2n}$$

Similarly, we can write down the expected homozygosity as $EF = 1/(2b-1)$, and the frequency spectrum, as used by Yamazaki and Maruyama[13] as $x^{2b-2} + (1-x)^{2b-2}$. Examination of these results shows that heterozygosity increases with *b*. From equations (3) and (4) we are led to the observation that increasing the environmental heterogeneity will increase the heterozygosity, while increasing the autocorrelation will decrease the heterozygosity.

It was quite unexpected that the infinite-allele random-environment model should behave in a manner completely analogous to the neutral-allele model. Ewens's[2] original derivation of the sampling distribution used intuition concerning the behaviour of unique alleles which appear in the population through mutation, continue to segregate for a time, and are then lost. Clearly this line of reasoning does not immediately carry over to the present model because of its inaccessible boundaries. Also, in the neutral model the frequency of a single allele is a Markovian variable whose behaviour can be studied in isolation by lumping the frequencies of all other alleles. This is not the case for the random environment alleles whose individual behaviour depend on *F* and cannot be studied without some knowledge of the actual frequencies of the other alleles.

The assumption of complete symmetry given in equation (6) is probably unnecessary. In the two allele case even asymmetric models give asymptotic β distributions. If this carries over to *K*-alleles, then the results of Kingman[10] indicate that even asymmetric Dirichlet distributions can have the Poisson–Dirichlet limit providing certain conditions are met. The common observation that there are 'too many' rare alleles in many samples from nature[11] can be accounted for by these asymmetries.

The present model is limited in that it does not include finite-population effects. Whether this will seriously affect the behaviour of alleles which are frequent enough to appear in samples is not known.

Finally, since many of the tests for neutrality are based on the asymptotic behaviour of the infinite-allele neutral model, the present results indicate that none of these tests can distinguish neutrality from random-environment behaviour. Included among these tests would be those of Ewens[2] Yamazaki and Maruyama[13], Johnson and Feldman[15] and Nei *et al.*[16].

I thank Warren Ewens for many helpful comments, including his mention of the work of J. F. C. Kingman.

Synthesis of compound chromosomes from a pericentric inversion in the onion fly *Hylemya antiqua*

STRUCTURAL chromosome mutations such as reciprocal translocations[1,2], pericentric inversions[3] and compound chromosomes[4,5] have been considered for the control of insect pests. Their exploitation is based on the capacity to reduce the fertility of a population, and they might be used to introduce a gene into a natural population to render the pest less harmful. This possibility arises from the fact that some structural chromosome mutations confer higher sterility in crosses to wild type, or in the hybrids from such crosses, than in matings within the mutant strain. This property is particularly evident with compound chromosomes which have homologous arms attached to common centromeres rather than to different centromeres. This causes intersterility with wild-type individuals, because all the hybrids carry chromosome duplications and deficiencies. In contrast to studies[5–7] in which compound chromosomes were isolated starting from two almost whole arm reciprocal translocations, I have used a pericentric inversion in the onion fly, *Hylemya antiqua*.

Four different types of chromosomes were produced if crossing over occurred anywhere within the loop of a pericentric inversion heterozygote[8]. Figure 1 shows how these types were discriminated on the basis of total length and arm ratio. The normal (3^n) and inverted (3^i) chromosomes are balanced. The other two crossover chromosomes (3^s and 3^l) both carry duplications and deficiencies and are considered as compound chromosomes, although the breakpoints are not in the immediate vicinity of the centromere. If both sexes were chiasmate, a compound chromosome strain could be made from crosses between inversion heterozygous parents. Because only female onion flies are chiasmate, I looked for males carrying a chromosomal rearrangement which gave products which would be complementary to one of the compound chromosomes produced by the inversion female (Fig. 2). Crosses between inversion females

and translocation males produced some progeny with the compound type of chromosome, consisting of a large recombinant chromosome (3^l) from the female and a short complementary translocated chromosome (3^t) from the male. It was intended that subsequent backcrossing of such males with inversion females would give a compound chromosome strain carrying 3^l and 3^s

Cytological analysis (Fig. 3) of an X-linked translocation[9] showed that one of the translocated chromosomes (3^t) resembled the short chromosome (3^s) from the inversion. Four different chromosomes were involved in the translocation, which is a simple one with a breakpoint in the telomeric area of the X chromosome (Figs 2 and 3). Four different types of gametes were produced in equal frequency and 16 different embryonic karyotypes were assumed to occur when the translocation males are crossed to inversion females. As Table 1 shows, five karyotypes were deficient for segment ab (about the distal two-thirds) of the long arm of chromosome 3. Indeed these types were not observed in the larval stage and died as embryos.

Eleven different karyotypes were expected to be viable in the larval stage, but observations on mitotic preparations with somatic pairing revealed only eight types. Of the three missing categories I could not explain the absence of $3^t3^iX^3X$ larvae which are no more duplicated than, for example, the viable 3^i3^nXY type. The $3^i3^nX^3X$ type is tetrasomic for segment ab and therefore probably too duplicated to survive. The $3^s3^nX^3X$ larval karyotype is probably indistinguishable from the translocation heterozygote ($3^t3^nX^3X$). Out of 40 larvae analysed, three were of the male compound type (3^t3^lXY) (Fig. 3*d*, *e* and *f*). Unfortunately no compound karyotype was observed among adult males (30) and therefore no compound strain was isolated. Probably a small terminal deficiency (segment e), distal to the breakpoint in the short arm of chromosome 3 (one-tenth of the chromosome), caused inviability. This was unfortunate because the

The letter combinations indicate the presence of duplications and/or deficiencies. The compound type is indicated by an asterisk. The Δ types are expected to die in the embryonic stage. Y is the male determining factor. Photomicrographs of some karyotypes (larvae) are shown in Fig. 3.

presence of a small duplication for a tiny interstitial segment, located between the long arm breakpoints of two rearrangements, usually has little influence[6,9,10].

To avoid the problem of trying to obtain a translocation which is more exactly complementary to the crossover products of the inversion, another suggested method for the production of a compound chromosome strain is the irradiation of inversion heterozygous males to stimulate crossing over in the loop[11]. Then the recombinant chromosomes 3^s and 3^l could be generated through both sexes. The usefulness of the pericentric inversion would be much reduced if the distances of both breakpoints to the centromere are too large. Otherwise crossing over is to be expected between the two compound chromosomes, thus producing normal and inverted chromosomes again and hence intersterility with the wild type would be incomplete. This would prevent use of the system to replace completely a wild population by a harmless form. But in a species with achiasmate males, this sex from such a compound chromosome strain would be fully sterile in matings to wild type. Thus such a strain could be used as a source of material for a sterile male release programme.

I thank C. F. Curtis for criticising the manuscript.

Regulation of dimorphism in the pathogenic fungus *Histoplasma capsulatum*

Histoplasma capsulatum is a dimorphic pathogenic fungus which is the causative agent of the disease histoplasmosis. The disease is worldwide in occurrence and approximately 40 million people have been infected in the USA[1]. In soil the fungus is filamentous, but in the infected host it exists as a budding yeast and it is believed that the phase transition is important in the pathogenicity. In the laboratory, the mycelial form can convert to the yeast phase when the temperature of incubation is shifted from room temperature (25 °C) to body temperature (37 °C). In this report we show that the elevated temperature initiates a series of reactions leading to changes in the intracellular level of 3′,5′-cyclic adenosine monophosphate (cyclic AMP); the shifts in intracellular cyclic AMP levels are an important determinant of the morphological phase of the organism and therefore of its disease producing potential.

Earlier studies[2-9] have already shown that the natural signal of temperature is not by itself critical to cause the phase transition. Rather, temperature seemed to affect the level of sulphydryl groups or the redox potential, which in turn determined the phase of the organism. For example, added sulphydryl, usually in the form of cysteine, could force mycelia into the yeast phase even at 25 °C (ref. 3). Moreover, Rippon showed[10] that a low redox potential imposed even in the absence of added cysteine, stimulated the conversion of mycelia to yeast at 25 °C, whereas yeast converted to mycelia when the medium had a higher redox potential.

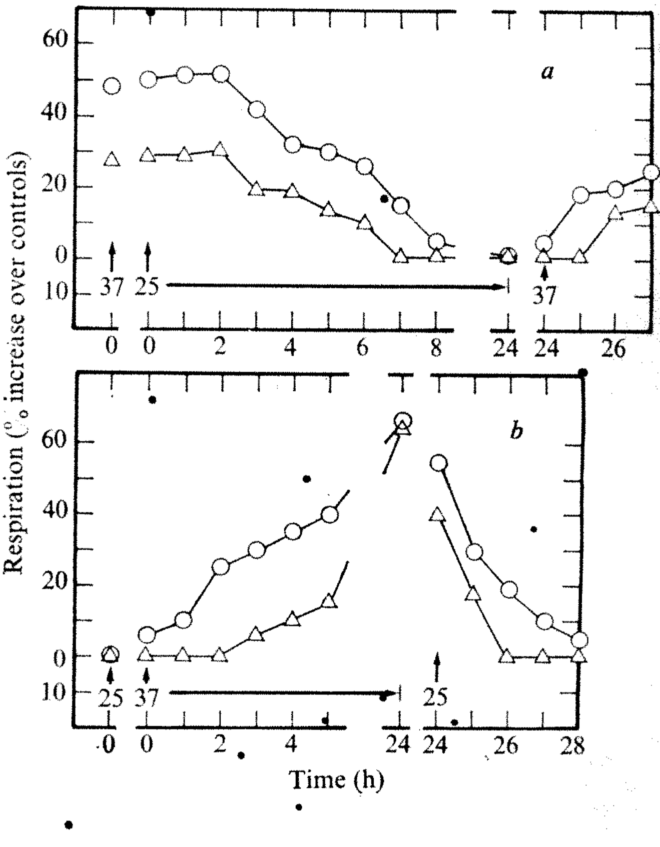
In attempting to analyse further the role of sulphydryl groups, we started from the observations of Garrison that cysteine and cystine were actively transported into yeast by an ATP-dependent permease, and that they stimulated fungal respiration by entering the Krebs cycle as pyruvic acid[11]. Garrison also found that the effects on respiration were a good measure of the active uptake of these compounds.

We found that yeast incubated at 37 °C had a higher level of respiration than mycelia incubated at 25 °C (6.6 and 2.8 nmol O_2 per min per mg dry weight, respectively). When yeast cells were brought to 25 °C, however, respiration immediately fell to the level characteristic of mycelia (2.2 nmol). Similarly, when mycelia were incubated at 37 °C, there was an immediate increase to the level observed with yeast (6.5 nmol). We concluded that the baseline level of respiration in the two phases of *H. capsulatum* was a direct response to temperature of incubation and reflected only the QO_2 of mitochondrial function.

The addition of cysteine or cystine to the medium stimulated the respiration of yeast but not of mycelia. When yeast cells were switched from 37 to 25 °C, respiration fell immediately and the stimulus to respiration of cysteine and cystine gradually diminished to zero over 8 h (Fig. 1). After 24 h of incubation at 25 °C, the temperature was abruptly brought back to 37 °C. Baseline respiration increased immediately and there was a rapid return of the stimulus to respiration by added cysteine (within 5 min) and a later return with added cystine (Fig. 1). When the temperature was switched to 37 °C in the presence of 1 mg ml^{-1} cycloheximide and 1 mg ml^{-1} chloramphenicol, the cysteine-induced change in respiration still occurred. At these concentrations of antibiotics, protein synthesis was less than 20% of control cells[12].

Mycelia incubated at 25 °C did not respond to cysteine or cystine, but when the cells were switched to 37 °C they became responsive to these amino acids within 5 min (Fig. 1). The rapid changes in uptake of cysteine and cystine, even in

Fig. 1 Effect of cysteine (○) and cystine (△). *H. capsulatum* (Down's strain mating type [−]) was grown in 2% glucose 1% yeast extract (GYE) in a New Brunswick rotary shaker. An inoculum of 10 mg dry weight of mycelia per ml was incubated at 25 °C, and an inoculum of 5 × 10^6 yeast cells per ml was incubated at 37 °C. Oxygen consumption was measured using a Clark electrode. The dry weights were determined by filtering 5 ml culture through 0.22-μm Millipore filters and drying the filters at 60 °C to constant weight. Daily fresh solutions of cysteine (pH 6.4) and cystine were prepared. The final concentrations were respectively 10 mM and 21 μM. Rate of growth of the two phases as determined by dry weights was the same. *a*, Yeast cells; *b*, mycelial cells.



cycloheximide–chloramphenicol-treated cells, suggested that this process did not require new protein synthesis and that transport protein(s) may be present on cell membranes of both phases of *H. capsulatum*, but only active at 37 °C.

If the action of temperature is to change membrane redox potential, and this can be facilitated by activating a permease for cysteine uptake, fungal dimorphism may be controlled by some critical sulphydryl groups, or by a general change in reducing state. To test this, *p*-chloromercurphenisulphonic acid (PCMS), a sulphydryl-blocking agent, and dithiothreitol (DTT), a sulphydryl protector, were tested for their effects on the phase transition. Mycelia were exposed to 100 μM PCMS for different lengths of time (5 min to 2 weeks) and were then washed twice, resuspended in fresh medium without PCMS and plated on GYE agar plates at 37 °C. The cells grew continuously after this treatment but never reverted to the yeast form (Fig. 2). PCMS (100 μM) also accelerated the transition of yeast to mycelia at 25 °C. After exposure to PCMS and incubation at 25 °C, yeast transformed to mycelia in 5–6 d instead of the usual 12–14 d. Even yeast incubated at 37 °C began to transform to mycelia in the presence of PCMS, but reverted to normal yeast when PCMS was washed out.

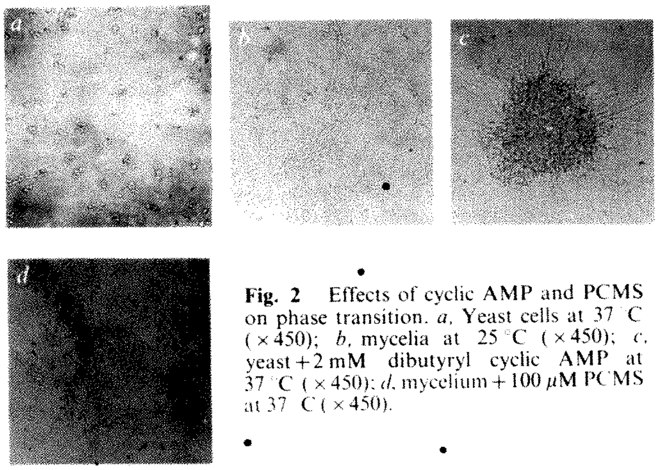


Fig. 2 Effects of cyclic AMP and PCMS on phase transition. *a*, Yeast cells at 37 °C (×450); *b*, mycelia at 25 °C (×450); *c*, yeast + 2 mM dibutyryl cyclic AMP at 37 °C (×450); *d*, mycelium + 100 μM PCMS at 37 °C (×450).

Opposite effects were found when cells were treated with DTT. For example, when yeast were incubated at 25 °C in the presence of 5 mM DTT, transformation to mycelia did not occur (although in this case the transition to mycelia still occurred when DTT was removed from the medium). Neither PCMS nor DTT were toxic to either phase of *H. capsulatum* at the concentrations used.

The effects of PCMS and DTT argue that sulphydryl groups, most likely at the surface of the cell, are critical for determining the phase of *H. capsulatum*. The irreversibility of the PCMS effect was unexpected, but also suggested that some surface feature was critical. The next question was how critical sulphydryl groups, especially at the membrane of the organism, could regulate a complex transition of yeast to mycelium. One possible explanation was that this phenomenon was similar to the effects of many hormones on eukaryotic cells, which often begin with a membrane change that modifies the intracellular level of a cyclic nucleotide.

In *H. capsulatum*, we found that the level of cyclic AMP was about five times higher in the mycelial phase than in the yeast phase. Cyclic AMP was assayed in yeast and mycelia by the radioimmunoassay of Steiner *et al.*[13] or with the Amersham–Searle cyclic AMP assay kit. The cells were collected by filtration, washed three times in ice-cold water, suspended in either 5% TCA, 0.1 N HCl or 0.05 M Tris-HCl buffer, *p*H 7.5, containing 1 mM 3-isobutyl-1-methylxanthine (Aldrich Chemicals). Glass beads (diameter 0.45–0.50 mm) were added to the suspension and the cells were disrupted at 4,000 r.p.m. for 3 min in a B. Braun Cell Homogeniser MSK, cooled with liquid CO_2. The resulting homogenates were centrifuged and an aliquot of the supernatant was lyophilised directly, or, in the case of cells homogenised in TCA, after extraction in ether. The dried material was resuspended in the appropriate buffer, and the cyclic AMP content determined. The recovery of added cyclic AMP in controls was 80–90%. The supernatant of cells homogenised in Tris buffer containing methylxanthine and precipitates of HCl and TCA-extracted cells redissolved in 1 N NaOH were assayed for protein according to Lowry *et al.*[14]. The average of three determinations showed that mycelia contained 46.9 and yeast 9.8 pmol cyclic AMP per mg protein. In addition, 2 mM dibutyryl cyclic AMP or 5 mM theophylline added to yeast cultures resulted in the conversion of yeast to mycelia, even at 37 °C, the temperature characteristic for the yeast phase (Fig. 2).

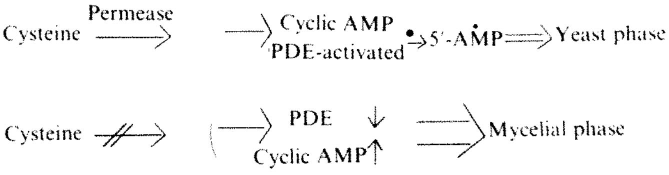

Fig. 3 Working hypothesis for role of cysteine and cystine in morphogenesis of *H. capsulatum*.

Thus, although the role of cysteine and cystine in morphogenesis of *H. capsulatum* is not understood, it seems likely that they satisfy a requirement for critical sulphydryl groups that then determine the level of intracellular cyclic AMP. We do not know how this might occur, but possibly, as in *Escherichia coli*, the activity of cyclic AMP-phosphodiesterase (cyclic AMP-PDE) requires the presence of a reducing substance[15]. The redox potential, governed by sulphydryl groups, could then have a regulatory role in the level of cyclic AMP, which in turn would control morphogenesis. Therefore, we suggest as a working hypothesis the schema of Fig. 3. At 37 °C the cells are able to bring cysteine to critical membrane sites. There it would activate cyclic AMP–PDE, thereby lowering intracellular cyclic AMP and maintaining the yeast phase. When the temperature is switched to 25 °C, transport of cysteine decreases and cyclic AMP–PDE activity falls. This results in an increase in cyclic AMP levels and a shift to the mycelial phase.

The role of chemotaxis in the ecology of bacterial pathogens of mucosal surfaces

ALTHOUGH the ecological role of bacterial chemotaxis has been the object of considerable speculation, little is known of its role in nature[1]. Moreover, chemotaxis as a factor in the interaction between the mammalian host and its indigenous or pathogenic microflora remains unexplored. Studies with *Vibrio cholerae* and other intestinal pathogens have shown that bacterial association with the mucosa is influenced by bacterial motility, adhesion to brush border membranes, the presence of an indigenous flora and by the inhibitory effects of local antibodies

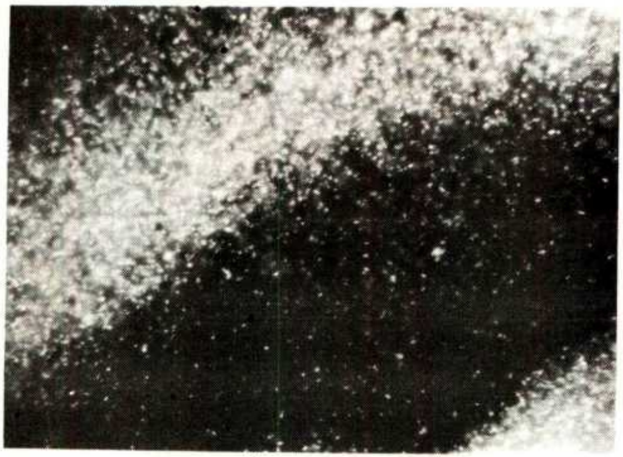

Fig. 1 A chemotactic strain of *S. typhimurium* forming a receding band at some distance from the mucosal surface. The bright triangular area in the lower right corner is the surface of the mucus gel overlaying the villi. The band had originally formed within the mucus gel and some bacteria have been retained there. The diffuse light within the band emanates from bacteria outside the focal plane of the microscope. The diffuse light in the mucus is due to light scattering by the gel itself. Darkfield (×110).

(summarised in refs 2, 3). We have shown previously that a pepsin digest of rabbit intestinal mucosa (PMS) inhibits the association of cholera vibrios and *Salmonella enteritidis* with rabbit intestine, and speculated that this extract was inhibitory because it neutralised the adhesion of the bacteria to a hypothetical receptor in the mucus gel[3]. We report here that PMS neutralises a positive chemotactic response of several bacterial species to the mucosa and in that way reduces bacterial association with intestinal tissue. Chemotaxis thus seems to be one of several mechanisms controlling interactions of bacteria with mucosal surfaces.

Observation under a phase-contrast or darkfield microscope of pieces of mouse or rabbit small intestine immersed in a suspension of *V. cholerae* revealed that very high concentrations of vibrios aggregated at the villous surface of this tissue in approximately 1 min. Three non-chemotactic vibrio mutants were selected using a modification of the method of Aswad and Koshland[4] and differed from the parent strain in that they did not accumulate at the surface of intestinal tissues, but remained randomly distributed throughout the suspending buffer. Similarly rapid attraction to mucosal tissue was shown by *Escherichia coli* (AW 405) and *Salmonella typhimurium* (SL 1634), but not by their non-chemotactic mutants (cheB 590 and SL 2538, respectively). None of the mutants used in this study differed from their respective parents in the rate of motility as determined by direct microscopic observation.

After chemotactic strains of the three bacterial species had accumulated on the surface of intestinal tissues for a period of approximately 2–5 min, the bacterial accumulation began to move away to form a clearly visible band of motile bacteria some distance from the tissue surface (Fig. 1). The distance of separation increased with time until the band eventually reached the edge of the coverslip. No such bands were formed by any of the non-chemotactic mutants. The formation of these bands may be caused by the local consumption of oxygen at the tissue surface or by the generation of metabolites with negative chemotactic activity by the tissue and/or by the bacteria. Such negative chemotactic gradients would compete with the positive chemotactic gradient generated by the tissue. Accordingly, the bacteria would be expected to accumulate in an area defined by the interaction of opposing gradients. Similar banding phenomena in broth or agar cultures of various bacteria have been described by others[5-7]. Whatever the actual mechanisms may be, our direct microscopic observations indicate that strikingly effective chemotactic attraction and repulsion of a variety of bacteria can occur at the mucosal surface.

Agar blocks infused with an ultrafiltrate of PMS could be substituted for the mucosal tissue slices. Such blocks attracted *E. coli*, vibrios and salmonellae to their surfaces, indicating that PMS contained one or several attractants. Agar blocks soaked in buffer had no effect. Moreover, the addition of PMS to the bacterial suspension reduced or prevented the chemotactic attraction of vibrios to rabbit mucosal tissue in the microscopic assay. By analogy with other chemotactic systems[7] it seems likely that the attractants in PMS saturated those chemotactic receptors of bacteria which normally reacted with the attractants emanating from the mucosa, thereby blocking the reactivity of the bacteria. These interactions were also demonstrated with Adler's capillary test for chemotactic activity[8]. Cholera vibrios were attracted into capillaries containing dilutions either of PMS or of a soluble fraction obtained by centrifuging freshly prepared scrapings from the mucosa of rabbit small intestine (Muc. Sn.) (Table 1). The latter preparation presumably contained the chemotactic mediators of mucosal tissue in relatively unaltered form. When PMS was added to the bacterial suspension as well as to the capillaries, no chemotactic gradient could form and no migration into the capillaries occurred. Similarly, the presence of PMS in the vibrio suspension considerably reduced the entry of vibrios into capillaries containing Muc. Sn. (Table 1), suggesting that at least some of the attractants in PMS and Muc. Sn. were similar. No response in the capillary test was observed with the non-chemotactic mutant vibrios.

The effect of chemotaxis on the association of vibrios with intact slices of rabbit ileal tissue was determined as described before[3], with the modification that the tissues were incubated in buffer containing 5×10^5 cells per ml of each of the chemotactic parent strain plus one non-chemotactic mutant. The proportions of mutant to parent strains that remained on the washed tissues were determined by preparing agar plate cultures and subsequently transferring a number of individual colonies to semisolid tryptone agar[8]. The proportion of non-chemotactic mutants associated with the tissue slices was 3.0 to 3.8 times lower than their proportion in the suspending fluid, indicating that the mutants had a significantly lower chance of associating with the mucosal tissue than the parent strain (Table 2). PMS in the suspending medium had no effect on the association of the non-chemotactic mutants with tissue slices. In contrast, PMS in the suspending medium reduced the association of the parent strain with mucosal slices by a

factor of two to four[3]. Consequently, when the chemotactic attraction of the parent strain towards the mucosa was blocked by PMS, its ability to associate with the mucosa was reduced to a level similar to that of the non-chemotactic mutants.

Results obtained in three different experimental systems thus indicate that chemotactic mechanisms can promote as well as inhibit the initial invasion of mucosal surfaces by bacteria. Attractive and possibly repellent substances produced by the tissue are obviously important factors in these processes, but chemotactically active substances such as PMS in the medium bathing the mucosal surface seem to be equally potent modifiers of bacterial invasion. It is tempting to speculate about the *in vivo* role of chemotaxis in the interaction between bacteria and their mammalian host. For example, in the initial stages of infection an intestinal pathogen is rapidly propelled along the small intestine in a bolus of digesta, and the duration of its contact with any given area of the mucosal surface may not be longer than a few seconds. The ability of chemotactically attracted bacteria to quickly approach and penetrate the mucus gel may well be of even greater importance in that situation than in the invasion of the statically incubated tissues studied in the present experiments. Indeed, Chet and Mitchell[1] quote data showing rapid chemotactic movement of bacteria across and against fluid flow planes in flowing streams, that is, in conditions which kinetically resemble those of the small intestine. Furthermore, intestinal contents almost certainly contain chemotactically active substances which may either promote or inhibit chemotactic attraction of bacteria into the mucosa. Such a phenomenon may relate to certain aspects of the long-recognised relationship between diet and susceptibility to infection, a phenomenon for which exact mechanisms are still to be delineated[9]. It is also possible that chemotactically active substances added to the diet may exert a prophylactic effect against infections such as traveller's diarrhoea. The association of indigenous bacterial flora with the mucus layer of the large intestine may also be governed in part by chemotactic mechanisms.

We thank Drs Julius Adler and Bruce A. Stocker for supplying *E. coli* and *Salmonella* strains, respectively. This study was supported by US Public Health Service grants from the National Institute of Allergy and Infectious Diseases.

Helical shape and wall synthesis in a bacterium

THE main skeletal components of most bacterial cell walls are complex polymers called peptidoglycans[1]. The primary chemical structures of these and other wall components are well understood but little is known about the arrangement of the molecules in the wall or how new wall material is incorporated during growth[1]. We report here that several factors cause cells of *Bacillus subtilis*, normally straight rods (Fig. 1*b–e*), to assume a regular helical shape. We suggest a model for the structure and synthesis of Gram positive cell walls which could explain these observations. Explanations suggested by Mendelson[2] for an apparently different type of helical growth in *B. subtilis* do not account for our results.

In the model which most satisfactorily explained his observations, Mendelson[2] suggested that the pattern of wall growth in his mutant, and perhaps other strains, results in the rotation of the two ends of a cell relative to one another. When, in his strain, both ends of a cell filament remain attached to the old spore case this rotation is prevented and the resulting torque is relieved by the whole filament distorting to a helix.

We have observed that helices predominate among the abnormally-shaped cell filaments that occur in cultures of *B. subtilis* in the following conditions (f = approximate frequency of helical filaments in the populations).

(1) In medium supplemented with the local anaesthetics chlorpromazine (3×10^{-5} to 4×10^{-5} M; 37 °C) or methochlorpromazine (5×10^{-5} to 6×10^{-5} M; 37 °C); $f = 50\%$.

(2) In medium containing penicillin G (0.1–0.25 U ml^{-1}; 30 °C); $f = 1\%$ (Fig. 1*b–e*).

(3) Certain mutants of strain 168 (ref. 3) resistant to the detergent Triton X-100 (unpublished work) grow predominantly in a helical form, especially near the end of exponential growth. $f > 95\%$ (Fig. 1*a* and *f*).

(4) In cultures restarting growth after subculturing from stationary phase. $f < 1\%$.

(For (1) and (2) exponentially growing cells were subcultured, to an initial density of 2×10^6 ml^{-1}, into media containing the drugs. Strain 168*ind*⁻ (ref. 3) and Penassy broth (Difco) were used in (2), (3) and (4) but wild-type Marburg strain and nutrient broth (Difco) in (1).)

Our bacteria were not grown from spores, did not appear as closed loops (Fig. 1) and were grown in liquid media. Therefore, unlike Mendelson's example, anchorage of cell ends could not have contributed to their morphogenesis. In addition, the helices we observed were usually much more tightly coiled (Fig. 1).

Mendelson considered it improbable that helical shape could result from unequal growth rates at different points around the cell circumference because of the complexity of the necessary growth pattern[2]. This argument also applies to our observations—perhaps even more so because of the variety of circumstances involved.

Highton and Hobbs[4] described penicillin-induced helical growth, very similar to that reported here, in a penicillin-resistant mutant of *B. licheniformis*. They found abnormal wall thickening at the inside curvatures of bent cells. Similar thicken-

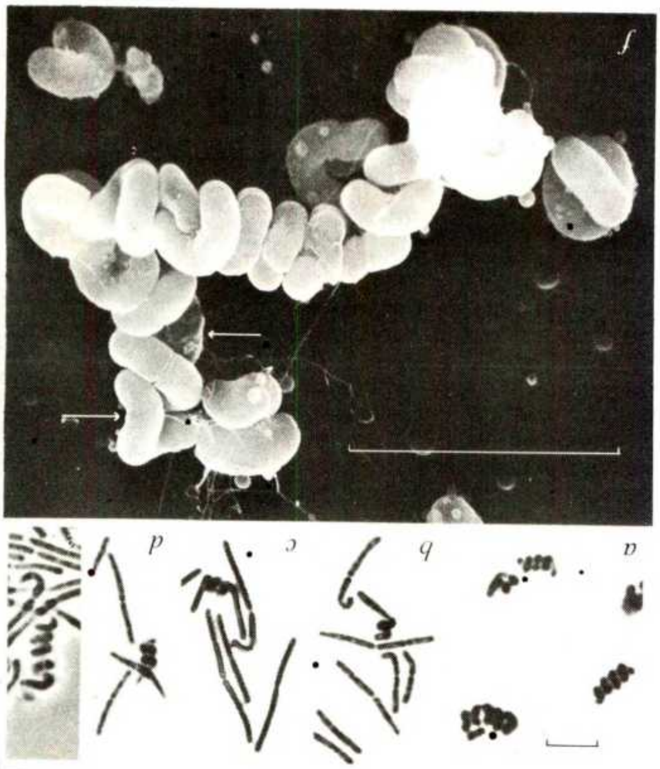

Fig. 1 *a* and *f*, Triton-resistant mutant (TR61) grown in Penassy broth. Arrows in *f* show points of change in direction of helix; *b–e*, normal (straight) and helical forms of strain 168*ind*⁻ grown in Penassy broth containing Penicillin G (0.25 U ml^{-1}); *a–e*, light micrographs of cells fixed in 1% formalin and dried on to slides; *a–d*, stained with crystal violet; *e*, unstained, and phase contrast illumination; *f*, critical point dried bacteria in the scanning electron microscope. Bar, 5 μm.

ing was present in an irregularly bent mutant of *B. subtilis*[5]. The thickening was attributed to an altered and irregular growth pattern[1] or to lack of wall expansion due to insufficient lytic enzyme[5]. Without an explanation for the development of a regular pattern of wall thickening, these suggestions alone cannot account for long regular helix formation.

Helical shape may also occur if the cell wall consisted, at least in part, of fibres wound in a helical manner around the cell. If the quantity or quality of right- and left-hand wound fibres were unequal, and if the fibres were in a state of tension or compression, the cell might assume a helical shape, the direction of which would depend on which class of fibre predominated. This characteristic has been mentioned in a theoretical analysis of the structure of body walls of certain worms[6].

Helical shape in a bacterium may occur in the following circumstances.

(1) If, in a cell wall normally composed of unequal quantities or qualities of right- and left-hand wound fibres, tension or compression forces along the fibres were introduced through imbalance in wall formation, expansion and turnover.

(1*a*) As (1) but fibres are normally wound in only one direction in the same wall area or at the same time. Helical cell shape may then also result from the inclusion of abnormal contrarily wound fibres.

(2) If, in a cell wall normally containing equal quantities and qualities of right and left hand wound fibres under tension or compression, the equality is disturbed.

(3) If, in a cell wall where the fibres are not normally helically arranged (that is, are parallel or at right angles to the cell's long axis), the pattern is disturbed to give unequal right- and left-hand wound helical components.

None of these models involves anchorage of cell ends and therefore they can explain our observations.

There is evidence that Gram positive cell wall material is synthesised in the form of fibres. During early stages of reversion of *B. licheniformis* protoplasts to bacilli, murein and teichoic acid are in the form of distinct fibres[7]. In addition, a fibrillar structure has been seen in sections[1] although the latter observation is not a reliable guide to wall structure. Pooley[8] suggested that wall material in *B. subtilis* is arranged in somewhat discrete fibres or sheets to facilitate the complex expansion and reorganisation that accompanies growth.

The glycan chains of *B. subtilis* peptidoglycan are too long to be oriented radially in the wall[9] but are short (< 200 nm (ref. 9)) compared with the cell circumference (~ 1.8 μm, unpublished data) and fibres[7]. It is, however, easily conceivable that fibres consist of several overlapping cross-linked glycan chains. They could be formed in a manner comparable with the apparent mode of cellulose fibre synthesis in higher plants[10], that is, by membrane-embedded enzyme complexes. Whole fibres could be cross-linked after deployment in the wall.

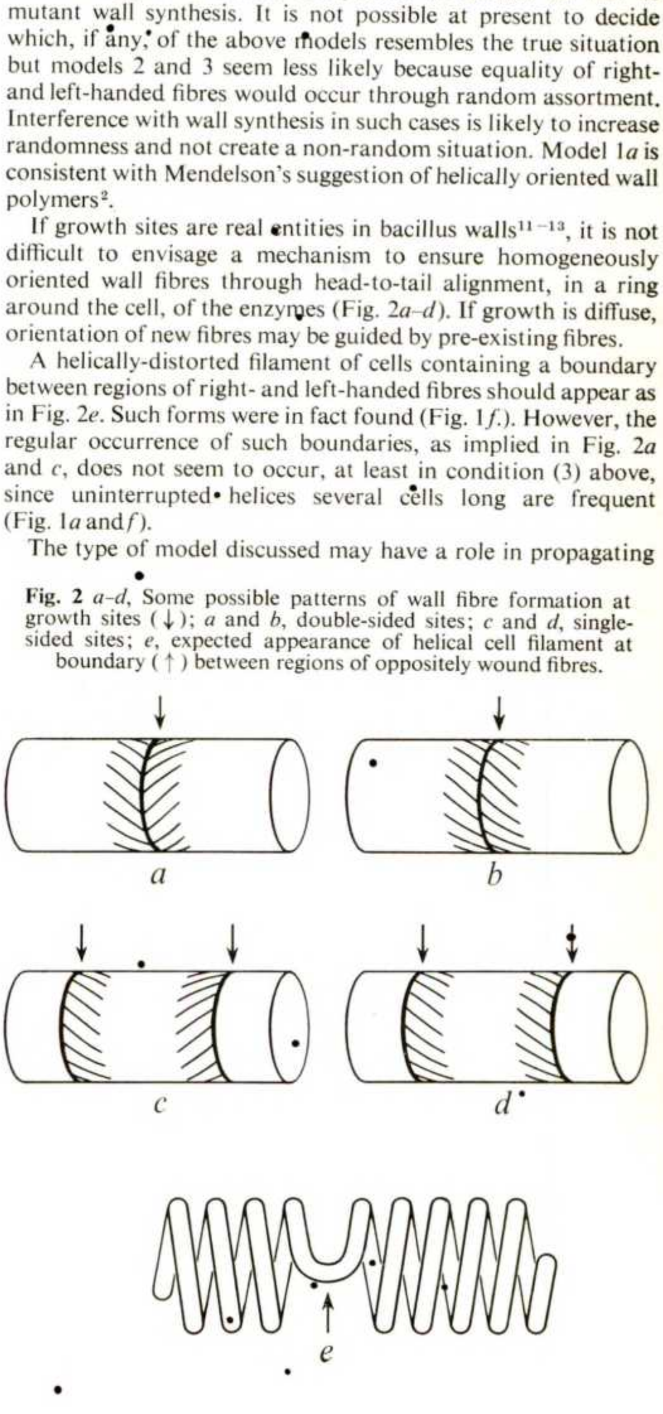
The ease with which wall metabolism can be unbalanced is not surprising considering its biochemical and spatial complexity. The fact that helical cell shapes have been observed by ourselves, Mendelson[2] and Highton and Hobbs[4] in a variety of circumstances suggests a helical component in normal as well as mutant wall synthesis. It is not possible at present to decide which, if any, of the above models resembles the true situation but models 2 and 3 seem less likely because equality of right- and left-handed fibres would occur through random assortment. Interference with wall synthesis in such cases is likely to increase randomness and not create a non-random situation. Model 1*a* is consistent with Mendelson's suggestion of helically oriented wall polymers[2].

If growth sites are real entities in bacillus walls[11–13], it is not difficult to envisage a mechanism to ensure homogeneously oriented wall fibres through head-to-tail alignment, in a ring around the cell, of the enzymes (Fig. 2*a–d*). If growth is diffuse, orientation of new fibres may be guided by pre-existing fibres.

A helically-distorted filament of cells containing a boundary between regions of right- and left-handed fibres should appear as in Fig. 2*e*. Such forms were in fact found (Fig. 1*f*.). However, the regular occurrence of such boundaries, as implied in Fig. 2*a* and *c*, does not seem to occur, at least in condition (3) above, since uninterrupted helices several cells long are frequent (Fig. 1*a* and *f*).

The type of model discussed may have a role in propagating

Fig. 2 *a–d*, Some possible patterns of wall fibre formation at growth sites (↓); *a* and *b*, double-sided sites; *c* and *d*, single-sided sites; *e*, expected appearance of helical cell filament at boundary (↑) between regions of oppositely wound fibres.



the normal very regular shape of *B. subtilis* and could readily explain, in principle, the normal helical shape of spirilla[14].

I thank Professor U. Henning for valuable discussions and criticism, Mr. M. Claviez (MPI für Virusforschung) for doing the scanning electronmicroscopy and Dr H. Schwarz for help with and suggestions on photomicrography.

Neoplastic transformation of hamster embryo cells irradiated *in utero* and assayed *in vitro*

INDUCTION of neoplastic transformation *in vitro* by X rays[1-5] and neutrons[4] has been reported. Using short term cultures of hamster embryo cells we found previously[1-4] that transformation by X rays can be detected with doses as low as 1 rad. The rate of transformation increases with dose reaching a peak of 1% between 150 and 300 rad. This frequency of neoplastic transformation *in vitro* is much higher than the frequency of radiation-induced tumours observed after exposing animals to similar doses of radiation[6]. We report here that malignant transformed cells can be obtained from embryos irradiated *in utero* and assayed *in vitro* and that the frequency of transformation is at least tenfold lower than that obtained when the irradiations are performed *in vitro*, and thus closer to the incidence in animals.

Pregnant Syrian hamster strain LSH (Lakeview) were irradiated at 12 d of gestation with 300 rad of X rays. The embryos were surgically removed within 30 min after irradiation. Passaging was carried out as described below and in Table 1. We tried to conserve in culture as many of the original cells as was technically possible. The cultures were passaged twice a week and each flask was handled individually. At every passage half the population of the freshly dissociated cells, resuspended in fresh medium, was replated back into the original flask while the rest of the cells were seeded into a new flask containing 5×10^4 feeder cells (syngeneic cells irradiated with 4,000 rad (ref. 7)). After the third passage cells were replated only into the flasks from which they had been removed. Embryos at 12 d of gestation from non-irradiated hamsters of the same litter served as controls and were cultured as above.

Transformed cells were initially identified by their altered morphology and growth patterns[1-4]. An additional criterion of transformation is the ability of cells to grow in low serum concentration, which will not support the growth of normal cells. Cells which, from morphological considerations, seemed to be transformed were isolated and grown into mass cultures in medium fortified with either 10% or 1% foetal calf serum. The ability of the cells to proliferate at the lower serum concentration served as an immediate and simple check of their transformed nature.

Within 30–40 d (7–9 passages) after primary cultures had been established from irradiated embryos, cell transformation was observed in four out of five experiments. In each experiment five to six foci were isolated and a number of cell lines were established. Two established transformed lines designated LSH 1 and LSH 5, each from a different experiment, have been studied extensively. The results of these investigations are summarised for LSH 5 in Table 1.

Chromosome analysis carried out at early passages after transformation (see Table 1) indicated that the modal number of the transformed cells was close to the diploid, 44. The number of chromosomes per cell in LSH 1 ranged from 40 to 56; modal chromosome number 46 (in 40% of the cells), and in LSH 5 the range was 38–60, modal chromosome number 48 (in 30% of the cells). There was no difference between the banding patterns of specific metaphase chromosomes from the transformed cells as compared with the normal.

While the two lines differed from one another in their saturation density, they both reached a higher saturation density than the normal cells in the two sets of conditions. The doubling time of the transformed cells of both cell lines was about 16 h which does not differ greatly from that of normal cells grown in optimal condition (Table 1).

A scanning electron microscopy study indicated that the cells which express transformation *in vitro* following X-ray irradiation *in utero* are similar to those transformed *in vitro*[3].

Changes in cellular surface microstructure, following neoplastic transformation, result in the ability of the transformed cells to be agglutinated by low concentrations of plant lectins[8-10]. The normal counterparts are not agglutinable at similar concentrations (Table 1). The ability of transformed cells to grow in agar is associated with their loss of anchorage dependence. Normal cells derived from solid tissue do not form colonies in semi-solid agar. Following an incubation period of 2 weeks in 0.33% agar[11] the control plates showed no sign of colonies, while the plates containing the transformed cells exhibited distinct colonies with a plating efficiency of 5% and 10% at passage nine for LSH 1 and 5, respectively.

We investigated some biochemical markers associated with the neoplastic state of the cells; namely the fibrinolytic activity

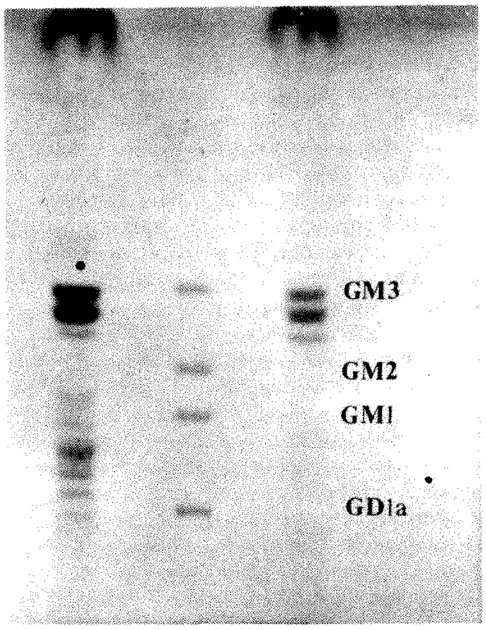

Fig. 1 Thin-layer chromatogram of gangliosides from normal hamster embryo cells and X-ray transformed LSH 5 cells. Lane 1 gangliosides in control cells, lane 2 ganglioside standards, and lane 3 gangliosides in X-ray transformed cells. Note that in the transformed cells gangliosides higher than GM3 are absent. Analysis was by Drs P. H. Fishman, R. O. Brady and R. M. Bradley, using published procedures[17].

Table 1 Characteristics of LSH 5 cells transformed *in utero* by X-irradiation

	Normal (Secondary culture)	Transformed (4th to 30th passage after isolation)	Tumour (1st to 10th passage) after reculturing
Karyotype	Diploid	Near diploid	Aneuploid
Growth in culture	Monolayers	Multilayers	Multilayers
Saturation density no. of cells cm^{-2}			
in 10% serum	7.6×10^4	1.8×10^5	1.5×10^5
in 1% serum	Minimum growth	10^5	10^5
Doubling time			
in 10% serum	16±2 h	14±2 h	16±2 h
in 1% serum	90±5 h	24±2 h	25±2 h
Morphology—scanning electron microscope	Flat and regular surface features except during mitosis	Pleomorphic with complex surface features throughout the cell cycle	Pleomorphic with complex surface features throughout the cell cycle
Agglutinability by con A (20 μg ml^{-1}) and WGA (50 μg ml^{-1})	−	+	+
Plating efficiency			
in 10% serum	2.75±1%	52.5±5.5%	49.5±6.5%
in 1% serum	0.05±0.05%	5.5±2.5%	6.0±2.5%
Efficiency in 0.33% agar	0	10%	30%
Plasminogen activator	low	high	high
Lysosomal hydrolases: phosphatase	low	high	high
Production of MIF	absent	high	high
Gangliosides	Presence of full range of gangliosides	Absence of gangliosides higher than GM$_3$	Absence of gangliosides higher than GM$_3$
Presence of radiation leukemia virus	—	—	—
Tumorigenicity (invasive malignant sarcomas and carcinomas)	none	29/30	Transplantable 12/12

Cells were cultured from a malignant sarcoma which grew in the syngeneic host following subcutaneous (s.c.) injection of 10^5 of the transformed cells and from normal embryonic cells of a secondary culture. Irradiations (see text) were performed in a parallel opposed set-up, so that animals were irradiated simultaneously from above and below with two X-ray tubes operated at 180 kV, 30 mA, with added filters of 0.28 mm aluminium and 0.28 mm copper. The dose rate in the position occupied by the animals was 250 rad min^{-1}. Embryos were removed within 30 min of irradiation. Primary cultures were established by progressive dissociation of the minced fresh tissue[11]. Cells (2×10^7) were seeded into eight 75 cm^2 flasks (Falcon) and incubated at 37 C in a humidified incubator with a constant flow of 5% CO$_2$ in air. Medium, composed of Dulbecco's modified Eagle's medium fortified with 10% foetal calf serum (Grand Island Biological), was replaced 12 h after seeding and the cells were allowed to grow to confluency. Cells were passaged twice a week at a ratio of 1:2 (see text). Transformed foci were observed at passages 7–9 in 6 or 10 of 64 flasks. Foci were isolated using reported techniques[7]. Chromosomes were analysed at the 6th passage after isolation using quinacrine fluorescent banding[21]. Saturation densities and doubling time were determined by seeding 10^5 cells in 60-mm Petri dishes in medium containing 1% or 10% foetal calf serum and following cell growth daily with a Coulter counter. Methods used for scanning electron microscopy[3], testing for concanavalin A (con A) 20–50 μg ml^{-1} and wheat germ agglutinin (WGA) 20–50 μg ml^{-1} induced agglutination[10], colony formation in 0.33% agar[11], testing plating efficiency (PE; PE = (No. clones countered/no. cells plated) × 100), and assays of fibrinolytic activity (plasminogen activator)[12], migration inhibitory factor (MIF)[15], lysosomal acid hydrolases[16], ganglioside content[17,18] and presence of radiation leukaemia virus[19] were as reported before. Tumorogenicity was established by s.c. injection of 10^5–10^7 cells in 0.1 ml of serum-free medium into 2-week-old syngeneic hosts or into the cheek pouch of allogeneic LHC strain hamsters. Portions of the tumours were fixed and stained for histopathological examination and other portions were implanted s.c. in 2-week-old syngeneic hosts; a third portion of the tumours was cultured *in vitro*[11]. Cultured tumour cells were studied as described for the transformed cells. In quantitative studies cells were freshly dissociated from embryos irradiated with 300 rad *in utero* and cloned on feeder cells[1,2]. Seeding levels were 2×10^3–10^4 cells per 60-mm Petri dish (Falcon); 400 dishes were used in each assay. Non-irradiated embryos cultured in the same manner served as controls. The criteria for transformation and the analysis of transformation rate were as before[1–4].

of the transformed cells, the release of macrophage inhibitory factor (MIF), the pattern of cellular lysosomal hydrolases and the ganglioside content of the cells. Fibrinolytic activity[12,13] of the transformed cells was over 20-fold greater than normal; MIF activity[14,15] was confined exclusively to the transformed cell population. Out of 15 cellular acid hydrolases which were determined fluorometrically[16], only acid phosphatase seemed to be significantly elevated in the transformed cells (a twofold increase over the normal). While the full range of gangliosides[17,18] was present in the normal cells the transformed cells showed a complete absence of gangliosides larger than GM$_3$ (see Fig. 1).

Experiments performed by Drs H. S. Kaplan and A. Dèclève, using a reported immunofluorescent assay[19], demonstrated that there was no radiation leukaemia virus (Rad LV) present in the radiation transformed cell lines.

The critical assay for the malignant nature of transformed cells is their ability to give rise to tumours when injected into appropriate hosts. The cells transformed *in utero* by radiation and cultured into cell lines *in vitro* have all given rise to tumours in syngeneic LSH hamsters and also in hamsters of the LHC strain. All animals were 2 weeks old when injected. The tumours were characterised as non-metastesising malignant invasive sarcomas or carcinomas (Fig. 2). They grew progressively and killed the animals.

The tumours are transplantable and have been cultured *in vitro*. The morphological and biochemical properties of the cells cultured from the tumours are similar to those of the original transformed cells (Table 1).

Malignancy varied from one transformed cell line to another (details to be reported elsewhere). In the 2 lines discussed above 10^5 cells of LSH 5 and 10^6 cells of LSH 1 can induce a palpable tumour, 2 cm in diameter, within 2 weeks after injection. Our quantitative studies on transformation *in utero* are outlined in the legend to Table 1. In three experiments we observed a transformation rate ranging from 0.07 to 0.1 following a dose of 300 rad. This frequency is about tenfold lower than that obtained in earlier *in vitro* experiments. It is closer to the frequency observed in some of the studies carried out *in vivo*[6].

Several intriguing questions are evoked. Does the host mediate in modulating transformation by radiation? Is there a repair of transforming events before they can be expressed? How significant is the state of cells during irradiation in determining the rate of transformation? It is well known from *in vitro* studies that cell replication is required for fixation of the transformation[20,4,5]. With the *in vitro* technique, cells are seeded as single cells with ample opportunity to divide. In addition, of course, they are not in contact with one another, and constitute a mixture of cell types from many tissues. *In utero* the situation is quite different; the embryonic cells are irradiated as tissues where there is cell to cell contact in

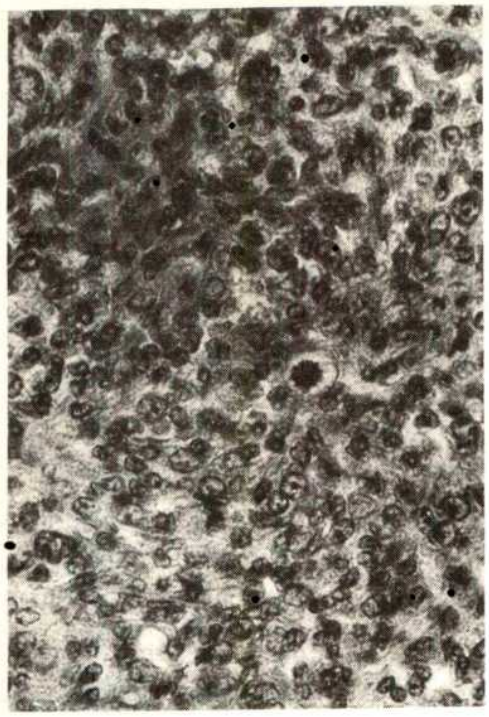

Fig. 2 Section of 3-week-old malignant invasive carcinoma growing in a Syrian hamster following s.c. injection of 5 × 10⁵ cells of a cell line (LSH 5) transformed *in utero* by X-ray irradiation (× 220).

tissue-specific arrangements, and where the rate of cell replication varies with the tissue. It remains to be seen which of these factors, if any, is responsible for the lowered yield of transformed cells characteristic of *in utero* as opposed to *in vitro* irradiation.

We thank Dr Jacob Furth for histopathological examination of tumours, and Drs I. B. Weinstein, W. G. Johnson and G. Poste for help with the assays of plasminogen activator, lysosomes and MIF, respectively. This work was supported by the US NCI and ERDA.

Local inhibition of centripetal particle transport where LETS protein patterns appear on 3T3 cells

WE try here to establish a link between a motility phenomenon in animal cells and the presence of the so-called 'large external transformation-sensitive (LETS)' protein on the surface of the cells. Through studies of this protein a new and still puzzling aspect of animal cell surfaces became apparent. Originally discovered as a major surface glycoprotein of molecular weight 220,000–250,000 which disappeared on cell transformation (for review, see ref. 1), it has since become quite likely that various differently named surface glycoproteins—galactoprotein a (ref. 2), fibroblast surface antigen[3], Zeta protein[4], 'cell-surface protein' (CSP)[5], and 'cold-insoluble globulin' (CIG)[6–8]—which were studied independently by different investigators, are identical to or at least very closely related to LETS protein.

If studied by the methods of indirect immunofluorescence, the distributions of LETS protein on the dorsal surface of fibroblastic cells show intriguing aspects. The protein distribution patterns, or at least their antigenic availability, seem to originate from cell–cell contact areas[9]. Later on, the protein can cover large cell surface areas in the form of streaks, indicating a major inhomogeneity in the cell surface composition. Furthermore, it does not remain localised on the cell which produced it. In several-day-old cultures it can form three-dimensional fibrous networks which span between cells throughout the whole culture. The biological function of this protein is not yet entirely clear; however, it has been found to restore normal cell morphology in transformed cells[10], to correlate inversely with tumorigenicity[9], and to change from a dense fibrillar network in prefused myoblasts (Yaffe's rat myogenic cell line L8) to a sparse dot pattern in myotubes[11].

The centripetal surface flow[12–15], that is, the radial transport of particles attached to the cell surface along that surface at speeds of 0.2–3 μm min^{-1} towards the perinuclear region in cultured fibroblastic or epithelial cells (see Fig. 2), is another quite puzzling surface phenomenon. It is not restricted to the cell body but is also expressed on the surface of lamellipodia, blebs and even in the only 0.2-μm thin needle-shaped filopodia[16,17]. At present, neither a molecular mechanism nor a cellular structure are known which could explain this unidirectional and radial particle movement. Although it is generally believed that the whole cell surface flows constantly towards the nucleus[15,21], it is not yet ruled out that the particle movement may be induced only locally at the site of encounter between the cell surface and non-cellular material.

Assuming a constant centripetal flow, one might expect that fibrillar surface components like LETS protein eventually have to orient themselves parallel to the radial flow lines. The complex distribution patterns of LETS protein of all cell lines investigated so far seemed hard to reconcile, however, with a radial centripetal flow (see Fig. 1). One may suspect, therefore, that the flow has ceased in areas covered with LETS protein.

Indeed, the observation of movements of fluorescent antibody-labelled LETS protein patterns in live 3T3 cells showed only slow distortions of the fibre arrangement (Fig. 1). LETS protein fibres could stretch, shorten, fold, move towards or away from the nucleus; however, the combined movements seemed to be unidirectional and very slow. We also observed gold particles of 2,000–4,000 Å diameter (particle clusters up to 1 μm diameter)[16,17] which had attached to the dorsal cell surfaces inside an area covered with LETS protein, and did not find that they moved centripetally.

One may argue that these experiments do not reflect the natural cell surface movement any more, because the antibody treatment, necessary for the visualisation of LETS protein patterns, influenced the cells. Therefore, we allowed 3T3 cells to first centripetally transport the gold particles, and subsequently detected the LETS protein on the dorsal cell surface by indirect immunofluorescence with CIG antibody. Figure 2 shows in the case of isolated cells two stages of the radial and centripetal movement of the particles from the cell edge where they were picked up, towards the perinuclear region (Fig. 2*a*) where they accumulated and eventually became internalised (Fig. 2*b*). It took 4–6 h before 10–20% of the cells had accumulated sufficient particles to show recognisable particle rings around the nucleus. The rings of particles (Fig. 2*a*) were not always completely closed, not even in isolated cells.

Four hours after exposure to gold particles—that is, before the particles became internalised, we fixed 3T3 cell cultures on glass coverslips and stained them for LETS protein. The result is shown in Fig. 3. Cells which were able to accumulate the gold particles all round the nucleus in the form of a ring showed only a few patches or no LETS protein at all (Fig. 3*a*, cell a), whereas cells with extended patterns of LETS protein still had the particles scattered randomly all over their surface (Fig. 3*a*, cells b and c). We also observed quite a few cells with incomplete gold rings. In many such cases the ring segment marked a cell-surface sector without LETS protein, whereas the complementary sector contained extended LETS protein patterns (Fig. 3*b*). We never found a big particle cluster on top of an extended LETS protein pattern. Clusters were often located, however, at the edge of a pattern.

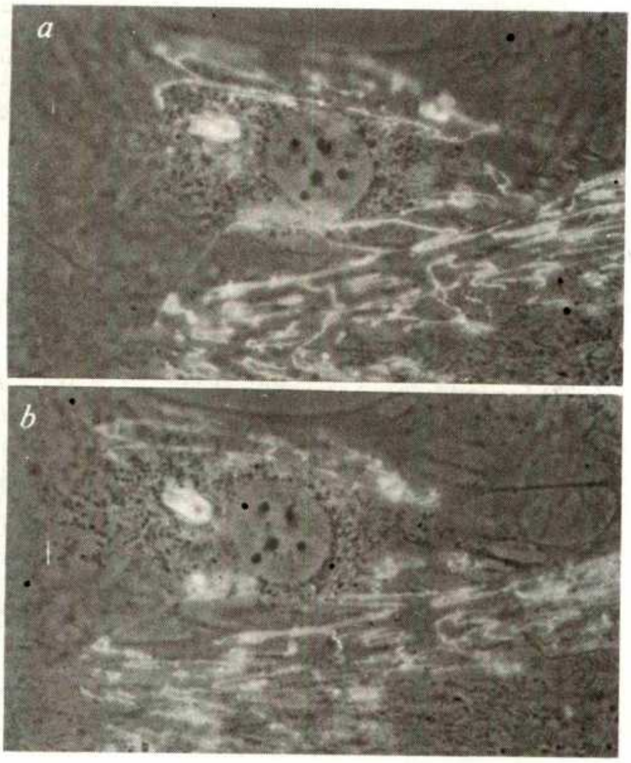

Fig. 1 Movements of LETS protein patterns on live 3T3 cells. Bar indicates 10 μm. 3T3 cells grown for 3 d on glass coverslips in DME + 10% calf serum were washed in DME, incubated at 37 °C for 15 min in rabbit anti-cold-insoluble globulin antibody (anti-CIG antibody) in DME (dilution 1:80). Anti-CIG antibodies bind to LETS protein[18] and also stain the same cellular structure as anti-LETS antibodies[6,9,11]. CIG antigen purification and antibody preparation were as described previously[9,11]. After a further washing in DME, the coverslips were incubated for 15 min at 37 °C in DME containing fluoresceinisothiocyanate-labelled goat anti-rabbit IgG (Meloy, Springfield, Virginia; dilution 1:20), washed again, and returned to DME + 10% calf serum. Live cells were observed in a Zeiss Photomicroscope III (63x; N.A. 1.4) as described previously[22]. *a*, LETS protein pattern on the dorsal surfaces of two adjacent 3T3 cells. Pictures were taken such that a phase-contrast image was created by the illumination from below the stage while an epi-illuminator produced and superimposed the fluorescent image. *b*, Same pattern 48 min later.

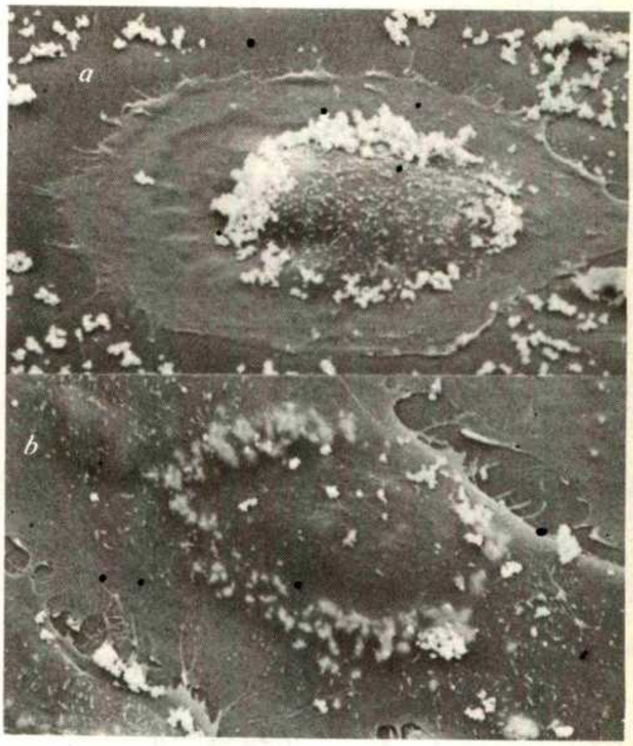

Fig. 2 Centripetal transport of gold particles in 3T3 cells. (Scanning electron microscopy; bar indicates 10 μm in horizontal direction.) Swiss 3T3 cells (Dr H. Green, MIT) were grown for 2–3 d on glass coverslips in DME supplemented with 10% calf serum. After adjusting a colloidal suspension of gold particles[16,17] to 290 mOsm by adding 49 mg ml^{-1} D-glucose (Baker, Phillipsburg, New Jersey), the 3T3 cell cultures were rinsed in PBS and incubated for 5 min in gold suspension at 37 °C. During this time the particles settled on top of the substrate and dorsal cell surfaces. The density of adherent particles is much higher in the substrate than on the cell surfaces. After exposure to gold particles, the coverslips were washed, incubated again in DME + 10% calf serum and returned to the incubator. Cells of cultures which are 3 d old or younger often retracted slightly after the staining procedure, but reverted rapidly to normal morphology. *a*, Isolated 3T3 cell with a complete ring of particles (arrow) 4 h after exposure to the staining procedure (tilt angle 60°). *b*, Another cell 22 h after staining. Between 12 and 22 h the rings of particles become internalised, as seen by the blurred image of the ring which is now below the cell surface (tilt angle 45°).

These observations suggest that the particles cannot move radially into or inside areas where LETS protein covers the cell surface in the form of extended patterns. One would expect, therefore, that removal of LETS protein from the cell surface would increase the centripetal transport of particles.

During a 10-min treatment of a 3T3 cell culture with 5 μg ml^{-1} trypsin in Dulbecco's Modification of Eagle's medium (DME), the predominant component removed from the dorsal cell surfaces is LETS protein[4,19,20]; yet the cells show no detectable shape alteration in response to this treatment. Therefore, 3T3 cells, grown for 5 d on glass coverslips, were washed in DME and incubated at 37 °C for 10 min in DME containing 5 μg ml^{-1} trypsin (Miles Laboratories, Kankahee, Illinois) and then returned to their previous culture medium for 45 min. Control cultures were similarly treated with DME or DME containing 5 μg ml^{-1} thrombin (Dr J. Fenton, Albany, New York) since it has been shown earlier that neither treatment affects the LETS protein[20]. Subsequently, the cells were exposed to gold particles as described in Fig. 2, and returned to their previous culture media for 4 h. After fixation of the preparations, we determined the percentage of cells which had accumulated particle clusters. In 20 randomly selected fields we counted

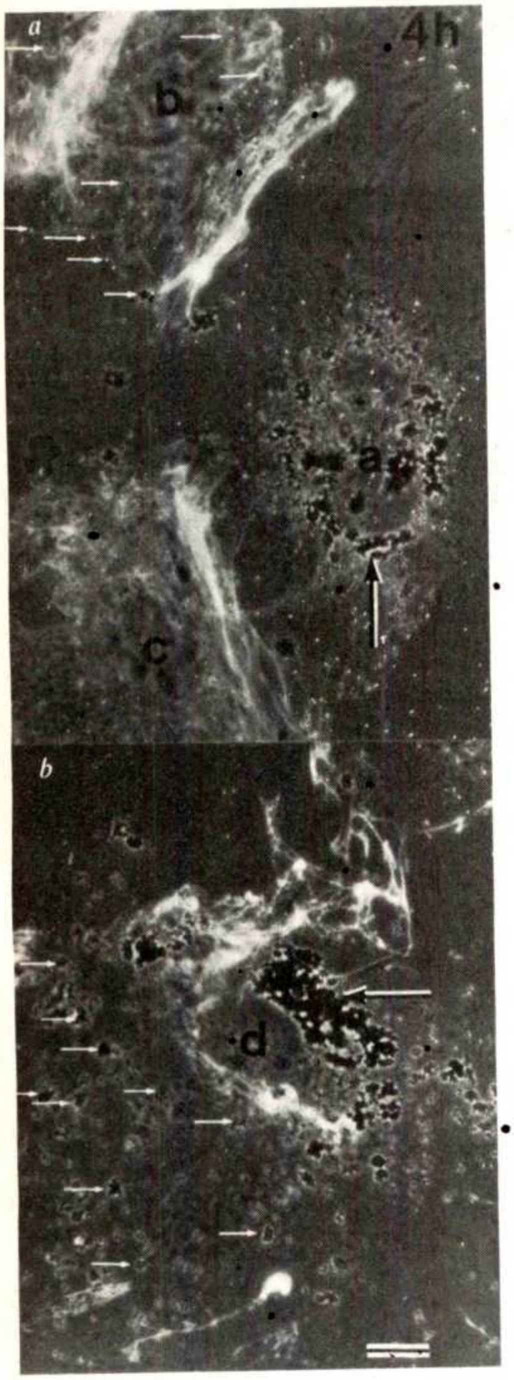

Fig. 3 Mutual exclusion of extended LETS protein patterns and areas with centripetal particle transport (bar indicates 10 µm). 3T3 cells were grown for 5 d without medium change on 12 × 12-mm glass coverslips and incubated in gold particle suspension as described in Fig. 2. Four hours later, the cells were fixed in 3.5% formaldehyde in PBS and incubated for 30 min at 37 °C with anti-CIG antibody in PBS (dilution 1:80). After a further washing in PBS, the coverslips were incubated for 30 min in DME containing fluoresceinisothiocyanate-labelled goat anti-rabbit IgG (dilution 1:20), washed again, mounted and observed in the same conditions as described in Fig. 1. *a*, 3T3 cell (a) with a complete ring of gold particles (arrow) and no LETS protein on the surface, and two other cells (b, c) with extended LETS protein nets but no particle ring. Randomly scattered small particle clusters are indicated by small white arrows. Big particle clusters appear black. *b*, Incomplete particle ring (arrow) with LETS protein patterns covering the complementary ring segment. Opposite to the ring a 'barrier' of LETS protein can be seen and behind it many particle clusters (arrow points to one of them), which were not moved towards the nucleus (d).

approximately 300 cells in each preparation and found the following percentages of cells with particle clusters. (Standard deviations describe variations over the selected fields). DME + 5 µg ml^{-1} trypsin: 64% (s.d. 15%); DME + 5 µg ml^{-1} thrombin: 20% (s.d. 8%); DME: 13% (s.d. 10%). The three- to four-fold increase in particle accumulation by the trypsin-treated cells compared with controls suggests that removal of LETS protein from the cell surfaces does increase the speed and extent of the centripetal particle transport around the cells' perimeters.

It seems, therefore, that the centripetal transport of surface-attached particles and, perhaps, the surface flow itself are locally inhibited by those surface networks which are predominantly built of LETS protein. It remains to be seen whether there is an inhibitory effect of LETS protein on cell motility in general, as was originally postulated by Hynes[23]. In view of the observation that LETS protein networks seem to originate from cell–cell contacts, the possibility that those networks inhibit surface flow seems to offer an intriguing mechanism of cell–cell interaction: It would suggest a way by which the surface movements in two or more cells become altered depending on direction and extent of their mutual contacts.

We thank Dr J. D. Watson for encouragement and support and Dr F. Solomon (MIT) for discussions. The experimental help of R. Lancaster, the photographic work of Ms S. Chait, and the excellent typing of Ms Madeline Szadkowski are gratefully acknowledged. This work was supported by the Cold Spring Harbor Laboratory Cancer Center (National Cancer Institute). G.A.B. is supported by the National Science Foundation. L.B.C. is supported by a fellowship from the Muscular Dystrophy Association.

Complement enhances antiviral antibody-dependent cell cytotoxicity

ANTIBODY-DEPENDENT cell cytotoxicity (ADCC) is an *in vitro* phenomenon that can be demonstrated with a variety of target cell systems and can be mediated by several types of effector cells[1–3]. The effectors in ADCC must bear a surface receptor for Fc, and this receptor binds with antibody which is in turn bound to the target cell. Only certain classes and subclasses of immunoglobulins can sensitise cells for ADCC[4,5]. Although the presence of a Fc receptor is necessary for ADCC, it is not sufficient since cells bearing such receptors may fail to mediate ADCC against a

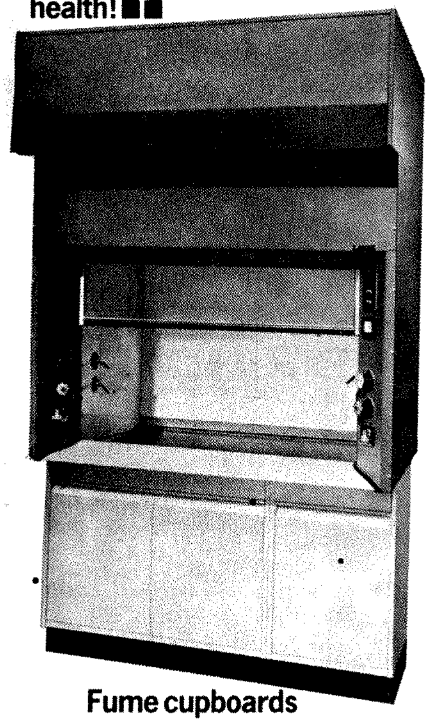
How to get in on the act

HEALTH AND SAFETY AT WORK

"It shall be the duty of every employer to ensure, so far as is reasonably practicable, the health, safety and welfare at work of all his employees...the matters to which that duty extends include in particular–the provision and maintenance of plant and systems of work that are, so far as is reasonably practicable, safe and without risks to health!"

"It shall be the duty of the person having control of any premises...to use the best practicable means for preventing the emission into the atmosphere from the premises of noxious or offensive substances and for rendering harmless and inoffensive such substances as may be emitted."

"It shall be the duty of every employer to conduct his undertakings in such a way as to ensure, so far as is reasonably practicable, that persons not in his employment who may be affected thereby are not thereby exposed to risks to their health or safety."



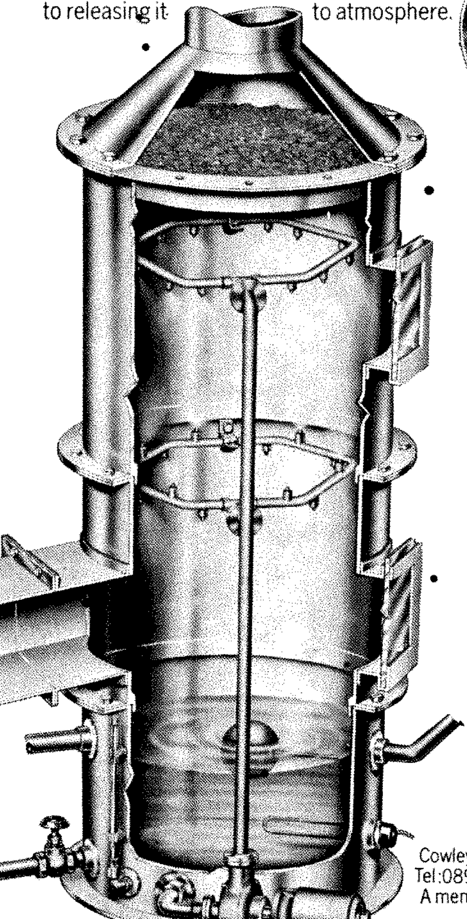
Fume cupboards

A poorly designed fume cupboard or fume extraction system can allow dangerous and corrosive fumes to leak back into a laboratory, which can not only ruin expensive instruments but also injure or even kill people working in the room.

Morgan and Grundy are specialists in the science of fume extraction and, to meet every conceivable need, our design engineers have evolved the widest range of fume cupboards in Europe.

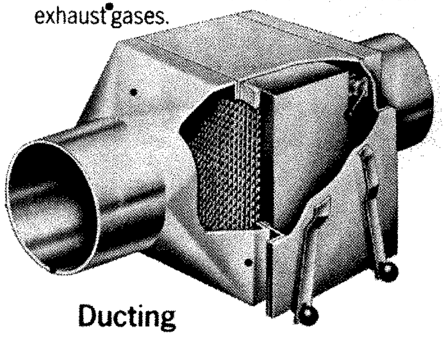
Fume Scrubbers

Morgan and Grundy can supply Fume Scrubbers to remove aerosols and vapours from fume extraction exhausts. The exhaust gases are fed into the 'wet' side of the scrubber and a suitable liquid (caustic solution, for example, for acid vapours) is pumped in as a fine jet at the top. It is dispersed over a medium and picks up the vapour. The cleaned exhaust air is then forced up the 'dry' side of the scrubber to remove the majority of the moisture prior to releasing it to atmosphere.



Filters

One type of filter supplied by Morgan and Grundy cleans input air, the other removes contamination from the exhaust. The Absolute Filter shown here, for example, can be mounted singly or in banks to remove radioactive material from exhaust gases.



Ducting

In the design of fume extraction systems, Morgan and Grundy specify the most suitable ducting material and ensure that noise levels are kept to a minimum by the use of swept bends and fittings and the use of ducting of sufficient cross sectional area to maintain a velocity of between 300/395m/min.

Where condensation is liable to occur adequate falls are allowed, with suitable drain points.

Where necessary we fit fire dampers. This especially applies where PVC ducting passes through fire break walls.

If you're concerned with Health and Safety at work and you want to get in on the act, we'll be pleased to help.

REASON, EXPERIMENT & MYSTICISM IN THE SCIENTIFIC REVOLUTION

Edited by
M. L. RIGHINI BONELLI AND
WILLIAM R. SHEA

Until recently mysticism was excluded from the history of science and medicine on the grounds that it was irrelevant to the mainstream of scientific thought. New developments in the philosophy of science have cast doubt upon the overall achievement of modern science. Consequently the distinction between steps in the progress of science that have led to great discoveries, and those which have led to dead ends has become blurred. This means that historians of science have had to busy themselves with false starts as well as successful arrivals.

In this collection of essays by outstanding European and American scholars the interplay between reason, experiment and mysticism in the scientific revolution of the seventeenth century is discussed and the crucial question is asked: are mystical traditions and 'modern' elements in the scientific revolution antagonistic or, paradoxically, complementary extremes?

£13.00

LORD KELVIN & THE AGE OF THE EARTH

JOE D. BURCHFIELD

A controversial figure during his lifetime, Lord Kelvin's wide-ranging interests led him to become involved in a public dispute on the validity of the doctrine of uniformitarianism in geology.

Equally at home with both the abstract theories and the practical applications of science, Kelvin was an accomplished mathematician, a successful engineer, and a scientific theorist whose interests ranged over every branch of physics including physical astronomy and physical geology.

This book discusses Kelvin's influence on late Victorian geology, his passionate belief that uniformitarianism ignored the established laws of physics and that a great reform was needed to return geology to the path of true science. It describes the disputes in which Kelvin's beliefs involved him with such eminent scientists as Darwin, Huxley and Wallace, and how his theories influenced their work.

particular target[1–3,6,7]. Similarly, union of effectors with targets by means of a different receptor such as the complement receptor may not result in cytotoxicity[8,9]. Whether the efficiency of different cells at mediating ADCC depends on the number, type or affinity of Fc receptors, whether a cooperation between different types of surface receptors is needed[10] or whether some property of the target cells decides the outcome of contact between effectors and targets, has not been established. It is likely that ADCC occurs only if a sufficient union is established between effector and target cell. Such a union could be generated by bonds between the target cell and two types of surface receptors on the effectors—such as the Fc receptor and the complement receptor, both of which are present on effector cells[10–12]. Using herpes-virus infected target cells we here provide support for this hypothesis and show that the addition of complement, at levels below those required for antibody–complement lysis, considerably enhances

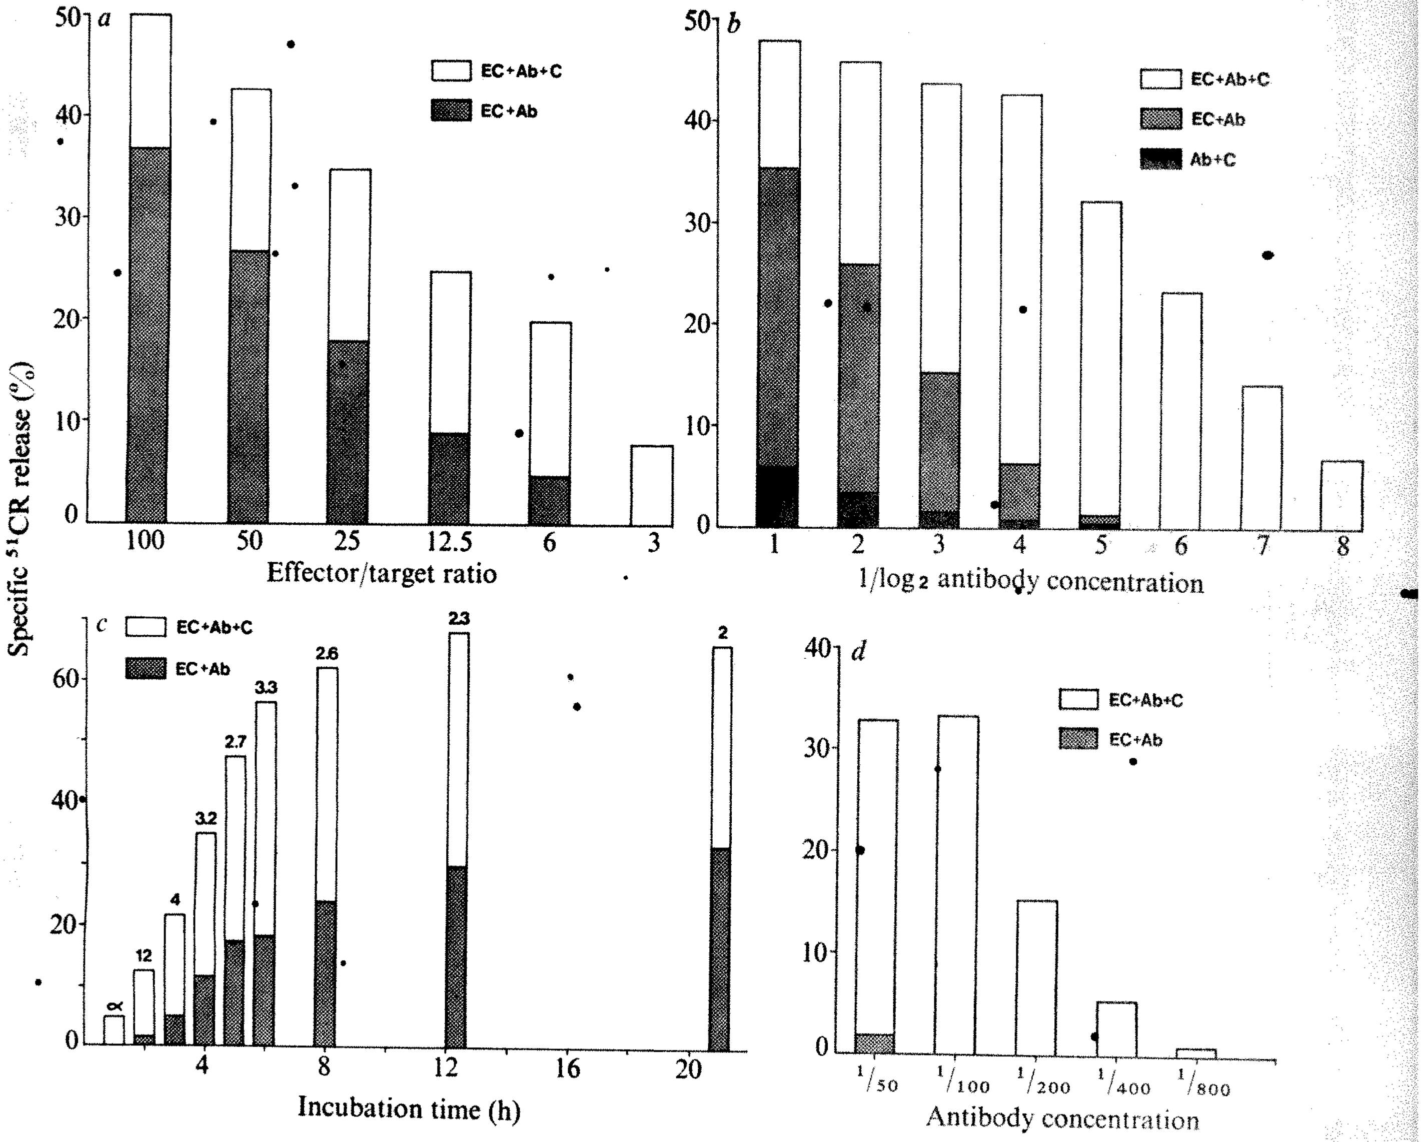

Fig. 1*a*, Enhancement of neutrophil-mediated ADCC at various effector-to-target cell ratios by rabbit complement. Neutrophils were collected from the bovine mammary gland and purified[14]. Target cells were infected with IBR virus and labelled with $Na_2\ ^{51}CrO_4$ 16 h before the start of assays[6]. Target cells were sensitised with a 1/800 final concentration of hyperimmune bovine anti-IBR serum. Rabbit complement was added at a final concentration of 1/70. At this concentration, lysis of antibody-sensitised target cells in the absence of effector cells was 2% above background (12% in a 6-h assay). Assays were performed in microtitre trays[5]. The percentage specific ^{51}Cr release was computed by the formula

$$\text{specific release (\%)} = \frac{\text{radioactivity in test supernate} - \text{control}}{\text{total releasable radioactivity} - \text{control}} \times 100.$$

The neutrophils in the absence of anti-IBR serum failed to give release of ^{51}Cr above background either in the presence of media alone or media plus 1/70 rabbit complement. EC, effector cells; Ab, anti-IBR serum; C, complement, *b*, Enhancement by complement of neutrophil-mediated ADCC at different concentrations of anti-IBR serum. Assay as for (*a*). The assay was run at a neutrophil/target cell ratio of 100:1. The final antiserum concentration at level 1 was 1/100 and 8, 1/12,800. Rabbit complement was included at a final concentration of 1/70. *c*, Enhancement by complement of neutrophil-mediated ADCC at different durations of assay. The neutrophil/target cell ratio was 100:1, the final concentration of sensitising anti-IBR serum 1/800 and rabbit complement 1/70. Figures at the top of each column refer to the magnitude of the specific release in the presence of complement compared to that without complement. The background releases ranged from 6.7% at 1 h to 18.4% at 21 h in media alone and from 8.9% at 1 h to 22% at 21 h in the presence of complement. *d*, Enhancement of lymphocyte-mediated ADCC by rabbit complement. Lymphocytes were collected from peripheral blood by Ficoll–Hypaque flotation and were further purified by passage over glass wool to remove adherent cells[13]. The preparation gave a low level of specific ^{51}Cr release (2%) at the highest concentration of serum tested, possibly due to some remaining macrophages or neutrophils. The assay was performed for 6 h in the presence or absence of 1/70 final concentration of rabbit complement. The level of specific release by complement in the absence of effector cells was 5% at 1/50, 3% at 1/100 and 2% at 1/200 of anti-IBR serum, respectively.

ADCC and, furthermore, permits cells to mediate ADCC that in the absence of complement could not do so.

Previously, we have described the cell types and conditions necessary to demonstrate ADCC against bovine antibody sensitised bovine target cells infected with infectious bovine rhinotracheitis (IBR) virus—a bovine herpesvirus[6]. We have compared several cell types and have shown that neutrophils perform best and that lymphocytes fail to mediate ADCC[13]. Lymphocytes, however, do show activity against erythrocyte target cells[6]. We hypothesised that since the cells that mediate ADCC had complement receptors as well as Fc receptors[11,12], then if bonds between effectors and targets were additionally engaged by the complement receptor then cytotoxicity should be enhanced. Such enhancement should be more apparent in those conditions where cytotoxicity was submaximal, such as low effector-to-target cell ratios, low concentrations of sensitising antiserum and short term assays. That the addition of complement does enhance ADCC is shown in Figs 1–3. Also shown are data that support the predictions—enhancement was more apparent at low effector-to-target cell ratios (Fig. 1*a*), low concentrations of sensitising antiserum (Fig. 1*b*) and short duration assays (Fig. 1*c*). One explanation for the enhanced cytotoxicity could be that in addition to ADCC we were also observing antibody-complement mediated cytotoxicity. This possibility was considered remote since the levels of complement used in the experiments either failed to exhibit or gave only low levels of cytotoxicity against targets in the absence of effector cells. At high complement concentrations, however, such antibody-complement cytotoxicity was observed, indicating that the material did possess complement activity (data not shown). Furthermore, the rabbit complement preparation was not providing an additional sensitising antibody since heat inactivated material failed to give enhancement.

Not only could the addition of complement lead to enhancement of cytotoxicity, but cell types incapable of mediating ADCC against the virus-infected cells could be made to do so by the addition of complement. Thus lymphocytes alone could not mediate ADCC (Fig. 1*d*), but ADCC became readily apparent on addition of complement.

These experiments support the hypothesis that multiple binding of effectors to target cells will be followed by enhanced cytotoxicity. It needs to be established if the effect is the result of a more tenacious bond or has some other explanation such as the generation of a biochemical signal that results in target cell lysis. Finally, since ADCC has been considered as an *in vitro* model for an antiviral mechanism of defense[6], the implications of our results should be considered in terms of the possible part that complement might have in enhancing recovery from certain viral infections.

Selective incorporation of H-2 antigenic determinants into Friend virus particles

IN susceptible mice, Friend murine leukaemia virus (FV) produces fatal erythroleukaemia[1] characterised by rapid onset of splenomegaly and viraemia in 4–5 d and leading to the death of the animal in as little as 3–4 weeks. In the replication of this enveloped, C-type RNA virus, assembly occurs at the surface of infected cells where the particles mature by budding[2]. We have examined the question of whether host cell surface glycoproteins are incorporated into the virion as the host cell membrane becomes part of the completed particle during the budding process. In particular, serologically identifiable alloantigens governed by the $H\text{–}2K$ and $H\text{–}2D$ genes of the major histocompatibility complex and found on cell surfaces have been sought in lysates of serum-derived FV.

Serum collected from mice infected 10–14 d previously with a high dose of NB-tropic FV was the source of virus. After clarification of the serum at 6,800*g*, virus was pelleted by centrifugation at 100,000*g*. The pellet was resuspended in buffered saline containing detergent (Nonidet P-40, 0.25%) to disrupt the virus. This preparation was then examined for the presence of $H\text{–}2K$ and $H\text{–}2D$ antigens of the host mouse by determining its capacity to inhibit the cytotoxic activity of various anti-$H\text{–}2$ antisera. Figure 1 shows the results of an experiment with virus collected from the serum of FV-infected (BALB/c × BALB.B)F_1 mice ($H\text{–}2^{\mathrm{b}}/H\text{–}2^{\mathrm{d}}$). The preparation was tested for its capacity to inhibit the complement-mediated lysis of uninfected (BALB/c × BALB.B)F_1 lymph node target cells with antisera monospecific for either $H\text{–}2K^{\mathrm{b}}$, $H\text{–}2D^{\mathrm{b}}$, $H\text{–}2K^{\mathrm{d}}$ or $H\text{–}2D^{\mathrm{d}}$ antigenic specificities (Table 1). Only lysis by anti-$H\text{–}2D^{\mathrm{b}}$ antiserum {(A × HTI)F_1 anti-EL4; $H\text{–}2^{\mathrm{a}}/H\text{–}2^{\mathrm{i}}$ anti-$H\text{–}2^{\mathrm{b}}$} was detectably inhibited (Fig. 1*a*). An identical pattern of inhibition was seen using a second anti-$H\text{–}2D^{\mathrm{b}}$ antiserum (BALB/c anti-BALB.G; $H\text{–}2^{\mathrm{d}}$ anti-$H\text{–}2^{\mathrm{g}}$) raised against normal spleen cells rather than EL4 tumour cells. Similarly, in virus grown in (C57BL/6 × DBA/2)F_1 mice, which are also $H\text{–}2^{\mathrm{b}}/H\text{–}2^{\mathrm{d}}$ heterozygotes but with a different genetic background, $H\text{–}2D^{\mathrm{b}}$ alloantigen but not $H\text{–}2K^{\mathrm{b}}$, $H\text{–}2K^{\mathrm{d}}$ or $H\text{–}2D^{\mathrm{d}}$ was detected. Neither sham virus preparations made from non-viraemic BALB.B mouse serum nor preparations made from viraemic BALB/c mouse serum produced inhibition of lysis by any of the four antisera (data not shown).

Table 1 Anti-H-2 antisera characteristics

	Alleles recognised	Private specificity
(A × BALB.B) F_1 anti-BALB/c	$H\text{–}2K^{\mathrm{d}}$, $H\text{–}2I^{\mathrm{d}}$	H-2K.31
BALB.G anti-BALB/c	$H\text{–}2D^{\mathrm{d}}$	H-2D.4
(A × BALB.G) F_1 anti-BALB.B	$H\text{–}2K^{\mathrm{b}}$, $H\text{–}2I^{\mathrm{b}}$, $H\text{–}2S^{\mathrm{b}}$	H-2K.33
(A × HTI) F_1 anti-EL4	$H\text{–}2D^{\mathrm{b}}$	H-2D.2
BALB/c anti-BALB.G	$H\text{–}2D^{\mathrm{b}}$	H-2D.2

Several criticisms of the experimental techniques used are in order. The augmentation of lysis in the presence of virus above controls is difficult to rationalise (Fig. 1*b*, *c* and *d*). It is not due to the NP-40 detergent, since controls contain identical amounts of detergent. A contaminant in the 100,000*g* pellet may be responsible, because no such augmentation of lysis was observed in recent preliminary experiments using sucrose density-gradient purified virus. Contamination was not the cause of inhibition of anti-$H\text{–}2D^{\mathrm{b}}$-mediated cytolysis, however, for three reasons. First, inhibition of lysis by contaminating plasma membranes would be expected to produce inhibition of all four antisera. Second, BALB.B ($H\text{–}2^{\mathrm{b}}$) non-viraemic serum preparations were not inhibitory. And third, BALB/c ($H\text{–}2^{\mathrm{d}}$) virus preparations were also not inhibitory. Thus, $H\text{–}2D^{\mathrm{b}}$ was the

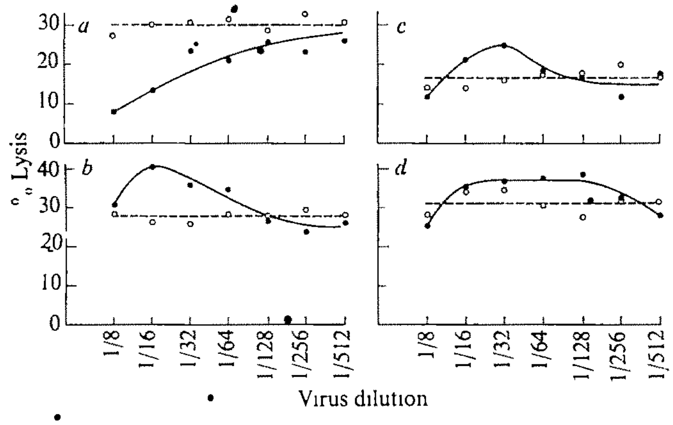

Fig. 1 Serum, prepared from blood collected from (BALB.B ×BALB/c)F_1 mice given 10^4 spleen focus forming units of Friend virus 10–14 d previously, was centrifuged at 6,800*g* for 15 min and the supernatant recovered After re-centrifugation of the serum at 100,000*g* for 90 min, the supernatant was discarded and the pellet resuspended in 0 1 ml phosphate-buffered saline (PBS) containing 1mM EDTA to which was added 0.01 ml of a 2.75% (v/v) solution of NP-40. After 1 h incubation at 4 °C, 0 11 ml of a 25% (w/v) bovine serum albumin (BSA) solution was added to neutralise the NP-40 and the entire mixture diluted 1:8 with medium 199 containing 20% foetal calf serum. Control preparations, lacking viraemic serum pellets, contained only PBS, EDTA, NP-40, BSA and 199 with 20% FCS in proportions identical to virus preparations. One-tenth ml of either virus or control preparations was aliquoted into 5-ml Falcon plastic culture tubes in serial twofold dilutions. To these was added 0.1 ml of monospecific anti-*H–2* antiserum appropriately diluted in 199 with 20% FCS After 10 min incubation at room temperature, 0 05 ml of ^{51}Cr-labelled (BALB.B×BALB/c)F_1 mesenteric lymph node cells (10^6 ml^{-1}) was added followed by the addition of 0 05 ml of neat guinea pig serum as a complement source. After 1 h at 37 °C in a 5% CO_2 atmosphere, 0.3 ml of PBS containing 10 mM EDTA was added to terminate the reaction, the cultures spun at 300*g* for 5 min and 0.3 ml of supernatant recovered for counting γ radiation Curves were generated in the presence of either virus preparations (●) or control preparations (○). Anti-*H–2* antisera were raised by the alloimmunisations—*a*, (A×HTI)F_1 anti-EL4, $H{-}2^{a}/H{-}2^{i}$ anti-$H{-}2^{b}$—anti-$H{-}D^{b}$ antiserum; *b*, (A×BALB.G)F_1 anti-BALB.B, $H{-}2^{a}/H{-}2^{g}$ anti-$H{-}2^{b}$—anti-$H{-}2K^{b}$, *c*, BALB.G anti-BALB/c, $H{-}2^{g}$ anti-$H{-}2^{d}$—anti-$H{-}2D^{d}$, and *d*, (A×BALB.B)F_1 anti-BALB/c, $H{-}2^{a}/H{-}2^{b}$ anti-$H{-}2^{d}$—anti-$H{-}2K^{d}$.

sole antigen detected, and it was only detected in virus-containing preparations from mice with the $H{-}2D^{b}$ allele.

H–2 antigen activity of host cell specificity has been detected before in an enveloped RNA virus. Hecht and Summers[3] observed inhibition of cytolysis mediated by anti-$H{-}2^{k}$ antisera in the presence of highly purified vesicular stomatitis virus grown in L cells ($H{-}2^{k}$). Because of the purification techniques used, they concluded that the *H–2* antigens were an integral part of the virion. Their finding that both $H{-}2K^{k}$ and $H{-}2D^{k}$ antigens were present in the virion could be explained by the random distribution of *H–2* molecules on plasma membrane destined to become virus envelope. Our finding of only one of four host cell *H–2* specificities in FV suggests that the inclusion of *H–2* antigens in virus particles is selective rather than random.

The $H{-}2^{b}$ haplotype confers relative resistance to FV disease[4]. One gene responsible for this resistance, *Rfv*-1, maps in or near the $H{-}2D^{b}$ region[5] Resistance in BALB.B mice results in strong rejection of implanted cells of syngeneic FV-induced tumour lines, whereas BALB/c mice resist implants of syngeneic FV tumour cells poorly[6]. Characteristic of resistance in BALB.B but not BALB/c mice is the appearance of cytotoxic T lymphocytes specific for the syngeneic tumour. The lytic activity of these BALB B T cells *in vitro* is subject to *H–2* restriction; that is, lysis can only be demonstrated against target cells expressing both FV and $H{-}2^{b}$ antigens[7].

Present evidence for the basis of *H–2* restriction in this and other T-cell killing systems supports the hypothesis that *H–2* molecules associate with virus molecules on the target cell surface in such a way as to serve as an 'altered-self' marker recognisable by the immune T lymphocyte[8]. Evidence in favour of a physical association at the cell surface between virus and *H–2* molecules has been obtained in this laboratory with the demonstration that capping of FV antigens on $H{-}2^{b}$ tumour cell surfaces causes partial co-capping of *H–2D* but not *H–2K* antigens[9].

If, as the evidence indicates, *H–2* antigens physically associate with virus antigens on the cell surface, then the appearance of *H–2* in the virion is most likely the consequence of such an association at the site of virus budding. The inclusion of only one of four possible *H–2* antigens in the virus, however, implies that not all *H–2* molecules are equal in their capacity to bind to cell surface virus antigens. The selective inclusion of *H–2* molecules in C-type virus particles is in keeping with the sporadic detection during biochemical analysis of MuLV of a glycoprotein[10] of 45,000 molecular weight. The molecular weight and irregular detection of this constituent suggests that it may consist in part of host cell *H–2*, inclusion of which in virions depends on its capacity to bind to virus molecules.

Prevention of experimental allergic encephalitis in Lewis rats by rat and bovine spinal cord proteins

EXPERIMENTAL allergic encephalitis (EAE) is an inflammatory autoimmune disease of the central nervous system (CNS) that is mediated by T lymphocytes sensitised to the organ-specific basic protein (BP) of CNS myelin[1]. Lesions of delayed hypersensitivity develop in the brain and spinal cord when sensitised lymphocytes traverse the walls of CNS blood vessels and react with the target antigen in myelin[1]. EAE can be prevented by injecting BP in Freund's incomplete adjuvant (FIA) before challenge, suppressed by injecting BP soon after challenge and treated by injections of BP after clinical symptoms appear[4]. Prevention, suppression and treatment are immunologically specific for BP and can be dissociated from the production of humoral antibody against BP[5]. The demonstration that pretreatment of guinea pigs with bovine spinal cord protein (BSCP)[6,7] prevented the development of EAE[8,9] is thus of considerable importance because BSCP is chemically and antigenically distinct from bovine BP and is not encephalitogenic. As pretreatment with SCP induced a state of nonspecific unresponsiveness to bovine BP in the guinea pig, we investigated whether SCP had anti-encephalitogenic activity in the Lewis rat, a highly inbred rat strain used extensively for the study of EAE. We report here that Lewis rats pre-

Table 1 Encephalitogenicity of rat BP, RSCP and BSCP in Lewis rats

Rat BP	30	7/7	12.5	3.4	1.7
Rat BP	50	10/10	13	3.0	1.8
RSCP	300	0/6	—	0	0
BSCP	400	0,8	—	0	0

*Animals were injected in the left hind foot pad with 0.1 ml of an inoculum prepared by emulsifying the appropriate amount of antigen in 0.05 ml of saline with 0.05 ml of FIA containing 200 μg of *M. butyricum*.

†Average scores for clinical symptoms were graded as follows; +, transient weight loss; ++, limp tail; +++, hind end weakness and/or incontinence; ++++, complete loss of tone in tail (string tail) and paralysis.

‡Average score for lesions in brain and spinal cord graded from 0 to 2+ according to Levine *et al.*[12].

treated with rat SCP (ref. 10) were protected against EAE, as they did not develop the disease when they were subsequently immunised with rat myelin BP in complete Freund's adjuvant (CFA).

Homologous RSCP was investigated first because immunodiffusion studies with anti-BSCP serum and anti-RSCP serum indicated that bovine, monkey, human and rabbit SCP were antigenically closely related[7,10], while RSCP was significantly different. The homologous rat BP was used for the induction of EAE. RSCP was purified from rat spinal cord[10]. Rat BP containing both the L and the S BP was prepared from rat brain by the method of Deibler *et al.*[11].

Male Lewis rats weighing about 250 g were injected in the right hind foot pad at different intervals with 0.1 ml of inoculum prepared by emulsifying the required amount of RSCP with an equal volume of FIA. Control rats were not treated or were injected with bovine gamma globulin (BGG) emulsified with FIA. At the appropriate time, the animals were challenged by injecting 0.1 ml of an FIA emulsion containing 30 μg of rat BP and 200 μg of *Mycobacterium butyricum* into pads in the left hind foot.

Table 1 shows that 20 μg of rat BP was sufficient to produce clinical and histological EAE in all animals tested. Disease onset usually occurred 15 d after challenge. Higher doses of rat BP induced more severe disease with onset 12–13 d after challenge. The 30 μg of rat BP used to induce EAE in all pretreated animals was selected as a moderately severe challenge dose. Neither RSCP nor BSCP were encephalitogenic in Lewis rats at levels of 300 and 400 μg, respectively.

Results of pretreatment schedules in which the total amount of RSCP used varied from 300 to 900 μg, and the pretreatment interval extended from 5 to 21 d are recorded in Table 2. Pretreatment with three weekly doses of 100 μg of RSCP protected five out of six animals from clinical and histological EAE. Doubling or tripling the amount of RSCP injected over 2 or 3 week intervals gave complete protection of all animals, while control animals that received similar amounts of BGG were not protected.

‡Average score for lesions in brain and spinal cord graded from 0 to 2+.

When the pretreatment intervals were shortened to 10 or 5 d, however, three 100-μg doses of RSCP did not protect. The results suggest that the amount of RSCP needed for protection is inversely related to the length of the pretreatment period.

Heterologous BSCP also had the capacity to protect Lewis rats against EAE induced with rat BP, although approximately seven times as much BSCP was required to achieve the same degree of protection provided by 300 μg of RSCP (Table 3). The fact that RSCP and BSCP prevent EAE in the rat as well as in the guinea pig suggests that SCP may be used as a nonspecific anti-encephalitogenic agent

One possibility that can probably be ruled out is that of specific immunosuppression due to contamination of RSCP with rat BP because SCP was extracted from bovine or rat spinal cord (not de-fatted) with 0.05 M acetate buffers, a procedure that does not solubilise detectable amounts of BP. Furthermore, the amount of rat BP in 1.0 mg of purified RSCP was found not to exceed 30 ng by a competitive inhibition radioassay (unpublished results). This method measures the extent to which binding between a known amount of ^{125}I-rat BP and a fixed volume of a standard rabbit anti-rat BP serum is inhibited by varying amounts of non-radiolabelled BP using polyethylene glycol to precipitate antibody-bound ^{125}I-BP[13,15] A similar radioimmunoassay kindly performed by Dr V. Lennon of the Salk Institute, showed that 1.0 mg of BSCP contained 15 ng of BP. Thus the 2.0 mg of BSCP required for protection against EAE could not have contained more than 30 ng of BP, an amount far less than the 10,000 ng of BP reported to be the lowest amount capable of preventing EAE in the guinea pig[16].

The mechanism of the protective action of SCP is not clear. Data on the effect of SCP-pretreatment on the lymphocytes mediating EAE suggest that the mechanism is likely to be complex For example, SCP-pretreated guinea pigs regularly displayed delayed skin hypersensitivity to BP after challenge but there was no correlation between the degrees of cutaneous reactivity and protection from disease[9].

The protective activity may be related to the location of SCP in nervous tissue. Indirect immunofluorescence studies using rabbit anti-sera showed that SCP is localised in the axons of neurones in the central and peripheral nervous systems and seems to be absent from the surrounding myelin sheaths (unpublished results). Protective activity might also involve non-specific suppression of selected T-cell function by anti-SCP antibody in a manner analogous to that of the anti-θ thymic antibody because RSCP is a component of rat thymus[10]

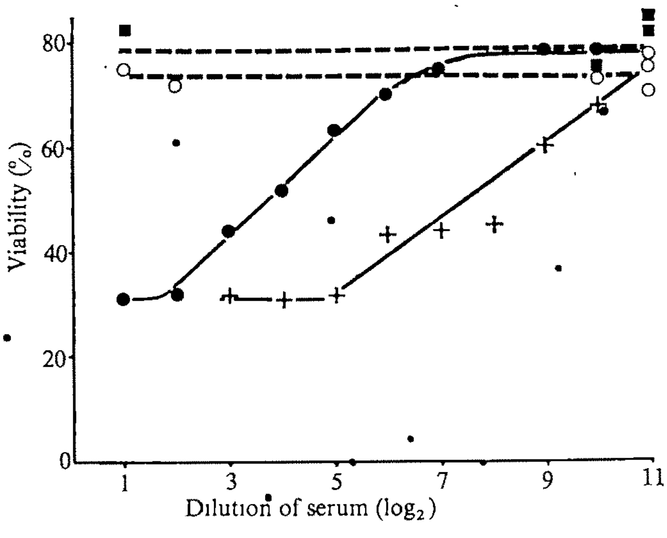
Gangliosides as surface antigens on cells isolated from the rat cerebellar cortex

GANGLIOSIDES are a class of complex glycolipids characterised by their content of *N*-acetyl neuraminic acid. They are present in many tissues, but are found in highest concentration in those of the nervous system. At one time they were thought to be characteristic of the neurone, but the analysis of cell fractions from a number of species indicates that they are present in glia and myelin as well as in the neuronal elements[1,2]. The investigation of subcellular fractions suggests that most of the ganglioside is located in the plasma membrane and their functional significance is still uncertain. We have investigated the effect of anti-ganglioside serum on suspensions of cerebellar cells from immature rats. Trypan blue exclusion and ^{51}Cr release methods were used as indicators of cytotoxic activity The results indicate that ganglioside is located at the outer surface of the plasma membrane in 60–80% of the cells. The remainder do not seem to exhibit the reactive hapten upon their surface. The experiments also demonstrate the value of complement mediated cytotoxicity as a method of studying surface lipid haptens in the cells of the nervous system.

Suspensions of cerebellar cells were freshly prepared from rats 5–12 d post-natally[3]. The final suspension contained 5–15 × 10^6 cells per ml in Krebs bicarbonate ringer containing glucose, 15 mM, and bovine serum albumin, 0.3% w/v Antisera were raised in rabbits against the total ganglioside fraction isolated from postmortem human brain tissue The total ganglioside fraction was isolated from the chloroform–methanol extract by partitioning against saline, and further purified from the upper phase by dialysis and barium precipitation by the method of Wolfe[4]. Rabbits were

Fig. 1 Cytotoxicity of rabbit anti-ganglioside serum for dissociated rat cerebellar cells. ●, Anti-ganglioside serum/cerebellar cells from 6-d-old rats, +, Anti-ganglioside serum/cerebellar cells from 12-d-old rats, ■, control normal rabbit serum/cerebellar cells from 6-d-old rats, ○, control. normal rabbit serum/cerebellar cells from 12-d-old rats Guinea pig complement (25 μl) was added followed by a further 0.5-h incubation Cytotoxicity assays using Trypan blue (0.2%) were carried out in micrtoture trays. The cell suspension was diluted to contain 10^6 cells ml^{-1} Antiserum (25 μl) was added to 50 μl cell suspension and incubated at 37 °C for 30 min Fresh neat guinea pig serum (25 μl) containing complement was then added and after shaking, incubated for a further 30 min. For counting, the supernatant was removed and one drop of Trypan blue (0.2%) in Krebs ringer added



immunised with the total ganglioside mixture and either bovine or human serum albumin as carrier, emulsified in complete Freunds adjuvant[5]

The viability of the cell preparation was generally better than 90% (mode of 96%, range 80–99%). Exposure to normal rabbit serum and guinea pig complement did not affect the viability over a period of hours Anti-ganglioside serum was found to be cytotoxic for cerebellar cells in the presence of guinea pig complement (Fig. 1). A fraction of the cells, however, were found to be resistant, and even repeated exposure to antiserum and complement failed to increase the proportion of the cells killed (Fig 2). From Fig 1 it can be seen that antiserum was more effective against cells from 10-d-old animals than those from 5-d-old animals, although the proportion of cells killed remains approximately constant. The total ganglioside concentration of the rat cerebellum increases sharply 5 d after birth, indicating an increase in membrane concentration[6]. The present findings suggest that this increase may initially be restricted to certain cells, at least for the gangliosides GM1 and GD1b, the suspected antigenic members of the ganglioside mixture[7,8].

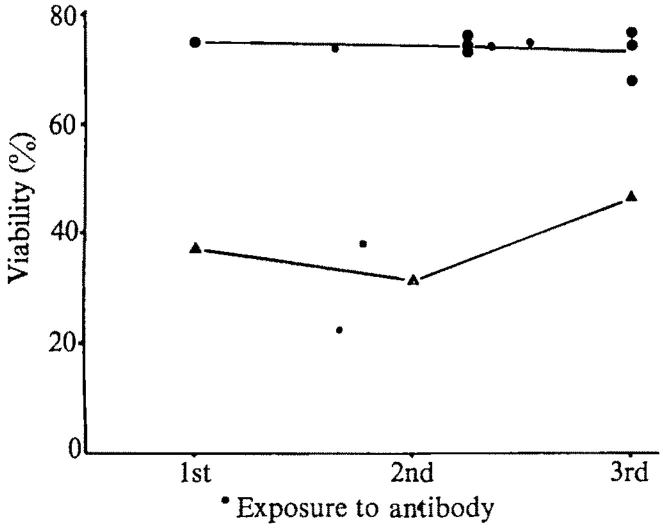


Fig. 2 Effect of repeated exposure of cerebellar cells to anti-ganglioside serum and complement. Viability declines to 30–40% on addition of antibody and reaches a plateau The surviving cells are unaffected by subsequent treatment with antibody ▲, Anti-ganglioside serum, ●, normal rabbit serum (control)

The specificity of the antibody for ganglioside was demonstrated by absorption with a hapten–lecithin mixture in the weight ratio of 1:3. Ganglioside (0.01 mg) completely removed all cytotoxic activity from 0.1 ml serum Lecithin alone was ineffective Absorption with an acetone dried rat brain powder removed both complement-fixing activity against ganglioside and cytotoxicity to cerebellar cells. The activity of the antiserum was unaffected by similar absorptions with rat liver powder A further indication of the specificity of the reaction for ganglioside is that anti-galactocerebroside sera having high titres of complement-fixing activity against galactocerebroside–auxiliary lipid mixtures and purified myelin fractions of rat brain, was not cytotoxic for cerebellar cells.

The antigen on the cell surface seems to be a glycolipid and not a glycoprotein. After partitioning of a chloroform–methanol extract of cerebellar cells the ability to absorb out cytotoxic acivity from antiganglioside serum was present in the water-soluble upper phase The lower phase lipids and the insoluble residue were ineffective (Fig 3). Absorption of antibody was dependent on the presence of the auxiliary lipid lecithin, further confirmation that we are dealing with a lipid hapten.

Ganglioside can be demonstrated in cells of the granular layer of the cerebellum of the adult rat by the immuno-peroxidase method[9] Histochemical localisation in tissue sections, however, does not provide information on the number of cells with surface antigen The present data suggests that in the immature animal, at least, this is in the region of 60–80%. The nature of the cell fraction

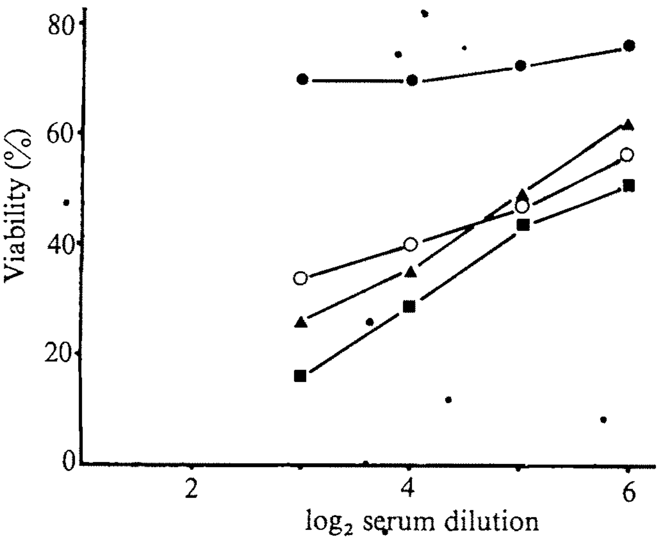

Fig. 3 Cytotoxicity of anti-ganglioside serum with fractions obtained by chloroform–methanol treatment of cerebellar cells. ●, Upper phase absorbed; ○, residue absorbed, ▲, lower phase absorbed, ■, unabsorbed serum About 5 × 10^7 cerebellar cells ml^{-1} were extracted in chloroform–methanol (1 1, v/v) This insoluble residue was centrifuged and resuspended by homogenisation and ultrasonication in 0 5 ml saline Chloroform was added to the lipid extract to make it 2:1 chloroform–methanol and then partitioned against 0 2 volume of saline Both upper and lower phases were evaporated to dryness under N_2 Lecithin (100 μg) was added to the upper phase Both residues were re-suspended in 0 5 ml saline with the aid of ultrasound One-quarter dilution of serum (0 5 ml) was added to each of the three fractions and stored at 4 °C overnight After centrifugation the cytotoxic activity of the absorbed and a control serum for rat cerebellar cells was determined Cytotoxicity was measured by ^{51}Cr release Cerebellar cells were incubated with 50 μCi ^{51}Cr in saline for 0 5 h They were diluted in 3 ml Krebs buffer and centrifuged through 4% bovine serum albumin in Krebs buffer to obtain labelled intact cells The supernatant was removed and the walls of the tube wiped before resuspending. Cell suspension (100 μl), serum (50 μl) and guinea pig complement (50 μl) were incubated for 1 h at 37 °C The reaction was stopped in an ice bath and 1 0 ml ice-cold medium added. After centrifugation 0 6 ml supernatant was removed and the radioactivity in supernatant and infranatant counted

$$\%\text{Viability} = \frac{\%\,\text{Cr release (serum + complement} - \%\,\text{Cr release (complement alone)}}{\%\,\text{Cr release (in water)} - \%\,\text{Cr release (complement alone)}}$$

lacking surface ganglioside is unknown It may constitute a particular cell type or merely reflect the immaturity of a proportion of cerebellar cells at this stage of development The maximal rate of ganglioside increase in the developing rat brain occurs 10–20 d postnatally, although increased synthesis can be detected earlier—before the onset of myelination. The enzyme glucosyl transferase, which is thought to be involved in ganglioside synthesis, reaches maximal activity by day 7 (ref. 10).

The demonstration that at least some of the ganglioside in brain cells is accessible to antibody at the cell surface suggests that immunohistochemical methods may profitably be applied to localise these haptens on the cell membrane It also raises the possibility that gangliosides may furnish a range of cell-surface markers for the identification and separation of cell types in the central nervous system

Ciliary dyskinesia factors in cystic fibrosis and asthma

CYSTIC fibrosis (CF) homozygotes and heterozygotes carriers for CF harbour a factor in their serum (termed CDF) which causes ciliary dyskinesia when applied to ciliated epithelial tissue derived from rabbit trachea[1–4] Spock *et al.*[1] reported that serum ciliary dyskinesia activity (CDA) was a specific marker for the CF gene Conover *et al.*[5] have reported that a CDA is also found in sera from individuals with various respiratory and autoimmune disorders; they have since suggested that the CF-ciliary dyskinesia factor was C3a (anaphylatoxin), and proposed that a defect or deficiency in the anaphylatoxin inactivator was the primary gene defect in cystic fibrosis[6,7] Other laboratories have been unable to detect CF-CDF using a rabbit tracheal bioassay for the detection of the CF-CDF (refs 8–10) Using a modified rabbit tracheal bioassay, we have confirmed that serum from individuals with bronchial asthma and serum from homozygotes and heterozygotes for CF cause ciliary dyskinesia, whereas normal healthy control sera do not. Most individuals with asthma, however, were also found to have serum which causes a subsequent ciliostasis All sera tested by bioassay for CFP by electrofocusing indicated that all CDA-positive sera except sera from seven of eight individuals with asthma were also positive for cystic fibrosis protein (CFP) The CFP is a small (molecular weight 5,000–9,000), positively charged compound and is found in sera from most homozygotes and heterozygotes for CF (refs 11–16). These two findings suggested that the CDAs in CF sera and in asthmatic sera could be due to two different substances. We have developed two simple chromatographic techniques which can separate CDAs in CF and asthmatic sera. Our results indicate that they may be useful in purifying a CF-specific CDA Purification of this CF-CDA is a prerequisite for its biochemical characterisation and for elucidating its role in the pathophysiology of CF (ref 17).

Our rabbit tracheal bioassay[4] involved tissue selection according to the criteria of Conover *et al*[2], and bioassay following the protocol of Spock *et al*[1] with minor modifications The assay can reliably detect a ciliary dyskinesia activity (CDA) in sera from both heterozygotes and homozygotes for CF without fractionation or concentration of the serum[1,4]. Unlike the assay of Conover *et al*[2], all sera can be screened at 27 °C. Prewarming the serum to 37 °C before bioassay increased the kinetics of the reaction sufficiently to allow the determination of CDA-positive individuals in 35 min or less. Using our methods, 16 CF homozygote sera reacted in 14±8 min (mean±s d.) and 15 OHCF sera required 25±8 min, whereas 13 of 14 normal healthy control sera failed to react by 60 min (the end of the assay period[4]) Our results using whole serum for analysis confirm those of Spock *et al*[1] and Conover *et al.*[2] in that sera from normal healthy donors does not elicit a ciliary dyskinesia reaction, whereas both homozygotes and heterozygotes for CF apparently do harbour a CDA.

To evaluate the specificity of the CDA detected, we bioassayed serum from eight patients with bronchial asthma[4,18] In agreement with Conover *et al.*, we found that all eight asthmatic sera caused a ciliary dyskinesia reaction; however, sera from asthmatics generally caused a subsequent ciliostasis (cessation of ciliary beating) Concurrent evaluation of all sera for CDA by bioassay and for CFP by electrofocusing showed that all CDA-positive sera except seven of the eight asthmatic sera were also positive for CFP (our specific marker for the CF gene)

These two findings indicated that the activity detected in patients with asthma and other respiratory diseases[5] could be a substance different from a CF-specific CDF To test our hypothesis we set out to purify the CDAs in asthmatic, CF homozygote and OHCF sera We found two simple chromatographic procedures for separating and therefore distinguishing between the CDA found in CF and asthmatic sera The first procedure involves fractionating whole serum on DEAE-cellulose (DE-52, Whatman) using 0 005 M Tris-HCl buffer, *p*H 8 6, and a two-step NaCl gradient (0.00 M NaCl, 0 05 M NaCl) for elution. The second procedure involves fractionation of whole serum by Sephadex G-200 (Pharmacia) gel filtration, using 0.01 M phosphate, 0 15 M NaCl buffer, *p*H 8 0, for elution[18]

For DEAE–cellulose chromatography, 2.0 ml of serum is dialysed overnight at 4 °C in Spectrapor 3 dialysis membrane tubing (Spectrum Medical). Spectapor 3 tubing has a known molecular weight retention of 3,500 and will effectively retain CFP, CF-CDF, and C3a if free in solution[7,12]. The serum is then applied to a column pre-equilibrated with eluting buffer. An initial IgG-containing fraction (Fraction DEAE-I) is obtained by elution with Tris-HCl without NaCl This fraction (DEAE-I) contains only the most cathodally migrating gamma-globulin fraction of serum [isoelectric point (*p*I) 8–9 (refs 18, 19)] The column is then eluted with Tris-HCl plus 0.05 M NaCl, and a second IgG-containing fraction (plus contaminants) is eluted (DEAE-II). Both DEAE fractions are lyophilised, reconstituted to 2 0 ml, and dialysed against PBS (0 01 M phosphate, 0 015 M NaCl, *p*H 7 2) in preparation for bioassay

For Sephadex G-200 chromatography, 2.0 ml of serum is fractionated and the effluent is separated into six fractions (Fig. 1) Each fraction is then prepared for bioassay as described for DEAE-I and II

Representative results (Table 1) clearly indicate that the asthmatic CDA is found in DEAE-II and Sephadex G-200 Fraction II, whereas the CDA found in CF and OHCF sera elutes in DEAE-I and Sephadex G-200 Fractions III and IV (weak CDA) Our CFP detected by electrofocusing is also found in DEAE-I and Sephadex G-200 Fraction III[12,18,19]. Fractionation of serum from a heterozygote carrier (CFP positive) with bronchial asthma confirmed the existence of two distinct activities in asthmatic and CF sera, as this serum had activity in DEAE-I and II and in Sephadex G-200 Fractions II, III and IV (Table 1).

We conclude that the CDAs in asthma and CF are distinct substances. Our findings may facilitate purification of what we feel is a CF-specific CDF from CF and OHCF serum Purification is a prerequisite to elucidating the exact nature of this substance and its role in the pathophysiology of CF.

Most recently, we have found that an 850-fold purified preparation of the CDF in asthmatic serum reacts with antisera to human C3a, whereas a 650-fold purified active preparation of CF-CDF (at the same protein concentration) does not[18,19] We feel the different reactivities with anti-C3a antiserum further distinguish the asthmatic and cystic CDAs

Of related interest, are the results of Bowman *et al.*[20,21] concerning the specificity and identification of a ciliotoxic factor (CTF) found in serum from homozygotes and heterozygotes for

Fig. 1 Fractionation of 2 0-ml samples of human sera by gel filtration on Sephadex G-200 Fractions (2 0 ml) were collected at a flow rate of 5 ml h^{-1}. V_0, V_T void volume and total column bed volume HSA human sera albumin

CF. This factor is now termed 'cystic fibrosis mucociliary inhibitor' (CFMI) CTF is detected using an oyster gill ciliary bioassay[22] The investigators claim that CTF is specific for the CF gene since sera from asthmatic, allergic and normal healthy control subjects do not harbour a CTF. Although this CTF has a molecular weight, cationic charge and other properties which resemble those described for the CDF of Conover *et al* [6,7], Barnett and Bowman[21] claim that the CTF is not C3a either.

Although the identity of CTF and the CF-specific CDF described here are unknown, neither our studies nor those of Bowman and co-workers[20,21], lend support results[6,7] which suggest that the CF-CDF is C3a. It remains possible, however, that the elusive 'CF factor(s)' could be related to some other component found in the complement, kinin[23], or fibrinolytic systems.

They could be, for example, abnormal fragments of C3a, C5a or other active agents which affect membrane permeability or ion transport (that is, polyamines or their aminoaldehyde derivatives [24–26]) We have recently shown that α_2 macroglobulin (α_2M) is abnormal in CF and have hypothesised that this abnormality can explain the presence of 'CF Factors' (whatever their exact biochemical nature may be) in various body fluids of CF patients due to defective regulation of serum and cellular derived proteases by CFα_2M In addition, a defective α_2M (possibly coupled with an abnormality in polyamine metabolism) may be responsible for the general pathophysiology of this disease[24–26] Our hypothesis and findings concerning α_2M have recently been confirmed by Shapira *et al.*[27]

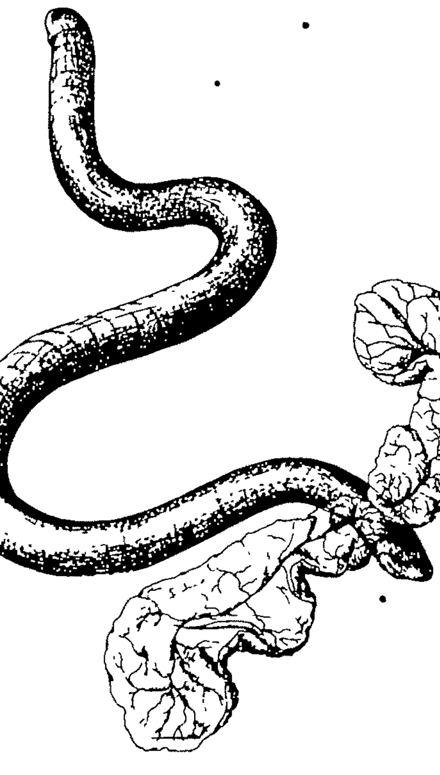
Blood respiratory properties of a viviparous amphibian

BURROWING apodan amphibians (order Gymnophiona) are relatively common in the Amazon River Basin of South America but the physiology of the group has been little studied. The animals are usually fossorial, living burrowed in the mud banks of small tributaries of the main river. The burrows, which they presumably dig, are small and conditions are often both hypoxic and hypercarbic. Animals 0.25–0.75 m long and weighing 100–600 g, found near the air–water interface, were dug out of the mud banks and immediately taken to the laboratory of the research vessel RV Alpha Helix for study. Several species of burrowing apodans occur in the area, but the most common is *Typhlonectes compressicauda*, the animal used in this study. We report here on the blood respiratory properties of this organism.

Most female *T compressicauda* captured had uteri containing several gilled larvae. The gills are large well vascularised jelly-like structures (Fig 1) and the gill surfaces make close contact with the internal lining of the uterus. The structural relationship between larvae and parent in *Typhlonectes* clearly suggested a maternal supply of oxygen, and oxygen equilibrium curves were therefore constructed using pooled blood from three pregnant adult females and 27 larvae removed from several animals. Whole blood was

Fig. 1 Gilled larva removed from the uterus of a female *Typhlonectes compressicauda*, a viviparous amphibian.



used in all determinations and the technique of Edwards and Martin[1] in curve construction was used

Adult blood at a P_{CO_2} of 11.4 torr showed a sigmoid oxygen equilibrium curve with a P_{50} of 22 2 torr (Fig. 2). Increasing the P_{CO_2} to 17.1 torr increased the P_{50} slightly to 22.6 torr, indicating no appreciable Bohr shift. The absence of a Bohr effect would be physiologically advantageous to these animals living in small mud burrows in which the ambient P_{CO_2} fluctuates extensively A Bohr effect in these conditions might result in the undesirable situation of facilitating oxygen unloading at the skin.

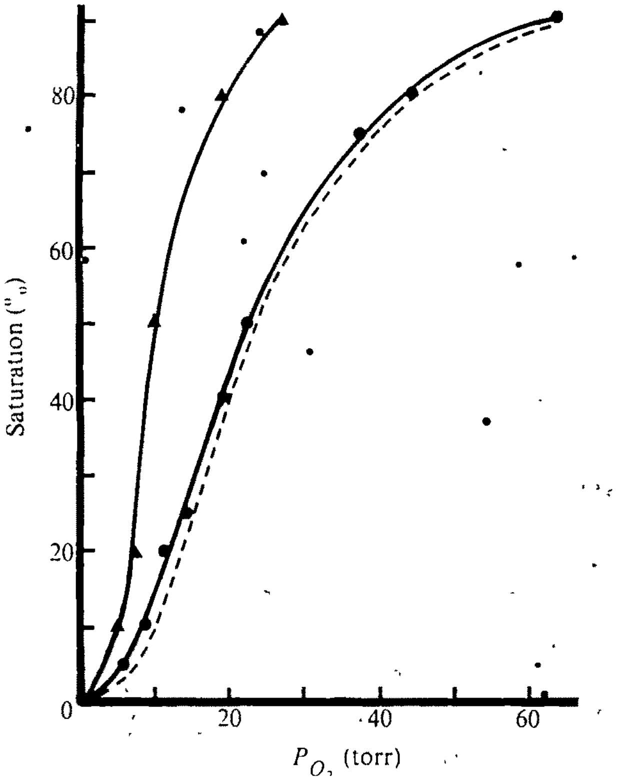


Fig. 2 Oxygen equilibrium curves of *T compressicauda*. ▲, Foetal curve from gilled larvae removed from uterus P_{CO_2} 11 4 torr.) ●, Maternal curve (P_{CO_2} 11.4 torr) Dashed line, maternal curve (P_{CO_2} 17.1 torr).

The foetal blood had an O_2 equilibrium shifted markedly to the left of the maternal blood (P_{50} 9.3, P_{CO_2} 11 4 torr) This intriguing feature would assist in maternal–foetal gas exchange across the uterine–gill membranes because high haemoglobin saturation of foetal blood is achieved with only moderate saturation levels of maternal blood.

Foetal–maternal shifts have been described in the viviparous garter snake *Thamnophis*[2], the ovoviviparous dogfish *Squalus*[1] and the oviparous teleost *Scorpaenichthys*[3], while Riggs[4] has shown bullfrog tadpole curves shifted to the left of the adult. We believe our report to be the first description of a foetal–maternal shift in the Amphibia

We thank the NRC of Canada for a grant to D.P.T. and for funding the Amazon Expedition Phase III of the RV Alpha Helix Research Programme.

One-to-one binding of a purified scorpion toxin to Na channels

DETAILED elucidation of the molecular organisation which controls ionic flow through the excitable membranes has been prevented by a difficulty in isolating substances to which characteristic features of the ionic channels can be attributed[1–3]. In the study of the cholinergic receptor, polypeptide α-toxins from certain snakes have been successfully used for the identification and purification of nicotinic receptors[4] Thus, agents analogous to snake toxins may be of a decisive value in the molecular approach to ionic channels, and toxins from certain scorpions are among the most promising candidates[5–8]. Scorpion toxins seem to act by modifying kinetic properties of Na channels as well as by suppressing the current through K channels[9–11] But, no quantitative analysis was made on an electrophysiological basis to show the precise nature of the toxin-binding We describe here a study of the effects of a toxin from *Leiurus quinquestriatus* on Na, Ca and K currents in the tunicate egg membrane, where each ionic current proved to be essentially identical with that in other excitable membranes[12,13] The discrete critical membrane potentials for the activation of these currents in the egg facilitate discrimination of the respective currents only by adjusting potential steps in the voltage-clamp condition Thus, quantitative aspects of the inactivation kinetics of Na current can be analysed conveniently in this preparation

A crude toxin (Sigma) induced a slowly inactivating component of the Na current and enhanced it in a dose-dependent manner (Fig. 1, inset). The effective component was therefore fractionated on a CM-Sephadex C-25 column, taking the amount of the current remaining at a definite time after the potential step as a measure of toxic activity Since the action of the toxin on the egg membrane was highly reversible, all recordings for the respective fractions were made with the same single preparation Active fractions were collected, rechromatographed and finally gel-filtered on Sephadex G-50 There was substantial agreement between the toxic activity and absorbance profiles during the last filtration procedure SDS-8 M urea gel electrophoresis[14] of the isolated toxin showed a purity of >90%. Molecular weight was estimated to be 6,000 by gel-filtration on a Sephadex G-50 column

The effect of varying concentration of this purified toxin on the Na current is illustrated in Fig 2*a* In the presence of the toxin, the current was inactivated in two phases—an initial fast phase (dotted line) and later slow phase (solid line) It is essential to note that an increase in the dose enhances the slow component with a unique time constant of 309 ± 6 ms (about 40-fold greater than toxin-free control) The slow components were subtracted from the respective original current traces and the fast components isolated analysed (Fig 2*b*), the fast components had a common inactivation time constant of 8 3 ± 0 3 ms regardless of the dosage The value was comparable with 8 5 ms obtained for the toxin-free control The amount of this fast component was decreased as the final concentration of the toxin in the medium was increased It was strongly suggested that the slow component is the current through Na channels modified by the binding of the toxin, while the fast one is that through intact Na channels To analyse the dose–response profile for the toxin, the slow component corrected to the initial zero time of the potential step (I_0^* in Fig 2*a*) was illustrated in a double reciprocal plot (Fig. 2*c*). A straight line was obtained, yielding K_D value of 0.46 μM. When the reciprocal of the fast component similarly corrected to zero time (I_0 in Fig 2*b*) was plotted directly against toxin concentration, a straight line was again obtained (Fig 2*d*) The extrapolated value of the I_0 to toxin-free condition (intercept on the ordinate) was in precise agreement with the peak value of the toxin-free control current, while from the intercept on the abscissa the same K_D value of 0 46 μM was deduced as in the case of the slow component Thus purified scorpion toxin binds to Na channel in one-to-one stoichiometry and modifies its inactivation kinetics. The maximum I_0^* was

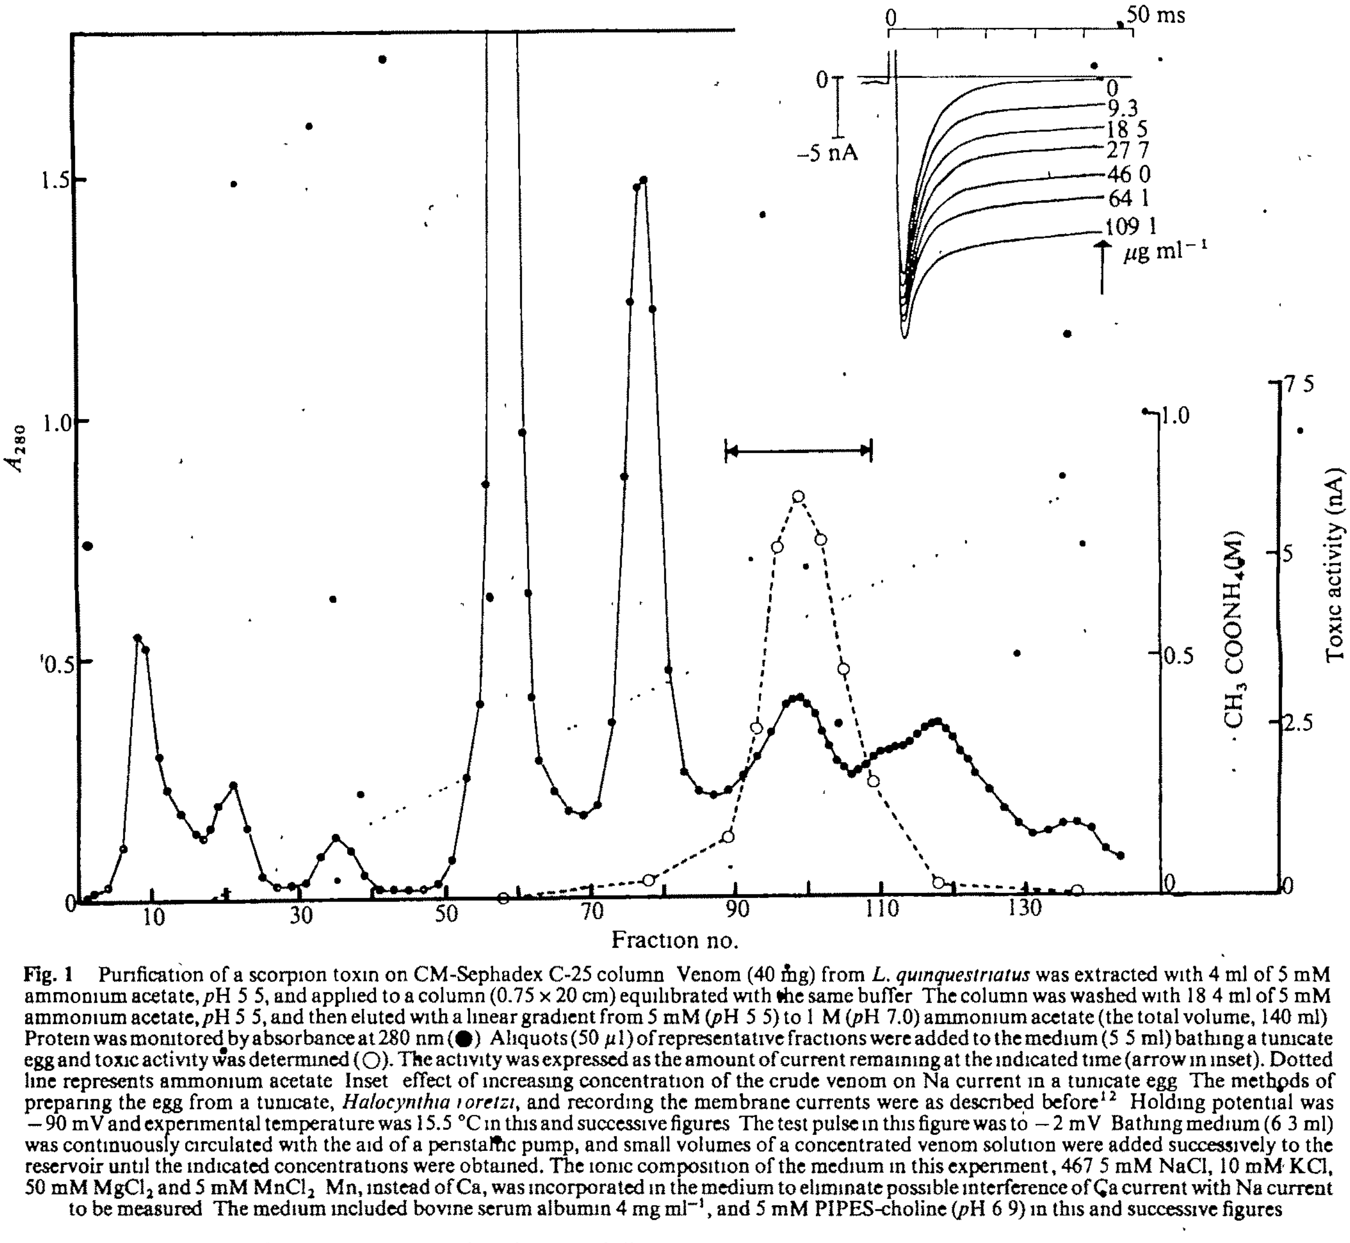

Fig. 1 Purification of a scorpion toxin on CM-Sephadex C-25 column Venom (40 mg) from *L. quinquestriatus* was extracted with 4 ml of 5 mM ammonium acetate, *p*H 5 5, and applied to a column (0.75 × 20 cm) equilibrated with the same buffer The column was washed with 18 4 ml of 5 mM ammonium acetate, *p*H 5 5, and then eluted with a linear gradient from 5 mM (*p*H 5 5) to 1 M (*p*H 7.0) ammonium acetate (the total volume, 140 ml) Protein was monitored by absorbance at 280 nm (●) Aliquots (50 μl) of representative fractions were added to the medium (5 5 ml) bathing a tunicate egg and toxic activity was determined (○). The activity was expressed as the amount of current remaining at the indicated time (arrow in inset). Dotted line represents ammonium acetate Inset effect of increasing concentration of the crude venom on Na current in a tunicate egg The methods of preparing the egg from a tunicate, *Halocynthia roretzi*, and recording the membrane currents were as described before[12] Holding potential was −90 mV and experimental temperature was 15.5 °C in this and successive figures The test pulse in this figure was to −2 mV Bathing medium (6 3 ml) was continuously circulated with the aid of a peristaltic pump, and small volumes of a concentrated venom solution were added successively to the reservoir until the indicated concentrations were obtained. The ionic composition of the medium in this experiment, 467 5 mM NaCl, 10 mM KCl, 50 mM $MgCl_2$ and 5 mM $MnCl_2$ Mn, instead of Ca, was incorporated in the medium to eliminate possible interference of Ca current with Na current to be measured The medium included bovine serum albumin 4 mg ml⁻¹, and 5 mM PIPES-choline (*p*H 6 9) in this and successive figures

slightly lower than that of I_0, suggesting a reduced permeability coefficient for the toxin-modified channels (about 85% of the control).

Figure 3 shows the channel specificity in the action of the purified toxin. Li current through Na channels[12] was modified as above (Fig 3*a*), but *K* and Ca channels were not affected (Figs 3*b*, *c*). Further, a detailed analysis indicated that the toxin exerts little, if any, influence on the activation kinetics of Na channels

Reduction of the cationic concentration in the medium led to a decrease in the K_D value of the toxin-binding When the ratio of unmodified (I_0) to modified (I_0^*) currents at varying external Na concentrations and at a constant level of toxin was plotted against $[Na]^2$, a linear relation was obtained (Fig. 2*e*). Since this ratio is expected to be proportional to the K_D value in case of one-to-one binding, the competitive inhibition of the toxin-binding by Na ions was indicated Essentially similar results were obtained with Li, Ca, Mn and La ions in the medium. This suggests that there are multiple binding sites for cations, the cooperativity of these sites may differ to a certain extent depending upon the ionic species to be bound, because Hill coefficients varied around 2 according to the species of cations tested.

Our results clearly demonstrate, on an electrophysiological basis, that a toxin purified from venom of *L. quinquestriatus* specifically binds to Na channels in the tunicate egg membrane and modifies almost exclusively the inactivation kinetics. Electrically excitable neuroblastoma cells have been shown to contain a similar

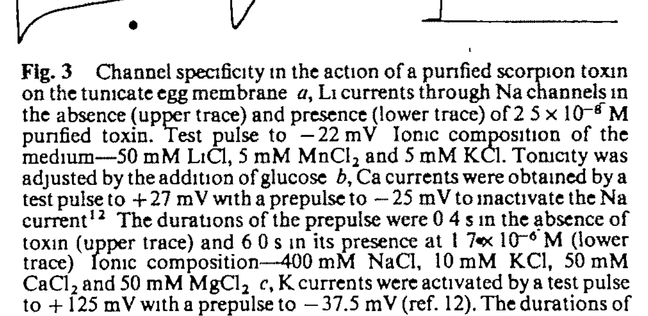

Fig. 3 Channel specificity in the action of a purified scorpion toxin on the tunicate egg membrane *a*, Li currents through Na channels in the absence (upper trace) and presence (lower trace) of 2 5 × 10^{-8} M purified toxin. Test pulse to −22 mV Ionic composition of the medium—50 mM LiCl, 5 mM $MnCl_2$ and 5 mM KCl. Tonicity was adjusted by the addition of glucose *b*, Ca currents were obtained by a test pulse to +27 mV with a prepulse to −25 mV to inactivate the Na current[12] The durations of the prepulse were 0 4 s in the absence of toxin (upper trace) and 6 0 s in its presence at 1 7 × 10^{-6} M (lower trace) Ionic composition—400 mM NaCl, 10 mM KCl, 50 mM $CaCl_2$ and 50 mM $MgCl_2$ *c*, K currents were activated by a test pulse to +125 mV with a prepulse to −37.5 mV (ref. 12). The durations of the prepulse were 0.4 s in the absence of toxin (upper trace) and 10 s in its presnce at 0.47 × 10^{-6} M (lower trace) Ionic composition was the same as in Fig 1 In *b* and *c*, it was confirmed that the toxin effectively modified the inactivation kinetics of Na current.

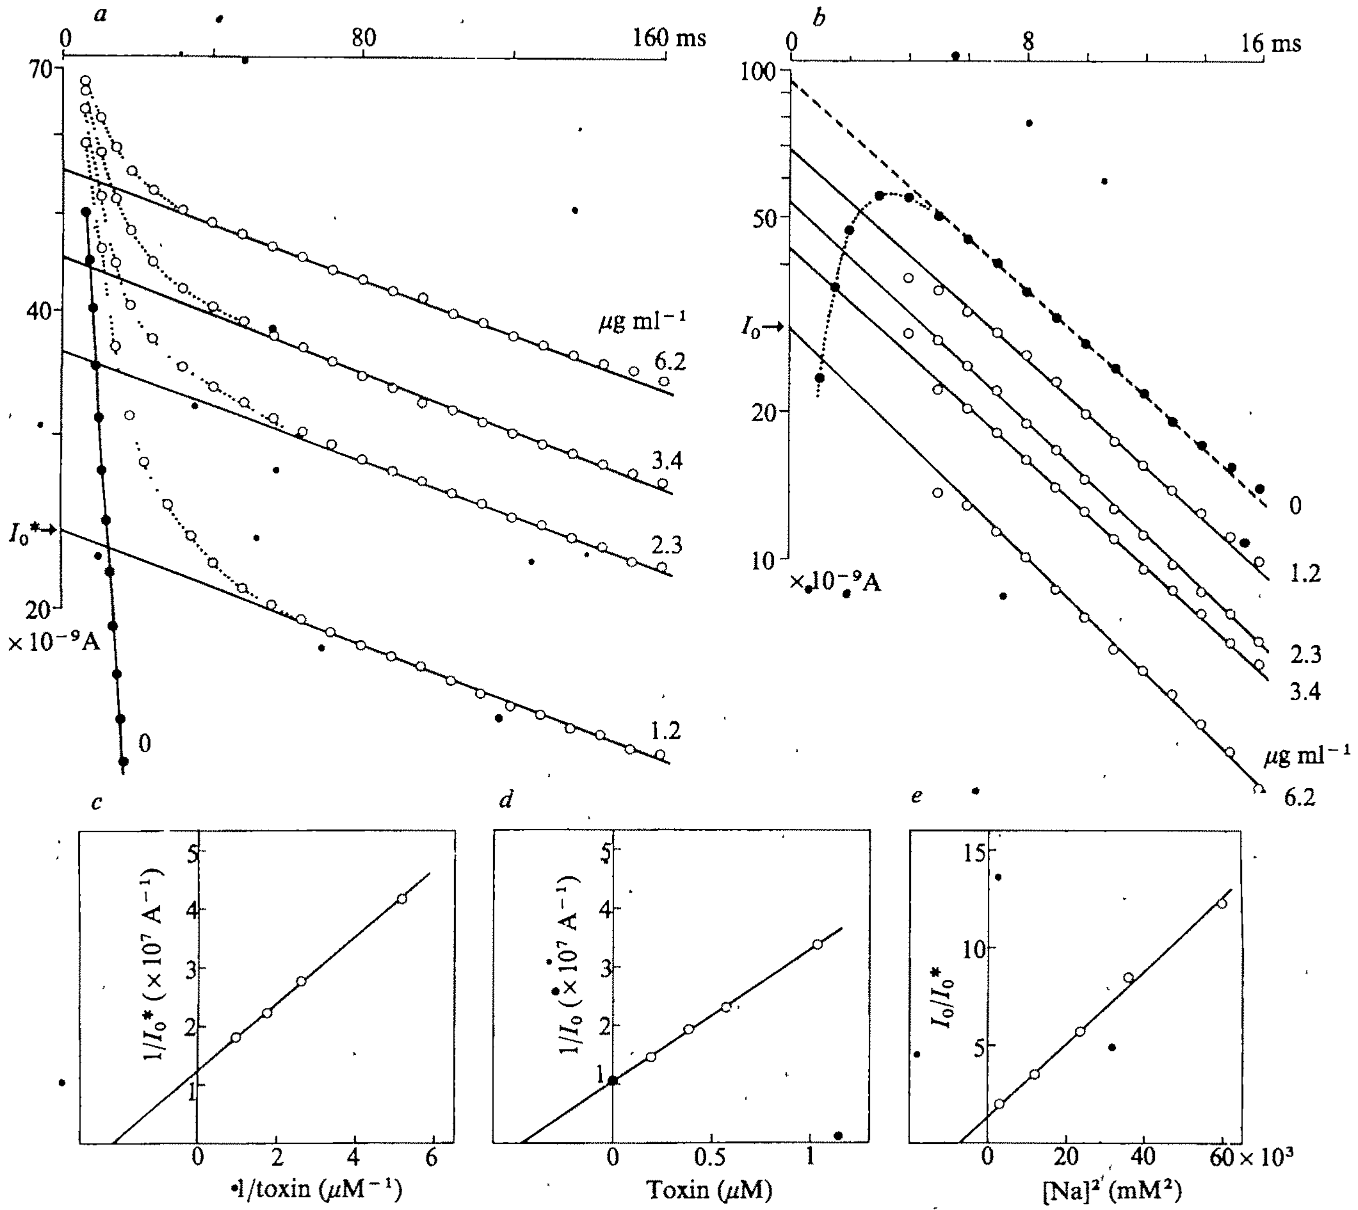

Fig. 2 Effect of a purified toxin on inactivation process of the Na current *a*, Na currents were measured as described for Fig 1, except for the test pulse to −9 5 mV Purified toxin was added successively until the indicated concentration was obtained The logarithm of the current in the presence (○) or absence (●) of the toxin was plotted against time *b*, The slow components (solid lines in *a*) were subtracted from the respective original currents and the logarithms of the fast components isolated were plotted against time (○) For a comparison, the Na current in toxin-free medium was also included (●) *c* and *d*, the reciprocals of the slow and fast components corrected to zero time (I_0^* in (*a*) and I_0 in (*b*)) were plotted against the reciprocal of toxin concentration (*c*), and against toxin concentration (*d*), respectively *e*, Inhibition of toxin-binding by Na ions External Na concentration was successively increased at a constant level of the toxin ($1\ 7 \times 10^{-8}$ M) and with 5 mM $MnCl_2$ and 5 mM KCl $MgCl_2$ was omitted and tonicity was adjusted by the addition of glucose The ratio of I_0 to I_0^* at the indicated concentration of Na was calculated as in (*a*) and (*b*), and was plotted against $[\text{Na}]^2$. The Na currents used for this estimation were obtained with a test pulse to −20 mV

single class of binding sites for the toxin from *L quinquestriatus*[7]. In this experiment the active toxin had been isolated by monitoring its stimulative effect on the tetrodotoxin-sensitive ^{22}Na influx induced by the simultaneous presence of veratridine, whereas our purification procedure was based directly on the electrophysiological effect of the toxin Although the purified toxin may be identical in these two experiments, the reported K_D values differ widely (1.3–2 4 nM in neuroblastoma and 460 nM in the tunicate egg) This apparent discrepancy, however, can largely be attributed to a higher cationic concentration in the artificial sea water used in our experiment. In fact, the K_D of about 10 nM was estimated in the tunicate egg in a cation-free condition, taking the competitive inhibition by cations in the medium into consideration. It is likely that the presumptive inactivation particles of Na channels[15] bear multiple sites that bind various cations, and these sites may be blocked by a single scorpion toxin molecule to result in the retardation of the inactivation gating.

We thank Professors Masanori Kurokawa and Akira Takeuchi for comments on our manuscript.

Does intracellular sodium modify membrane permeability to sodium ions?

IN sodium transporting epithelia the asymmetrical cells have the apical face specialised for sodium entry while the basolateral membranes are concerned with sodium export, the accompanying anion passing passively. Epithelia exposed to various sodium concentrations may need to control sodium entry as a way of regulating the intracellular concentration. Some amphibian epithelia can show adaptive changes in their transporting capacity with changes in the ambient sodium concentration[1–3]. In addition, rapid changes in permeability of the apical face occur with time constants of a few seconds when epithelia are exposed to step changes in sodium concentration[4]. While the slow adaptive changes may involve alterations in synthesis of membrane macromolecules important for membrane permeability, the rapid changes are likely to result from fast changes involving the existing membrane apparatus. One effector agent for the rapid reactions may be the intracellular sodium concentration and the experiments reported here were designed to test this hypothesis. We have manipulated frog skin epithelium in ways to increase the intracellular sodium content and found that the density of sodium channels in the apical face, measured by labelling with ^{14}C-amiloride, is reduced in these circumstances.

^{14}C-amiloride has been used previously to label sodium channels in frog skin and isolated toad bladder cells[3,5–7], and the amount of ^{14}C-amiloride displaced from binding sites by unlabelled drug when the former is used at a concentration of 10 nM in the presence of 1.1 mM Na^+ is a measure of binding to sodium channels. As external sodium is reduced the apparent affinity of amiloride increases[8]. Labelling is carried out with only low concentrations of sodium present to minimise the concentration of ligand required, and so reduce nonspecific binding.

Part of the evidence that amiloride binds at, or close to, sodium entry sites is given by the correlation of site density and the level of sodium transport which can be maintained by the tissue. Epithelia deprived of sodium for 1 week have been found to have a threefold increase in site density and can, when re-exposed to sodium, maintain a transport level three times that of control skins[3].

We measured ^{14}C-amiloride binding in the mucosal surface of frog abdominal skin (*Rana temporaria*, area 9.6 cm^2) as described before[3,5,6,8]. To increase sodium concentration on the inside of the apical membrane the serosal surface was treated with ouabain or K-free solution to reduce or abolish the activity of the sodium pumps. Throughout the experiments the transepithelial voltage was maintained at zero by an automatic voltage-clamp device.

In each experiment, five measurements were made of the amount of displaceable amiloride bound to the skin. Subsequently, a further five measurements were made after ouabain had been used to reduce transport to a low level (about 90% inhibition).

Results of experiments in which amiloride binding was measured in the presence of 1.1 mM Na^+ are given in Table 1. After transport had been inhibited by ouabain there was no significant difference in the amount of amiloride bound. In these experiments, and before ouabain inhibition, the intracellular sodium concentration was in a steady state, in which sodium influx through the mucosal face was equal to sodium efflux through the serosal face. After ouabain, it is unlikely that the intracellular sodium concentration increased as the mucosal concentration was only 1.1 mM, and furthermore, the favourable electrical gradient for sodium entry could only decrease after sodium pump inhibition. Sodium can enter and leave the cells only by the mucosal face after pump inhibition, as shown by studies with the electron probe[9].

If the mucosal face of the skin is flushed with high sodium solution (111 mM) and then returned to low sodium (1.1 mM) conditions before binding is measured, the increased intracellular sodium concentration is lowered rapidly, mainly by pumping through the serosal surface. After ouabain, however, this exit route will be blocked. Experiments such as those described in Table 1 were reapted except that each binding measurement was preceded by a high sodium flush. The results (Table 2) show that inhibition of transport with ouabain reduces amiloride binding to 36% of its control value. If the equivalence between amiloride-binding sites and sodium channels is accepted, the result after ouabain corresponds to a decrease in the mucosal sodium permeability, effected by a reduction in availability of channels. An ouabain-like effect was also obtained when potassium was omitted from the serosal bathing solution; this produced a 31% reduction in channel density.

So far, our results indicate that an increase in intracellular sodium (or possibly a decrease of intracellular potassium) reduces amiloride binding, and therefore the availability of sodium channels, in the mucosal face of the cells. This may not, however, be due to intracellular sodium changes *per se*, but to other effects, such as a potential change across the mucosal membrane. For example, changes in transepithelial potential, V_T, change the extent of amiloride binding[6]. This could be clarified if it were possible to control the potential across the mucosal membrane,

Table 1 Effect of ouabain on amiloride binding in low sodium solution

	Control	After ouabain (10^{-3} M)
Total binding (10 nM ^{14}C-amiloride)	1.44 ± 0.07	1.99 ± 0.05
Non-displaceable binding (10 nM ^{14}C-amiloride plus 1 μM unlabelled amiloride)	1.20 ± 0.07	1.76 ± 0.05
Displaceable binding	0.23 ± 0.03 ($P < 0.001$)	0.20 ± 0.04 ($P < 0.001$)
	Δ = 0.03 NS	

Amiloride binding is expressed as pmol per 9.6 cm^2. The concentration of sodium was 1.1 mM. Means and s.e. are from results for 15 determinations in three separate skins. The significance of the specific (displaceable) binding was estimated using a paired *t* test. The serosal surface was bathed in Ringer's solution (mM, NaCl, 111, $CaCl_2$, 1; KCl, 2, Tris, *p*H 7.6, 5 and glucose 11.0). The mucosal solution contained only 1.1 mM NaCl and no glucose. ^{14}C-amiloride had a specific activity of 54 Ci mol^{-1}. NS, not significant.

Table 2 Effect of ouabain on amiloride binding in low sodium solution following a high sodium flush

	Control	After ouabain (10^{-5} M)
Total binding (10 nM ^{14}C-amiloride)	1.72 ± 0.10	2.02 ± 0.07
Non-displaceable binding (10 nM ^{14}C-amiloride plus 1 μM unlabelled amiloride)	1.47 ± 0.09	1.93 ± 0.07
Displaceable binding	0.25 ± 0.03 ($P < 0.001$)	0.09 ± 0.04 ($P < 0.02$)
	Δ = 0.16 $P < 0.005$	

Amiloride binding is expressed as pmol per 9.6 cm^2. Concentrations of sodium were 1.1 mM (low) and 111 mM (high). Means and s.e. are from results for 20 determinations in four separate skins. Ringer's solution was used to flush the mucosal surface before returning to low sodium solution to measure binding.

V_m, rather than across the whole epithelium. To achieve this we have used the potassium depolarised preparation of Morel and Leblanc[10,11]. The serosal side of the skin was bathed in a potassium-rich solution so that the resistance and potential across the serosal border are reduced to low values[12]. In this situation the transepithelial resistance is located mainly at the mucosal membrane, presumably making it possible to clamp this membrane at, or close to, zero. K-depolarised skins are able to maintain low level transport, and are still sensitive to amiloride and ouabain[10,11].

Table 3 gives the results obtained with K-depolarised skins. Again, amiloride binding was measured in low sodium conditions immediately after a high sodium flush. After ouabain had been used to inhibit serosal efflux, the amount of binding was decreased by 64%. It seems, therefore, that in this situation the reduction in binding could not have been entirely due to potential changes, but was more likely due to increased intracellular sodium.

At this stage it was necessary to check that ouabain did not cause a change in affinity of amiloride for the binding site so as to lead to reduced binding. Apparent affinities for amiloride (reciprocal of concentrations producing 50% inhibition of transport) were determined in six control skins bathed on both sides with Ringer's solution. The mean value (520 nM) fell within the normal range. Ouabain was then used to reduce sodium transport to about 30% of its control value. The affinity was redetermined on the residual sodium currents. No significant difference in apparent affinity was found after ouabain. We concluded that the changes in binding caused by ouabain were not the result of changes in the affinity of the ligand for the binding sites.

Table 3 Effect of ouabain on amiloride binding in low sodium solution after a high sodium flush with the serosal surface bathed in high potassium solution

	Control	After ouabain (10^{-3} M)
Total binding (10 nM ^{14}C-amiloride)	1.35±0.06	1.73±0.05
Non-displaceable binding (10 nM ^{14}C-amiloride plus 1 μM unlabelled amiloride)	1.10±0.08	1.63±0.06
Displaceable binding	0.25±0.03 ($P<0.001$)	0.09±0.02 ($P<0.005$)
	$\Delta=0.16$ $P<0.005$	

Amiloride binding is expressed as pmol per 9.6 cm². Concentrations of sodium were 1.1 mM (low) and 111 mM (high). Means and s.e. are from results for ten determinations in two separate skins. The serosal bathing solution was Ringer's in which all the NaCl was replaced with KCl.

The mean value for specific amiloride binding in control conditions in the experiments reported here was 0.243 pmol per 9.6 cm². This corresponds to 153 binding sites per μm² at an occupancy of 30–40% with 10^{-8} M amiloride, or about 400 binding sites per μm² at 100% occupancy, a value comparable with those reported elsewhere[3,5–8].

Our results provide a direct demonstration that an increase in intracellular sodium is accompanied by a reduction in the availability of amiloride-binding sites, and presumably of sites through which sodium entry can occur. This finding provides a mechanism to explain why the measured sodium influx through the mucosal face is inhibited by ouabain[11,13] and shows that reduced influx is not simply a result of a reducing gradient as the transport pool fills up. When both sodium and amiloride are present in the external solution they show competition, perhaps at a site which needs to be occupied for sodium ions to be translocated through the channel. Intracellular sodium seems to make a fraction of the channels unavailable to external Na$^+$ or amiloride, thus reducing the transepithelial current, possibly by interaction at a regulator site different from the site for translocation. The slow time course of the effect of step changes in external sodium concentration[4] might indicate that this too affects transport by increasing intracellular sodium.

The simple feedback operated by intracellular sodium may be an important homeostatic device for the transporting cell. For example, with conditions where the supply of energy for the pump is impaired, the intracellular sodium content may be kept low. There is increasing evidence that intracellular sodium determines levels of intracellular calcium by a control exerted at the mitochondria[14–16]. Increases in intracellular calcium may well be unacceptable in a tight epithelium if they lead to a loss of cell coupling[17].

Endogenous C-type viral expression in primates

C-TYPE viruses are genetically transmitted in species representing several orders of vertebrates (for review see refs 1 and 2). So far the isolation of endogenous viruses of primates has been limited to species of *Papio*[3–5], although related viral nucleic acid sequences have been detected in cellular DNAs of several other Old World monkeys[6]. The extent of divergence of known endogenous primate viruses should be useful in predicting properties of the gene products of evolutionarily related endogenous viruses of primates from which such viruses have yet to be isolated. We report here an investigation of the antigenic divergence of different structural proteins of prototype endogenous primate C-type virus isolates. Endogenous viral antigen expression was also examined in tissues of primate species, representing the major genera of the order Anthropoidea. Immunologically divergent gene products of endogenous viruses were found to be expressed in tissues of Old World monkeys, including many species that have not yet yielded complete virus. These findings, together with the marked variations in viral antigen expression demonstrated among different primate genera, have implications for endogenous virus regulation in primates and the search for related viruses of humans.

The development of immunoassays for the 30,000 molecular weight major structural protein (p30)[7,8], the 70,000 molecular weight glycoprotein (gp70)[8] and a 15,000 molecular weight protein (p15)[9] of a prototype virus isolate of *P. cynocephalus* made it possible to compare the immunological relatedness of several endogenous primate viruses. Known C-type viral proteins contain a range of antigenic determinants that vary in their degree of cross-reactivity with analogous proteins of viruses of other species. In competition immunoassays using a given ^{125}I-labelled viral protein with limiting antiserum prepared against the same virus, the extent to which another virus can compete reflects the immunological relatedness of analogous proteins of the two viruses. As Fig. 1 shows, *P. cynocephalus* virus competed with high efficiency and to a final extent of more than 95% in immunoassays for three of its structural proteins. Endogenous viruses of *P. hamadryas* and *P. anubis* reacted as efficiently as *P. cynocephalus* virus in the immunoassay for *P. cynocephalus* virus in the immunoassay for *P. cynocephalus* virus p30 (Fig. 1*a*). In the assay for *P. cynocephalus* viral gp70, the other baboon viruses competed only as much as 80% (Fig. 1*b*), while neither competed more than 50% in the *P. cynocephalus* virus p15 immunoassay (Fig. 1*c*).

Certain endogenous viruses of the cat have been reported to be of primate origin and to have secondarily entered the cat lineage several million years ago[10,11]. Figure 1 demonstrates greater antigenic divergence of proteins of evolutionarily related feline viruses from those of the *P. cynocephalus* virus. Endogenous viruses of *Felis catus* and *F. sylvestris* showed significantly less ability to compete than the baboon viruses in the *P. cynocephalus* virus p30 assay (Fig. 1*a*) and even more striking antigenic divergence from *P. cynocephalus* virus in their p15 and gp70 reactivities (Fig. 1*b* and *c*). The relative conservation of p30 antigenic determinants suggests stronger evolutionary selective pressures for maintenance of the immunological integrity of this protein. Whether this also reflects preservation of some important biological function(s) is not resolved. In any event, it can be seen that the immunoassay for *P. cynocephalus* viral p30 was most broadly-reactive and thus most likely to be useful in a search for antigenic reactivity of related viruses in primate tissues.

Previous studies have demonstrated the expression of endogenous C-type viral antigens in normal tissues of vertebrates including the mouse[12–14], cat[15] and rhesus monkey[9,15]. In a systematic search for C-type viral gene products in tissues of a wide range of Old World monkeys, liver cell extracts were analysed for expression of antigens cross-reactive with *P. cynocephalus* viral p30. Cell extracts were subjected to DEAE–cellulose chromatography in an effort partially to purify p30 and reduce nonspecific reactivity[9].

As Table 1 shows, antigens cross reactive with *P. cynocephalus* viral p30 were detectable in tissues of species representing each of five genera of Old World monkeys (Table 1). The specificity of the antigenic reactivity was indicated by lack of competition in immunoassays for the p30s of other mammalian C-type viruses, including mouse and woolly monkey isolates (data not shown). Partially purified p30 antigens were subjected to molecular size analysis by gel filtration chromatography in both denaturing (6 M GuHCl) and non-denaturing conditions. In each case, tissue-associated p30 reactivity chromatographed with a molecular weight of about 30,000 relative to standards (data not shown). This sizing step generally provided a further 8–10-fold purification (Table 2) The degree of purification was sufficient to allow detection of p30 related to *P. cynocephalus* virus at a level about 50 times lower than that present in macaque tissues. The same procedures failed to reveal evidence of similar antigenic reactivity in more than 100 individual tissues analysed from higher apes or humans (Table 1).

As Table 1 shows, species representing two primate genera, *Papio* and *Macaca*, exhibited marked differences in their tissue expression of viral p30. Macaque tissues had relatively high p30 levels, from 15 to more than 100 ng per mg cellular protein. In most cases, baboon tissues had levels at least 20 times lower. Attempts to isolate endogenous C-type viruses from macaques have been unsuccessful. Yet, in similar conditions such viruses have been obtained readily from most species of baboon (refs 3–5 and our unpublished observations). This could reflect the release from macaque tissues of viruses with very different host ranges from those of known baboon endogenous viruses. Alternatively, the high levels of endogenous viral p30 expressed by macaque tissues in the absence of detectable virus release could be due to partial expression of a defective viral genome or to a late cellular block to release of a competent virus.

In view of the highly-conserved nature of p30 antigenic

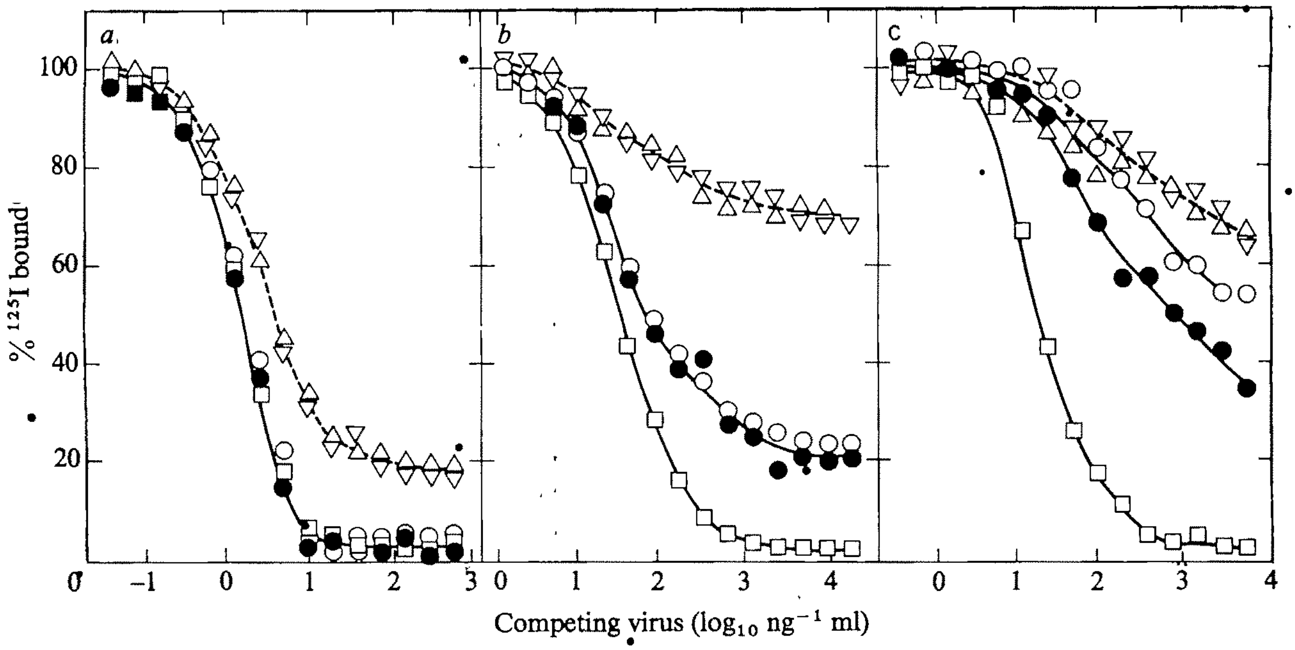

Fig. 1 Immunological divergence of viral structural proteins of endogenous primate C-type viruses Competition immunoassays were performed as described in Table 1 and included assays in which antiserum to the *P. cynocephalus* virus was used to precipitate ^{125}I-labelled *P. cynocephalus* viral p30 (*a*), gp70 (*b*) and p15 (*c*). Viruses, concentrated from tissue culture fluids by sucrose density centrifugation, were disrupted by incubation in 1% Triton X-100 at 37 °C for 30 min. Viruses tested included isolates of *P. cynocephalus* (□); *P. hamadryas* (○), and *P. anubis* (●); and endogenous viruses of two cat species, *F. catus* (△) and *F. sylvestris* (▽) The isolation of *P. cynocephalus*[3], *P. hamadryas*[5] and *F. catus* viruses[10] have been described. *P. anubis* and *F. sylvestris* viruses were isolated in our laboratory from normal kidney tissues of these species.

Table 1 Expression of antigen related to that of the major structural protein (p30) of *P. cynocephalus* virus

Liver cell extracts were prepared by homogenisation in an equal volume of 0.01 M Tris-HCl, *p*H 7 8, 0 1 M NaCl, 0.5 mM EDTA and 0.5% Triton X-100, and sonication for 1 min with a Biosonic II sonic oscillator. Supernatants were clarified by centrifugation for 1 h at 100,000*g*, and subjected to partial purification by DEAE ion exchange chromatography[8]. Both original and DEAE-purified cell extracts were tested at serial two-fold dilutions for ability to compete with ^{125}I-labelled *P cynocephalus* virus p30 (ref. 10) for binding limiting concentrations of goat antisera to detergent-disrupted *P cynocephalus* virus. Antiserum and competing antigen were incubated at 37 °C for 1 h in 0.15 ml of reaction mixture containing 10 mM Tris-HCl, *p*H 7.8, 10 mM EDTA, 0.4% Triton X-100, 1% bovine serum albumin, 0.1% normal goat serum, 10 mM NaCl and the protease inhibitor phenylmethane-sulphonyl fluoride (300 μg ml^{-1}, Pierce Chemicals). About 10,000 c.p.m. ^{125}I-labelled p30 in 0 05 ml of the same buffer was added and incubation continued for 3 h at 37 °C and a further 18 h at 4 °C. Antigen–antibody complexes were precipitated by pig antigoat IgG[8] and radioactivity in the precipitates was measured in a Searle gamma counter Model 1285. Levels of p30 antigen in partially-purified liver cell extracts were calculated on the basis of the displacement of the competition curve for the unknown relative to that achieved with purified viral antigen. Protein concentrations were determined according to the method of Lowry *et al.*[23]. Results expressed on the basis of p30 concentrations in the original extracts were determined by quantifying p30 levels in DEAE-purified extract and correcting for the degree of purification achieved.

determinants among baboon endogenous viruses, it was interesting to investigate the extent of immunological relatedness of endogenous viral p30s among other genera of Old World monkeys As Fig. 2 shows, p30 antigens partially purified from liver tissues of *Macaca mulatta, Cynopithecus niger*, and *Cercopithecus neglectus*, each representing a different genus, competed less efficiently than that of p30 partially purified from *P. cynocephalus* liver tissue in the immunoassay for *P. cynocephalus* virus p30. These findings demonstrate that endogenous viral p30s of species representing different genera of Old World monkeys have undergone sufficient evolutionary change to make them immunologically distinguishable.

Table 2 Partial purification of antigen related to the *P cynocephalus* viral p30 from cell extracts of representative Old World monkey species

Genus	Viral p30 antigenic reactivity (ng per mg cell protein) after AcA54 Ultragel chromatography
Macaca

P. anubis	28

P30 antigenic reactivity was purified partially from liver cell extracts by DEAE ion exchange chromatography as described in Table 1. Extracts were then subjected to molecular size analysis by AcA54 Ultragel column chromatography[24] and tested by competition immunoassay for *P cynocephalus* viral p30 reactivity as in Table 1. Results are expressed as ng p30 per mg cell protein after purification. Immunological specificity was established by absence of competition (<1 ng per mg cell protein) in immunoassays for mouse leukaemia virus and for a C-type virus of the woolly monkey[11].

The finding of gene products related to *P. cynocephalus* viral p30 in normal tissues of many species of Old World monkeys, together with previous molecular hybridisation studies[6], indicate the widespread distribution and expression of related endogenous viral sequences in these primates. In our studies, analogous translational products were not detected in tissues of higher apes or humans. Our findings that endogenous viral p30s of other Old World primate genera can be immunologically distinguished from those of baboons indicate that p30 of an evolutionarily related human endogenous virus would probably be distinguishable as well. Although other possibilities can be considered, previous claims of the detection of p30, indistinguishable from that of *P. cynocephalus* virus in certain human tumours[16,17], seem to favour infection of humans with baboon C-type virus. Such a model has been invoked[18,19] to explain the detection in certain human tumours of highly related nucleic acids[18,19] and even infectious virus[20], so far indistinguishable by the present techniques from *P. cynocephalus* virus[21]. The absence of viral antigens of the baboon virus in a large number of human tissues, as reported here, suggests that productive infection with a baboon C-type virus is likely to be infrequent if it occurs at all in humans.

The demonstrated presence of endogenous viral information in many species of Old World monkeys suggests that evolutionarily-related viruses exist in higher primates as well. Reports of low levels of genetic sequence homology between *P. cynocephalus* virus and normal cellular DNAs of apes and humans[6] would favour this possibility. The

Liver cell extracts were subjected to DEAE-cellulose ion exchange and AcA54 Ultragel chromatography before analysis in a p30 competition immunoassay utilising antiserum to the *P. cynocephalus* virus precipitate, ^{125}I-labelled *P. cynocephalus* viral p30. Reactivity of partially-purified p30s from *P. cynocephalus* (○); *M. mulatta* (□); *C. niger* (▼); and *C. neglectus* (△).

absence of antigenic reactivity related to *P. cynocephalus* virus in these tissues implies that endogenous viruses of apes and man are either very tightly restricted or have undergone sufficient antigenic divergence to have become undetectable by available immunological techniques. Knowledge that immunoassays can recognise antigenic relatedness between endogenous viruses that have diverged to the extent that nucleic acid sequence homology is no longer demonstrable[21], justifies further efforts to develop more broadly-reactive and sensitive immunological probes to search for endogenous virus expression in man.

Muscle histology and creatine kinase levels in the foetus in Duchenne muscular dystrophy

X-LINKED Duchenne muscular dystrophy is a serious genetic disorder for which at present there is no effective treatment. It is characterised by progressive muscle wasting and weakness which first becomes apparent around the age of 3–5 years, leading to death usually before the age of 20 (ref. 1) A proportion of female heterozygous carriers have significantly elevated serum levels of creatine kinase and a woman who is found to be at high risk of having an affected son can elect to have amniocentesis with antenatal foetal sexing and selective abortion of any male foetus. A proportion of such aborted foetuses will, however, be normal but since the cause of the disorder is not known it is not yet possible to diagnose an affected male foetus *in utero*. As a first step in this direction we have examined the muscle histology and levels of creatine kinase in serum, muscle and amniotic fluid in a number of therapeutically aborted male foetuses at risk for Duchenne muscular dystrophy. We report that muscle histology, and possibly the serum level of creatine kinase, may be abnormal in this disorder even by the second trimester of pregnancy.

Thirteen at-risk male foetuses were studied. In four cases (993, 1018, 75/479 and B105) the mothers were proven carriers and in the remaining cases the mothers were estimated to have a risk greater than one in five of being carriers (Table 1). In each case the sex of the foetus was established before abortion on the basis of cytogenetic studies on amniotic fluid cells obtained at amniocentesis As controls, 13 normal male foetuses of comparable gestation were obtained at abortion performed for social reasons where there was no family history of any neuromuscular disorder. The gestational ages of the foetuses were estimated by crown–rump and heel–toe measurements[2]

Cryostat sections of quadriceps muscle were stained with haematoxylin and eosin Muscle fibre diameters were measured using a calibrated Reichert Visospan projection microscope at a magnification of ×400. For each foetus 200 randomly chosen fibres were measured. The percentage of hyaline fibres was determined in 500 muscle fibres The cross-sectional areas of 100 randomly chosen nuclei, closely opposed to the surface of transversely sectioned muscle fibres, were estimated by planimetry at a final magnification of × 1000 Serum specimens were obtained by cardiac puncture and serum, cell-free amniotic fluid and muscle creatine kinase activities were measured according to the method of Rosalki[3] Creatine kinase activity in muscle was expressed in terms of total protein[4].

In affected boys muscle histology is characterised by variation in muscle fibre size, fibre necrosis and phagocytosis, and ultimately replacement by fat and connective tissue Muscle nuclear size is also increased[5]. Even in the preclinical stage of the disorder muscle histology is abnormal with hyalinisation of muscle fibres and increased variation in muscle fibre size[6–8]. In none of the at-risk foetuses was there any evidence of muscle fibre necrosis or phagocytosis or any increased amount of fat or connective tissue. Values outside the normal range, however, were found in six of the foetuses in regard to mean muscle fibre diameter and in five of the

In normal foetuses ($n = 13$) the results are expressed as the range; in at-risk foetuses individual results are given and italicised when outside the normal range. *P*, probability of a mother being heterozygous. *See ref. 12.

foetuses in regard to variance (σ^2) in fibre size (Table 1). There were very few hyaline fibres in normal foetuses (0.0–0.6%) but in two of the at-risk foetuses 2% or more of the muscle fibres were hyalinised, a finding which we have noted previously in a foetus at risk for Duchenne muscular dystrophy[9]. The mean muscle nuclear size seemed to be increased in four of the at-risk foetuses.

The serum level of creatine kinase is very high in the early stages of Duchenne muscular dystrophy and is moderately raised in infancy and even at birth[10,11]. In both normal and at risk foetuses there was considerable variation in serum levels of creatine kinase. The range in normal foetuses was 120–7350 IU and only one of the at risk foetuses (684) had a level outside this range (9140 IU). Creatine kinase levels in normal amniotic fluid were at the limit of accurate determination and no raised levels were found in any of the at-risk foetuses. Muscle creative kinase levels were within the normal range (1.3–9.6 IU per mg protein) in all of the at-risk foetuses.

Not all of the at-risk foetuses in this study would have been expected to be abnormal. In fact from pedigree data and maternal serum levels of creatine kinase the average probability of the mothers being heterozygous was 0.51 and therefore of the 13 at-risk foetuses it might be expected that (13) (0.5) (0.51) or 3.3 might be affected. In fact, using three or more criteria of abnormality, two foetuses could be classified as being affected, one of these (684) having a raised serum level of creatine kinase. Our results suggest that X-linked Duchenne muscular dystrophy is expressed, at least in muscle tissue, by the second trimester of pregnancy.

Foetal material was kindly supplied by Professor Victor Dubowitz and Drs W. M. Clow, R. Harris, B. Hargreaves, M. Manson, J. B. Scrimgeour and S. Walker. We thank Mr D. Burt, Mrs L. Bain and Mrs H. Cameron for technical assistance. This work was supported by the Muscular Dystrophy Group of Great Britain.

Degradation of deadenylated rabbit α-globin mRNA in *Xenopus* oocytes is associated with its translation

THE 3′-OH poly(A) segment of globin mRNA ensures the stability of the message when injected into *Xenopus* oocytes[1–4]. We recently developed[5] a specific method for the removal of the poly(A) tail from globin mRNA, based on synchronous processive phosphorolysis of mRNA using molar excess of *E. coli* polynucleotide phosphorylase at 0 °C. When injected into *Xenopus* oocytes, deadenylated globin mRNA is translated for a relatively short period and then rapidly degraded[1,2]. Native poly(A)-containing mRNA, however, is considerably more stable in the same conditions and is translated for extended periods of time[1,2,7]. The poly (A) segment itself is responsible for the stability of native globin mRNA in *Xenopus* oocytes since poly(A) re-addition to previously deadenylated mRNA restores the functional stability of the message[3]. We do not yet know, however, how poly(A) exerts its protective function; furthermore, the mechanism of degradation of poly(A)-free mRNA is not known. We report here the use of the enhancing effects of haemin on the translation of α-globin mRNA in frog oocytes[6] to establish that, in these cells, the degradation of injected poly(A)-free α-globin mRNA is linked to its translation.

Rabbit α-globin mRNA is much less efficiently translated than β-globin message when injected into frog oocytes. The efficiency of α-globin mRNA translation can, however, be dramatically increased if haemin is included in the injection mixture[6]. The stimulation of α-globin mRNA translation by haemin is shown in Fig. 1. We took advantage of this effect to determine whether the degradation of deadenylated α-globin mRNA is linked to its translation.

We examined the effect of haemin on the degradation of poly(A)-free rabbit α-globin mRNA injected into *Xenopus* oocytes. Rabbit globin mRNA enriched in α message was prepared from the post-ribosomal supernatant of reticulocytes lysate[8,9]; some was used as a template for the synthesis of a αH^3-cDNA probe by a reverse transcriptase reaction[10] and the remainder was deadenylated by processive phosphorolysis with polynucleotide phosphorylase[5]. Two samples of 100 oocytes from the same *X. laevis* female were microinjected[11] with an aqueous solution of poly(A)-free α-globin mRNA with or without haemin. Forty oocytes from each batch were stored immediately after injection and the remaining 60 oocytes of each batch were incubated for 72 h in

Barth medium at 20 °C. We then used molecular hybridisation with the ^{3}H-cDNA probe to compare the amount of globin mRNA remaining in oocytes microinjected with either poly(A)-free mRNA alone and with haemin. Increasing amounts of RNA from each sample of oocytes were hybridised to a constant amount of α-globin enriched ^{3}H-cDNA at concentration where less than 20% of the radioactive probe is annealed at the end of the reaction[2]. In these conditions, the amount of ^{3}H-cDNA annealed was proportional to the amount of globin mRNA present in the reaction medium for all samples tested (Fig. 2). The slopes of the straight lines corresponding to the four samples of oocytes thus constitute relative measurements of the amounts of globin mRNA present in each batch.

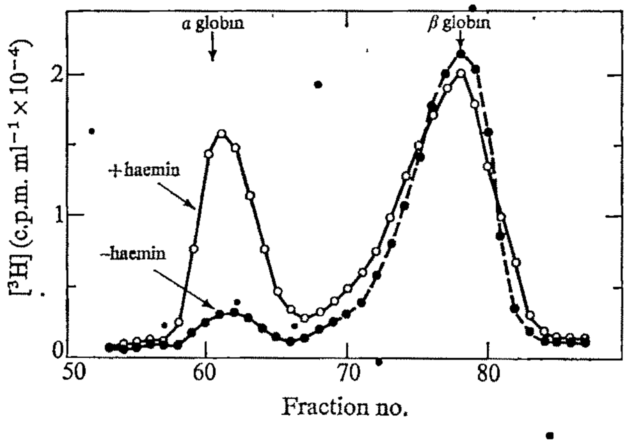
In the presence of haemin only 13% of the injected poly (A)-free α-globin mRNA remained intact at the end of the incubation, whereas 60% of the injected message remained hybridisable to the ^{3}H-cDNA probe in the absence of haemin (Fig. 2). Similar results were obtained in another experiment using different preparations of α-globin mRNA and H^3-cDNA as well as oocytes from a different frog.

From previous experiments[3] and controls data (not presented), it is known that haemin *per se* has no degradative effect on injected native globin mRNA. Thus, the simplest interpretation of our results is that, in *Xenopus* oocytes there is a mechanism for the degradation of poly(A)-free mRNA requiring or strongly activated by translation or at least its initiation.

Puromycin enhances the degradation of a microinjected *Dictiostyleum* RNA preparation enriched in mRNA[12]; this led to the suggestion that the release of mRNA from ribosomes reduces its stability. We cannot explain these results as, using purified native globin mRNA in the same kind of experiments, we did not observe any effect of puromycin on the stability of the message. It should be noted, however, that it has proven impossible to keep oocytes in healthy conditions for long periods of puromycin treatment. One may therefore question the physiological meaning of such experiments. The use of haemin to enhance the translation of α-globin mRNA does not have this disadvantage.

On the other hand, it has recently been claimed[13,14] that translation, or at least some of the step(s) involved in the process, are required for the degradation of mRNA in different systems. The observations presented here strengthen these claims.

Fig. 1 Relative synthesis of α-and β-rabbit globin chains in oocytes injected with native globin mRNA 5 ng per 50 nl. ●, In the absence of haemin; ○, in the presence of haemin (1.5 mM in the injection medium). Following injection, each set of oocytes was incubated for 15 h at 20 °C in Barth's medium containing ^{3}H-histidine (50 Ci mol^{-1}, 200 μCi ml^{-1}). After incubation, the oocytes were homogenised with carrier rabbit haemoglobin and globin was prepared from the 10,000*g* supernatant of the homogenate[15]. Globin chains were separated on carboxymethyl-cellulose columns by a pyridine–formic acid gradient[15] and the radioactivity of the eluted fractions was determined in a scintillation spectrometer.



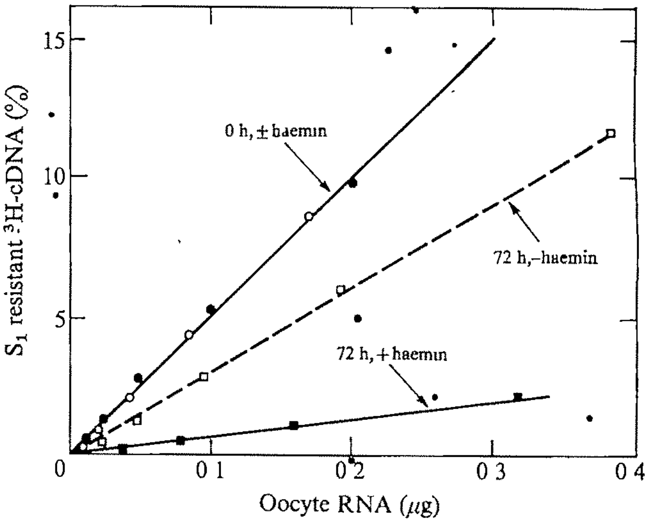


Fig. 2 Effect of haemin on the stability of poly(A)-free α-globin mRNA in *X, laevis* oocytes. Two hundred *Xenopus* oocytes were injected with poly (A)-free α-enriched globin mRNA 5 ng per 50 nl in aqueous solution; 100 oocytes were injected with mRNA in the absence of haemin, and a further 100 were injected with mRNA dissolved in a 1.5 mM haemin solution. Forty oocytes from each batch were frozen immediately after microinjection: the remaining 60 were incubated in Barth's medium at 20 °C for 72 h. Total RNA from each sample of oocytes was extracted using a phenol–chloroform procedure[4]. Increasing amounts of RNA from each sample of oocytes were hybridised to a fixed amount of globin ^{3}H-cDNA in conditions where the amount of annealed cDNA is proportional to the amount of globin mRNA present in the reaction medium. Hybrids were detected by their S$_1$ nuclease resistance[5]. Hybridisation of RNA to (^{3}H) globin cDNA: □, ○, RNA was extracted from oocytes micro-injected with poly (A)-free α-enriched globin mRNA without haemin; ○, RNA extracted immediately after injection; □, RNA extracted after 72 h of incubation of oocytes. ■, ●, the same with haemin.

matters arising

Backwarming due to circumstellar shells

IN a recent publication, Donnison and Williams[1] discussed the possible effects which a circumstellar dust shell could have on the evolution of a premain sequence star surrounded by it. If λ is the fraction of energy emitted by the star that returns back to it, then they concluded that $(1-\lambda)/\lambda$ can have a value as low as

$$(1-\lambda)/\lambda \simeq (T_O/T_I)^4 \quad (1)$$

where T_I and T_O represent the temperatures of the inner and the outer surfaces of the shell. We intend here to draw attention to the fact that equation (1) could be misleading since it represents the smallest value that can ever be allowed by the ratio, and is by no means a realistic limit. The full expression for this ratio can simply be derived as follows.

If we assume that the shell stores no energy, then

$$R^2T^4_{\mathrm{eff}}(1-\lambda) = \alpha_1 R^2_O T^4_O \quad (2)$$

where R and R_O are the stellar radius and outer radius of the shell and T_{eff} is the effective temperature of the star, α_1 is a constant, which is included because the outer surface in reality will not be a perfect black body characterised by the temperature T_O.

Simple geometry implies that the fraction of the radiation emitted by the inner surface which strikes the star is

$$\alpha_2 \mu R_I^2 T_I^4 \quad (3)$$

where α_2 compensates for the inner surface not being a perfect black body and μ is the fraction of the total solid angle which is subtended by the star at the inner surface of the shell, so that $\mu = \beta(R^2/R_I^2)$ with β a numerical constant which is easy to determine if the star is small but more complicated if the star and shell have similar radii. Hence, from (3)

$$\lambda R^2 T^4_{\mathrm{eff}} = \alpha_2 \beta R^2 T_I^4 \quad (4)$$

From (2) and (4)

$$\frac{(1-\lambda)}{\lambda} = \left(\frac{\alpha_1 R_O^2}{\alpha_2 \beta R^2}\right)\left(\frac{T_O}{T_I}\right)^4 \quad (5)$$

And it is immediately evident that equation (1) as used in the reference[1] is only applicable to a very restricted set of physical parameters where

$$\alpha_1 R_O^2 = \alpha_2 \beta R^2 \quad (6)$$

In general $R_O \gg R$ and the ratio $(1-\lambda)/\lambda$ is very much greater than the value given by equation (1) (that is, λ is smaller).

We conclude, therefore, that even though it is theoretically possible to have a situation where λ is close to unity, which results in a drastic change in the evolution of the central star, generally, in physical meaningful situations $\lambda \ll 1$ and backwarming has no real effect.

Possible solar control of North Atlantic oceanic climate

TRENDS in the climate of the North Atlantic Ocean over the past century have been described recently by Colebrook[1]. He discussed the variation in the average sea level, the number of cyclones and the sea-surface temperature. He showed that low sea-surface temperatures in the North Atlantic are associated with a higher-than-normal flow in the Gulf Stream and a lower-than-normal frequency of tropical cyclones, indicative of above average intensity in mid-latitude westerlies. The sea-surface temperature data were smoothed by the application of eigenvector filters which were approximately equivalent to 7-yr running means. A 10–11-yr periodicity, which tended to be in phase with the sunspot cycle, was found following the removal of long-term trends from the smoothed data. I point out here a very significant long-term correlation between the sea-surface temperature and the 7-yr running mean of the annual sunspot numbers. I have redrawn the sea-surface temperature data of Colebrook[1] and compared it with the 7-yr running mean of the annual sunspot number for Marsden squares 145 D and 182 B (Fig. 1). In both cases the vertical scales were adjusted so as to make the total amplitude of the long-term variation approximately the same on the graph.

There is very good correlation between the two sets of data for Marsden square 145 D (45°–50°N, 5°–10°W) while the correlation is less marked for Marsden square 182 B (50°–55°N, 15°–20°W). This difference in the degree of correlation between the two sets of data might be accounted for by the difference in latitude between the two areas under consideration. The effect of latitude on the

[1] Colebrook, J. M. *Nature* 163, 576–577 (1976).
[2] King, J. W *Aeronaut Astronaut.* 13, 109–118 (1975).

Colebrook replies—In the light of the very impressive correlation between sea-surface temperature and annual sunspot numbers demonstrated by Muir[1], I comment here in greater detail than was possible before[2] on the periodicities in sea-surface temperature data for Marsden squares 182 and 145. Figure 1 shows plots of filtered sea-surface temperatures representing the dominant periodic elements in the series following the removal of the long term trend. In each case there is a marked 10–11-yr periodicity. There is a fairly good phase relationship between the various temperature series and with the sunspot maxima

It should also be noted that Cohen and Sweetser[3] detected an 11-yr periodicity in their series of frequencies of tropical cyclones in the Atlantic.

In the light of all the evidence now available there seems little doubt that sunspot numbers do have an influence on the climate of the North Atlantic Ocean.

I suggested previously[2] that the effect on sea-surface temperatures in the north-east Atlantic was produced by variations in southerly anomaly winds, involving direct heat exchange with the atmosphere. The relationship found by Muir implies an influence on the atmospheric circulation over the whole North Atlantic with a consequent effect on the Gulf Stream. This is consistent with the results presented by Maximov[4] which indicated that the 10–11-yr cycle in sea-surface temperature occurs over most of the North Atlantic Ocean.

Oxygen isotope ratios in spruce cellulose

Although not affecting the practical significance of their work, Gray and Thompson's[1] finding that oxygen isotope fractionation in the cellulose of white spruce (*Picea glauca*) depends on winter rather than summer temperature warrants further discussion. It is unlikely that the tree is photosynthesising to any significant degree in the winter. I suggest here an alternative mechanism which would produce the observed results.

Two facts argue against winter photosynthesis: First, Fritts's[2] conifer, cited by Gray and Thompson, photosynthesised only when the temperature was above freezing and soil water stress was low—two conditions unlikely to hold for long periods in the Edmonton winter. Second, Norway spruce (*Picea abies*) chloroplasts function in carbohydrate synthesis only during the summer months[3]. If this is also true for white spruce, winter photosynthesis is probably not possible.

For energetic reasons a heavier isotope accumulates preferentially in that molecule having the highest bond multiplicity at the point of isotopic substitution[4,5]. Thus, when ^{18}O and ^{16}O distribute themselves between H_2O and CO_2, the CO_2 (in which oxygen is double bonded) will get proportionately more ^{18}O than the H_2O (in which oxygen is single bonded). This effect decreases with increasing temperature[6]. Therefore, if one looks at oxygen from CO_2 which has been in solution with H_2O, the δ ^{18}O-temperature curve will have a negative slope. But, Gray and Thompson's curve has a positive slope. The oxygen in their cellulose might have come from H_2O rather than CO_2, but this is not consistent with our current understanding of photosynthesis. Alternatively, starch may be hydrolysed to glucose within the cell during the winter. The glucose (single-bonded oxygen) would then exchange oxygen with cellular organic acids (or any other molecules containing double or triple oxygen bonds), producing the observed δ^{18}O–temperature curve.

The behaviour of Norway spruce chloroplasts[3] seems to support this idea. In autumn, they function primarily in starch storage. In winter, they group together and membranes become disorganised. In spring, they again store starch—of necessity the same starch which was stored in the autumn. This mechanism suggests that the bulk of radial growth in the tree is produced by the previous year's photosynthate, which is contrary to accepted thinking[7].

Hydrolysis of starch to sugars in the winter could have functional value. Sugar solutions protect at least some cell functions during freezing[8]. Heat of hydrolysis could conceivably provide a significant warming effect within the cell.

I thank Dr James Pickett for helpful discussions.

Isotope tree thermometers

WE wish to make several comments on the recent paper in *Nature* by Libby *et al.*[1]

They determine the δ^{18}O in wood by analysing the CO_2 produced by heating the total wood samples with $HgCl_2$.

$$\delta D‰ = \left(\frac{\text{D/H sample}}{\text{D/H standard}} - 1\right) 1000$$

The standard is usually standard mean ocean water (SMOW). δ^{18}O is defined similarly. The standard used in Libby *et al.*[1], is as given in their text. Neither Libby *et al.*[1] nor the original developers of this method[2] have shown that this procedure is valid for the high accuracy necessary in this work.

The δD data shown in their Fig. 3 (ref. 1) was originally published elsewhere[3] where they reported that these δD analyses were made on H_2 released by pyrolysis of a mixture of wood sawdust and powdered uranium. In their *Nature* article[1] they state that this same δD data were obtained by combustion of the wood with oxygen and passage of the resulting water over hot uranium. This apparent contradiction should be cleared up, since only the latter method has been shown to be reliable[4–6].

They assume that the δ^{18}O and δD values of the total wood can measure by proxy the δ^{18}O and δD of meteoric water used by the plants. It is the isotopic composition of the meteoric water which is the 'thermometer'. Their assumption is incorrect[6]. It is known[5,6] that the δD of lipids in the wood can be 100‰ lower than the δD of the total plant. Thus even if correct δD analyses are made on total wood, this δD also depends on the wood's variable chemical composition which is not temperature sensitive[6].

Their sole criteria for a valid relationship between temperature and the δD and δ^{18}O values of total wood is the existence of doubtful correlations between the isotope records in dated tree rings and the time-equivalent instrumentally recorded temperatures in cities. Their choice of climatic data for correlation purposes is subjective. For example, the isotopic data of their Fig. 1 is correlated with average annual temperature, whereas, in their Fig. 3 the correlation is between isotopic data and English winter temperature. Their data bear little correlation with the climatic history of Europe as estimated by Lamb[7].

Some of their data are very unusual. The δD for the German oak tree rings shown in their Fig. 3 changes by 150‰ between 1820 and 1940 θ⁻ and 190‰ between 1720 and 1820 θ⁻. This change is about three times as large as the δD change between summer and winter precipitation in Vienna in their Fig. 4, which corresponds to a 20 °C change in temperature. Also there is only a 180‰ range in the δD of average precipitation available to plants growing from tropical to subarctic temperatures[8] (Fig. 1 below). These changes in δD values in the oak tree could not be due to changes in δD of the precipitation in Germany nor to climatic changes. Similar questions can be raised about the unusually large changes in δ^{18}O in their Fig. 1[1].

We have made some δ^{18}O measurements on cellulose from tree wood and other plants (S. G., P. Thompson and C. J. Y., unpublished) and found that the relationship between the δD and δ^{18}O in cellulose is complicated by factors such as evaporation–transpiration in the plants. There is no *a priori* reason to expect the δD against δ^{18}O relationship to be similar to those for meteoric waters. Thus their claimed slope of 8 for the relationship between the δ^{18}O and δD for total wood shown in their Fig. 6, and the conclusions they draw from this figure are puzzling. The slope 8 is not by itself an indication that the tree is storing old water, nor does it support their stated hypothesis that atmospheric CO_2 and atmospheric H_2O are in isotopic equilibrium. The δ^{18}O of the atmospheric CO_2 varies little and is basically determined by the equilibration of CO_2 with ocean water[8–11].

Fourier analyses of a continuous 2,000-yr record of δD and δ^{18}O analyses for five-year intervals of tree rings should reveal the presence of shorter cycles than reported by them. It is difficult to understand why the shorter cycles were not included in their Fig. 7 considering their expressed interest in finding a 21-year cycle.

We conclude that the δD and δ^{18}O as determined by Libby, *et al.* on total wood do not give information about climate. On the other hand, we have shown that the δD analysis of the hydrogen from only the C–H groups in cellulose (isolated as nitrated cellulose) eliminates the problems of chemical heterogeneity and the exchange with water of the hydrogen in the OH groups[6]. The δD values of the cellulose C–H hydrogen and of the associated OH groups[6]. The δD values of the cellulos C–H hydrogen and of the ossociated environmental water were compared for 20 different species of land and aquatic plants including nine different species of trees, collected from areas including Scotland, the Yukon Territory, Wisconsin, California, Texas, and Miami, Florida. The comparison is shown in Fig. 1. The δD of the C–H hydrogen is, on the average −20±11% (1σ) relative to the δD of the environmental water. Thus, the δD of cellulose C–H hydrogen from plants systematically reflects the δD of the H_2O incorporated by them and should be a good climatic thermometer.

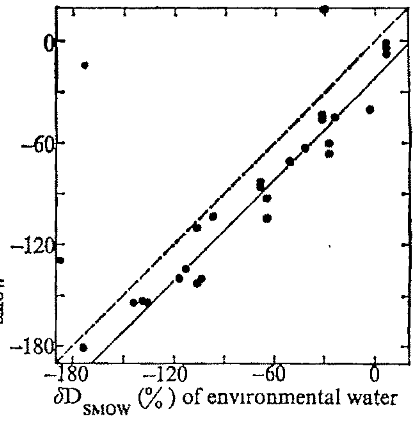

Fig. 1 The plot of δD of plant-derived cellulose C–H hydrogen (cellulose nitrate) against δD of environmental waters used in the plants, yields a linear regression curve (solid line) with a slope of 0 97 and intercept of −22‰. The linear correlation coefficient is 0.978. The dashed line is the $y = x$ curve. The samples include varieties of both land and aquatic plants from a wide geographic range.

Historically, Libby *et al.* should note that, by 1970, at least two laboratories[4,5] were measuring the isotopic composition of plants in order to determine by proxy the isotopic composition of meteoric water.

As far as the item on future research is concerned, we have already done much of what Libby *et al.*[1] recommend, including the identification of a 22-yr cycle in a 1,000-yr δD record[12] in the bristlecone pine of the White Mountains, California. We also analysed forty trees ranging in age from 9,000–22,000 yr to obtain a most interesting record of δD of meteoric water during the Wisconsin glacial period[13].

This work was supported by a grant from the National Science Foundation.

LEONA MARSHALL LIBBY AND LOUIS J. PANDOLFI REPLY—Long-term isotope changes in precipitation, caused by changes in climatic temperature, are well documented in polar ice caps; the heavier of the stable isotopes is depleted in ice laid down in the ice age by comparison with present-day ice. In 1970 we extended this concept to trees, suggesting that they are also thermometers. In trees which use rain to manufacture their rings, isotope variations in the rings should be climate indicators because the isotope composition in rain and CO_2 varies with temperature.

On May 17 1971, the Advanced Research Projects Agency funded our proposal that "temperature variations may be evaluated by measuring stable isotope ratios in natural data banks such as tree rings and varves." L.M.L. had previously calculated[1] the theoretical temperature coefficient of the isotope fractionation in manufacture of wood from CO_2 and H_2O, finding that the coefficient is small compared with that measured in rain.[2] Therefore isotope variations in rain should be dominant in trees that drink rain.

The next question is what to measure: whole wood, cellulose, lignin . . . ? It may be true that the ratio of cellulose to lignin differs in spring and summer wood and over spans of decades.[3] Tentatively it seems that there is more lignin when it is warmer as in later summer, and that lignin is more enriched in the heavy isotope. We choose to regard such variations as part of the response of trees to climate variations, namely as part of the record of climate history.

Thus it is valid to measure any one of these substances, depending how faithfully it tracks local mercury thermometers. Our measurements on whole wood track for both hydrogen and oxygen. We expect the same success for cellulose and lignin, but they will track with different amplitudes because in these compounds different sets of chemical bonds are fractionating when the temperature changes.

In the development of radiocarbon dating the same question arose whether to measure wood, cellulose, or lignin, that is the $^{13}C/^{12}C$ and $^{14}C/^{12}C$ ratios will be different in each of these materials just as D/H is. W. F. L. chose to measure whole wood.

The next problem is what chemistry to use. There is compelling evidence that when sapwood passes into heartwood it becomes sealed against exchange with sap.[4] It is also known that isotope exchange occurs when wood is finely ground and soaked in hydrogen containing liquids[5]. So we decided to use dry chemistries. For our first tree sequence[6,7] we measured D/H by reacting sawdust with uranium to release H^2, 99‰ quantitatively. For the later tree sequences[4] we burned wood to water and reacted it with uranium to release H_2. For measurement of $^{18}O^{16}O$ we modified the method of Rittenberg and Pontecorvo[8] by carrying it out at very high temperatures, 99% quantitatively.

Our third problem was which trees to study. We could not use bristlecones because there are no lengthy temperature records for hundreds of miles near where they grow and we were determined to calibrate the trees against local mercury thermometers. Because the longest temperature records are in Europe, we obtained a German oak from the only tree laboratory then existing in Europe[4].

For measurement of the oaks, we used per force a mass spectrometer of somewhat low accuracy, and achieved the accuracy necessary to demonstrate tree thermometers by making many measurements on each sample. On the later tree sequences[4] we used high-precision machines with accuracies of ±0.1 p.p.t. for $^{18}O/^{16}O$ and ±2 p.p.t. for D/H. Whether the oxygen in tree rings comes from water or from CO_2 is a non-question, because Cohn and Urey[9] showed that isotopic equilibrium between the two substances is obtained in the atmosphere in a few hours.

The least square correlation of D/H against $^{18}O/^{16}O$ in the 1,800 yr sequence yielded the relation,

$$\delta D = 8.2\,\delta^{18}O + \text{constant}$$

which is the same as in worldwide rain[10] within experimental error. If both the hydrogen and the oxygen in the OH groups exchanged with water vapour there is absolutely no way that the slope can be 8, because there are twice as many hydrogens bonded to carbon as to oxygen.

The Fourier transforms[4] of our five-year samples in the 1,800 yr sequence showed ten significant periods ranging between 50 and 300 yr, the same for D/H and for $^{18}O/^{16}O$. To look for periods of less than 50 yr in a sequence of five-year samples or to look for periods of more than 300 years in a sequence of 1,800 yr is meaningless. Such periods appear in the transforms but they do not necessarily represent reality. To understand this we generated random signals of values 0 and 1, and assigned them to 10-yr intervals of a 1,000-yr hypothetical sequence, and made a Fourier transform. In three such computer experiments we always obtained periods at 10 and about 20yr which are artefacts of the sampling interval. These statements can be understood by reading carefully ref. 11, particularly pages 30–33.

Obviously ring samples integrated over 5 or 10 yr cannot give proof of the 21-yr solar cycle; instead each ring must be measured.

Nine of our ten periods[4] are equal to[12] those evidenced in the Greenland ice wells.[13] One of the periods, that at 173 yr, has also been found by Houtermans and Suess[14] in bristlecone pines.

Our isotope ratios track better with winter temperatures than with the average temperatures. Dr John Fletcher suggested that when climate deteriorates summer is brief and January, February, and March represent the longer winters.

For the cellulose component of wood, Epstein and Yapp[15] and Gray and Thompson[16] have corroborated our work.

Tree-ring thermometry promises to evaluate past climates and predict future climates.

The Science Dictionaries

Three useful and up-to-date works of reference intended not only for students, teachers and researchers but also for science journalists and the general reader.
Each book is designed for easy use – entries are arranged alphabetically and defined under the most common form of term, with synonyms in brackets. S.I. units are used throughout and all entries are thoroughly cross-referenced.

A Dictionary of Life Sciences

E. A. Martin

The recent trend to treat the biological/life sciences as a whole rather than divided into separate units is reflected in this concise dictionary which brings together in one volume all the main branches of zoology and botany. Selected terms in related fields of biochemistry, endocrinology, animal behaviour and palaeontology are also included. All major plant and animal classes are fully described as well as the more important orders, and common names of animals and plants are cross-referenced to their appropriate taxonomic groups.
1976 £5.95 392pp

A Dictionary of Earth Sciences

Stella E. Stiegeler

The subjects covered here include geophysics, structural geology, geomorphology, oceanography, stratigraphy, palaeontology, sedimentology, climatology, meteorology, soil science, cartography, mineralogy, petrology and surveying. The terms defined reflect the recent modification of traditional concepts and the resulting development of terminology in the earth sciences. In soil science, for example, a new system of classification is now in in use, with a completely new terminology for the soil orders.
1976 £5.95 320pp

A Dictionary of Physical Sciences

John Daintith

This book covers the main branches of physics, chemistry and astromony – from Abbe condenser to zoom lens and zwitterion. A selection of relevant terms from the related fields of electronics, computer science and mathematics is included. Full accounts are given of the properties and uses of the chemical elements and many of their compounds. All the chemical terminology used is that recommended by the International Union of Pure and Applied Chemistry.

PALEOPATHOLOGICAL DIAGNOSIS AND INTERPRETATION: Bone Diseases in Ancient Human Populations *by* **R. Ted Steinbock,** *Harvard Medical School, Boston, Massachusetts. Foreword by* **T. Dale Stewart.** The author provides a systematic approach for diagnosing bone lesions in excavated skeletal series and interpreting the significance of such diseases in ancient human populations. Chapters discuss the biology and gross anatomy of normal bone to aid in understanding the bone changes produced by pathological conditions. The major traumatic, infectious, nutritional, metabolic, degenerative and neoplastic diseases of bone are also covered A special section is devoted to establishing nutritional deficiency as the cause of peculiar lesions found in large numbers of excavated crania. The chapter on bone tumors and tumor-like processes defines the gross morphology of each condition to aid in diagnosing dried bone specimens where histology is unavailable. *'76, 440 pp., 274 il., 16 tables, $22.75*

CLINICAL ECOLOGY *edited by* **Lawrence D. Dickey,** *Past President, Society for Clinical Ecology. (45 Contributors)* This presentation is concerned with certain environmental excitants such as chemical contaminants, pesticides, herbicides, additives, preservatives, vehicles and excipients found in air, water, food, drugs, and habitat Domiciliary air pollution is detailed, and natural biologic exposure to dust, mold spores, danders, pollens, contactants, food, odors and terpenes is covered. Also discussed are application of avoidance procedures where specific excitants are recognized; the use of hyposensitization, desensitization, immunization and neutralization techniques when exposures are unavoidable; and the improved tolerance that results with avoidance and dietary, nutritional, orthomolecular and immunotherapeutic procedures. *'76, 832 pp. (6 3/4 x 9 3/4), 47 il., 94 tables, $35.75*

AN INTRODUCTION TO BIO-INORGANIC CHEMISTRY *edited by* **David R. Williams,** *The Univ. of St. Andrews, St. Andrews, Scotland. (23 Contributors)* Since the realm of bio-inorganic chemistry entails the entire phenomena of human life, this volume could contain an infinite number of chapters. The selection has been limited, therefore, to sections describing the three natural divisions of the field: general principles of bio-inorganic chemistry, experimental methods used to produce the facts that gave rise to these principles, and application of these principles to medicine. This book does not present mere streams of chemical facts unrelated to the world outside the lecture hall or laboratory, but rather portrays bio-inorganic chemistry as the challenging, creative and relevant field of research that it is. *'76, 416 pp. (6 3/4 x 9 3/4), 341 il., 62 tables, $24.50*

SLEEP RESEARCH: A Critical Review (2nd Ptg.) *by* **Frank R. Freemon,** *Vanderbilt Univ. School of Medicine, Nashville, Tennessee.* The various aspects of sleep research are brought together in this volume and their results are incorporated into other sciences. The results can thus be used in the clinical treatment of patients. Theory is included when essential to an understanding of the factual material. Specific topics include sleep phenomenology in man, how the sleeper processes information and awakens, the application of sleep research to patient problems, problems of insomnia, and ways in which disease processes can change sleep patterns. 74, 220 pp., 17 il , 14 tables, $14.50

Chemotherapy of Herpes Simplex Virus

edited by J. S. Oxford, F. A. Drasar and J. D. Williams

May/June 1977, viii + 154pp., £4.80 (paperbound) 0.12.531760.3

Herpes virus infections of man are an important cause of ocular disease and virus encephalitis. In certain countries genital herpes is a sexually transmitted disease second only, in frequency, to gonorrhea. Virologists, clinicians, chemists, biochemists and molecular biologists have contributed to the text, as it is felt that progress in the control of the human virus depends on a multidisciplinary approach General aspects of herpes infection in man, domestic animals and birds are discussed, along with the basic virology. The usefulness of various laboratory model infections, in the search for new drugs, are examined and the few compounds used in clinical medicine are assessed.

Advances in Physical Organic Chemistry Volume 14

edited by V. Gold

associate editor: D. Bethell

April/May 1977, viii + 376pp., £16.00/$31.25 0.12.033514.X

From reviews of previous volumes. *'the editor is to be congratulated on his continued success in choosing subjects and authors to provide reviews of wide interest and varied content... This series is a necessity for any well stocked chemical library, and is likely to find its way into the shelves of many individual physical-organic chemists.'*

Transactions of the Faraday Society

Contents: *T. W. Bentley and P. von R. Schleyer:* Medium effects on the rates and mechanisms of solvotic reactions *A. Pross:* The reactivity-selectivity principle and its mechanistic applications *E. Buncel and H. Wilson:* Physical organic chemistry of reactions in dimethyl sulphoxide. *Michael J. Blandamer:* Kinetics of organic reactions in water and aqueous mixtures. Author index. Cumulative index to authors. Cumulative index to titles.

Linnean Society Symposium Series Number 4

Problems in Vertebrate Evolution

edited by S. Mahala Andrews, R. S. Miles and A. D. Walker

April/May 1977, xii + 412pp., 25 plates £18.50/$36.10 0.12.059950.3

This book provides a new look at a wider range of problems in vertebrate evolution dealing, amongst others, with agathans, fishes, birds, dinosaurs and lizards, and including studies on both fossil and Recent species The contributors present new evidence and also novel interpretations of existing data. Their work covers specialised problems in vertebrate history involving comparative and functional anatomy, microstructure and morphogenesis The papers reflect the rapid changes that have taken place in comparative biology in the last decade as a result of new discoveries, the introduction of new techniques and refinement of methodology, and they indicate the possible direction of future work

The Chemistry of Pyrroles

R. Alan Jones and G. P. Bean

May/June 1977, x + 528pp., £21.00/$41.00 0.12.389840.4

The aim of this textbook is to provide a comprehensive survey of the basic chemistry of pyrrole presented in a systematic modern manner. The eleven chapters discuss the structure, synthesis, and the reactivity of the pyrrole ring, the synthesis and reactivity of substituted pyrroles and the physical organic properties of pyrrole and its derivatives This new and very comprehensive book will be of great value to undergraduate and graduate students and workers in the fields of chemistry and biochemistry, as well as in pharmacy and medicinal chemistry.

Rare Gas Solids Volume 2

edited by M. L. Klein and J. A. Venables

May/June 1977, xiv + 644pp., £26.00/$50.75 0.12.413502.1

This book, together with Volume I, gives an up-to-date account of research on the rare gas solids. These solids, formed by condensing helium, neon, argon, krypton and xenon, are the simplest of all molecular solids, and consequently both theoretical and experimental research has progressed further than that on other molecular solids By describing achievements, and highlighting points of uncertainty, it is intended to stimulate further research on all these materials. The present volume contains largely the experimentalists's view of the subject, in contrast to Volume I which was mostly written by theoreticians. Volume 2 is to some extent technique orientated and contains extensive tabulations and critical evaluation of experimental data for the rare gas solids

Interferon as an anti-viral

Thomas C. Merigan

Interferon and Its Clinical Potential. By D. A. J. Tyrrell. Pp. viii+104. (Heinemann Medical: London, 1976.) £3.50.

THIS brief and timely monograph clearly presents the author's personal views of the interferon area. The 91-page review covers two decades of intensive research which has formed the basis for the present clinical investigations involving interferon, following its discovery in 1957. This remarkable molecule is not only of clinical interest as an anti-viral, but there is an emerging body of information supporting its role as a locally active cell regulator with a broad range of functions beyond its anti-viral action. It not only seems to influence malignant, immune and haematopoietic cell division, but certain specialised cell biosynthetic functions as well. This viral inhibitor discovered by Alick Isaacs now also attracts the efforts of molecular biologists as cell-free systems have been developed in which it can be produced and in which anti-viral action can be demonstrated. The recent discovery of cell membrane receptors for interferon, which seem to be gangliosides, should now allow elucidation of the mechanism of the first step in its action—that is, its binding to cells.

The book provides the clinician, basic virologist, and specialised investigator with a firm basis for understanding the potential of interferon in human medicine. It is digestable in an evening of solid reading by anyone with an understanding of modern biology. Although clinical trial results are appearing with greater frequency and views on its mechanism of action will be sharpened as more is learned of the fundamentals of viral replication, the basic description of the interferon system presented in this volume will be useful to future investigators.

The enthusiasm of the writer and his clear style of writing leads the reader through the voluminous recent literature in this area. One hundred and sixty-five carefully selected references are used to support a very readable discussion of interferon action and production in cell culture, animal models and human disease settings. Present concepts of the assay, properties and purification of interferon are also discussed. A number of well cast tables and easy-to-comprehend diagrams aid the reader in following the text. The methods for preparation and purification of human leukocyte interferon for clinical use, developed in Finland and in the UK, are discussed by the author, who was chairman of the UK Scientific Committee on Interferon, a group which planned and supported much of the early work with the material. The long experience of the author in this area insures the reader that the book accurately presents the basic biology of the interferon system, together with present accomplishments and perspectives for its use as a clinical anti-viral and anti-tumour agent. ☐

T. C. Merigan is Professor of Medicine and Head of the Division of Infectious Diseases at Stanford University School of Medicine, Stanford, California.

Arroyos in the American South-West

Arroyos and Environmental Change in the American South-West. By R. U. Cooke and R. W. Reeves. Pp. xii+213. (Clarendon: Oxford, 1976.) £8.50.

LARGE gullies with near vertical walls and flat, sandy bottoms, dissecting the alluvial valley floors of the American South-West, have attracted the attention of geologists and geographers for several decades. The arroyos, as they are called, seem to have developed after 1850, about the time of white settlement and the introduction of livestock in large numbers to the western plains. Not unnaturally, it was commonly supposed that land-use changes were responsible for the erosion, on account of depletion of the vegetation and greater runoff. Sedimentary sections showed, however, that there had been earlier periods of trenching in prehistoric times, and it was suggested that slight climatic changes were at least partly responsible.

It is known that overstocking occurred in Arizona about the same time as severe drought in the 1880s, and it is clear from J. R. Hastings and R. M. Turner in *The Changing Mile* (University of Arizona, Tucson, 1965) and from other sources that the vegetation has deteriorated markedly since that time. Cooke and Reeves show that in the coastal regions of southern California where arroyos also occur, rainfall records provide no support for the idea that secular or cyclic changes in precipitation have played a determining role in the formation of the arroyos. Furthermore, they present evidence that calls into question much that is commonly accepted about the effects of land-use on runoff coefficients.

Using archival records of various kinds, and in particular the field notebooks of the US General Land Office surveyors, Cooke and Reeves trace the development of a large number of individual arroyos. As they acknowledge, the extension of certain Californian arroyos was documented by W. B. Bull (*Am. J. Sci.* **262**, 249–258; 1964). Their own study is much more extensive. It demonstrates that wherever the history of an arroyo can be traced, individual events and acts of interference by man have been responsible for its initiation and enlargement. Cultivation of valley floors and destruction of vegetation along shallow watercourses have usually played an important part; but in the case of the San Simon arroyo, for example, a wagon route seems to have been the immediate cause of gullying, whereas the Santa Cruz arroyo was initiated by water supply channels. Elsewhere, concentration of drainage water by culverts or other man-made features started the downcutting.

Arroyos have destroyed floodplains, accentuated flood peaks and accelerated sedimentation to the detriment of the environment of the American South-West. We now know that they are the outcome of a multitude of individual events and that sweeping explanations are inadequate. Cooke and Reeves have labouriously but effectively sawn through the Gordian knot tied by earlier investigations.

A. T. Grove

A. T. Grove is Lecturer in the Department of Geography at the University of Cambridge, UK.

Stereochemistry

Stereochemistry: An Introductory Programme with Models. By J. Pearce and E. Glynn. Pp. 171+cut-out kit. (Wiley: London and New York, 1976.) £2.75; $5.

TEACHERS involved in imparting the basic principles of stereochemistry in organic molecules to their students are always faced with the problem of persuading the students to purchase sets of molecular models and to use them to build three-dimensional structures, thereby gaining a better understanding of stereochemistry. Pearce and Glynn have produced a kit of models and shapes together with a programmed text containing clear and detailed instructions, so that a student may work at his own pace, in discovering the essential principles of stereochemistry and conformation. A number of fascinating shapes are provided which enable the student to gain an understanding and appreciation of chirality and its importance in stereospecific reactions in both chemical and biochemical systems.

The models are of the well-known 'orbit' type and are easily assembled; cyclohexane and its derivatives in particular are easily constructed and manipulated. The programmed text includes a progressive series of questions for the student to answer, often as a result of the assembly and study of models or shapes. The answer is provided after each question and at the end of each section the essential principles relating to it are reviewed.

The text begins with a discussion of the various types of molecular models, and instructions relating to the construction of models of simple covalent molecules using the kit provided. Conformations of open-chain and ring compounds are discussed, followed by a consideration of chirality and restricted rotation. The various strategies for examining molecular shapes are explained, and the objectives of the learning program summarised. A series of appendices are provided at the end of the text, some of which the reviewer would have found more useful if given either at appropriate places in the text or at the beginning. The text might also have benefited from a more detailed consideration of the D/L and R/S conventions.

This is an excellent programmed text and set of models and shapes for a student to use in discovering the principles of stereochemistry. It is good value for money and can be strongly recommended. A larger set of models attached to the text, however, would be desirable for long-term use to enable the student to build larger models, pertaining to his own interests and possibly outside the range of the text.

D. I. Davies

D. I. Davies is Reader in Organic Chemistry at King's College, University of London, UK.

Aspects of hydrology

Facets of Hydrology. Edited by John Rodda. Pp. xvi+368. (Wiley: London and New York, 1976.) $39; £19.50.

THIS book is a bold attempt to bring together, in a single volume, papers describing much of the hydrological work which has been undertaken in the past decade. Most of the authors are internationally recognised experts, although a few are little known outside their own country.

The stated aim of the book is to provoke the interest of a range of readers, both researchers and practitioners, who are hydrologists or scientists working in allied fields. These aims are achieved with a fair measure of success but, as is often the case with a book produced for a wide and diverse audience, it is not entirely successful. At the one extreme some chapters may be regarded as superficial by experts in the particular subject; at the other there are chapters which are written for readers who themselves already have a very specialised knowledge.

Nevertheless, every reader will find much of interest in a book which will enable him to acquire knowledge of many of the facets of hydrology with which he was not familiar.

It is not possible to comment on each of the chapters in the book and to single out any particular chapter is simply to reflect the reviewer's own interests. The chapters on river gauging, water quality, basin studies, statistical methods, and law, however, each demonstrate in their own way, the diversity of material presented.

In the chapter on river gauging three new methods are discussed with a sensible balance between theory and practical applications. The fact that there is a chapter on water quality will be particularly welcomed by those people who have always argued that the division between water quality and water quantity is an artificial one. The chapter on basin studies presents a representative selection of the very wide range of work undertaken in recent years. That on statistical methods is one of the chapters requiring a fair degree of specialist knowledge. It tackles the problem of spatial variation in hydrological variables in a way which will be extremely useful to those people who are confronted with the problem. The chapter on law is a comprehensive review of the water law and will be of interest to all water resource engineers.

The overall impression is of a book which should find its way on to the shelves of most serious hydrologists and of all well stocked libraries.

M. J. Hamlin

M. J. Hamlin is Professor of Water Engineering at the University of Birmingham, UK.

Kew Record of Taxonomic Literature

This comprehensive annual publication indexes literature relating to the vascular plants of the world and includes all new names at all ranks with the exception of cultivars. No other single publication fulfils this need for unified coverage of the world's taxonomic and related literature. Since 1974 four volumes have been published, and volumes for literature published in 1975 and 1976 are at press.

1971	404pp	297mm	0 11 240518 5	£14 (£14.70)

CHEMISTRY OF THE FUNCTIONAL GROUPS: SUPPLEMENT A: THE CHEMISTRY OF DOUBLE-BONDED FUNCTIONAL GROUPS

edited by **S. Patai,** *The Hebrew University, Jerusalem.*

The series "The Chemistry of the Functional Groups" is planned to cover in each volume all aspects of the chemistry of one of the important functional groups in organic chemistry. This volume covers compounds containing a carbon-carbon, carbon-oxygen, carbon-nitrogen, or nitrogen-nitrogen double bond.

(Bound in 2 parts)

0471 66940 7	1374 pages	March 1977	£58.50/$107.50(set)
0471 99464 2	668 pages	,,	£29.00/$52.50(part 1)
0471 99465 0	706 pages	,,	£29.50/$55.00(part 2)

A TREATISE ON DINITROGEN FIXATION

edited by **R. W. F. Hardy,** *E. I. du Pont de Nemours & Co.,* and **W. S. Silver,** *University of South Florida*

Section III: Biology

This is devoted to a consideration of the broader aspects of dinitrogen fixation — the organisms involved, pertinent physiological processes of the microbe and the host plant, and, where appropriate, certain phytogeographical facets

0471 35138 5 approx. 688 pages In Press approx. £24.80/$41.10

Section IV: Agronomy and Ecology.

Emphasizes the nature and extent of the contribution of free-living and symbiotic diazotrophs in both natural habitats and agricultural situations.

0471 02343 4 approx. 544 pages In Press approx. £22.60/$37.50

TOPICS IN PHOSPHORUS CHEMISTRY Vol. 8

edited by **E. J. Griffith,** *Monsanto Co,* and **M. Grayson,** *American Cyanamid Co.*

This provides critical evaluations and reviews of progress in the diverse special areas of the subject, written by scientists actively engaged in work in the field. Topics include: Chemistry of Phosphorohydrazides and Azides, Mass Spectra of Organophosphorus Compounds; NMR Parameters of the Proton Directly Bonded to Phosphorus; A Study of Isolated Complexes of Neutral Ligands and the Chemical Analysis of Phosphate Rock.

0471 32789 1 672 pages February 1977 £30.70/$52.00

QUATERNARY STRATIGRAPHY OF NORTH AMERICA

edited by **W. C. Mahaney,** *York University.*

This volume summarizes the composition, sequence and correlation of Quaternary surficial materials in North America. It includes 24 papers which summarize the status of knowledge, research gaps, problem areas and future trends Particular emphasis is placed on research of the last decade. (Quaternary Stratigraphy Symposium 1976)

0470 98945 9 528 pages February 1977 £20.60/$34.95

Published by Dowden, Hutchinson & Ross Inc., and distributed by John Wiley & Sons Ltd.

THE ENZYMES OF BIOLOGICAL MEMBRANES

edited by **A. N. Martonosi,** *Department of Biochemistry, School of Medicine, Saint Louis University.*

Vol. 1: Physical and Chemical Techniques

Deals with the physical and chemical techniques (X-ray crystallography, nuclear magnetic and electron spin resonance, flourescence spectroscopy, immunochemistry, etc.) used in the characterization of membrane enzymes.

0471 99427 8 272 pages November 1976 £10.50/$20.00

Vol. 2: Biosynthesis of Cell Components

Emphasizes the importance of membrane linked enzymes participating in phospholipid, sterol, protein, and glycoprotein synthesis or in the synthesis of the bacterial cell wall.

0471 99428 6 672 pages November 1976 £28.00/$55.00

Vol. 3: Membrane Transport

Contains information on the transport systems of bacterial and animal cell membranes and their mode of coupling to a metabolic supply of energy.

0471 99429 4 476 pages November 1976 £21.00/$39.00

Vol. 4: Electron Transport Systems and Receptors

Deals with electron transport providing a concise, critical, and up-to-date picture of the problems and accomplishments of the field.

0471 99430 8 448 pages November 1976 £20.00/$37.00

MECHANICS OF THRUST FAULTS AND DECOLLEMENT

edited by **B. Voight,** *Pennsylvania State University.*

Through a selection of classic papers from the research literature, this presents a history of the development of thrust fault analysis, and therefore, a history of tectonic geology. This book will be of particular interest to structural geologists, petroleum geologists, and soils specialists. (Benchmark Papers in Geology Vol. 32)

0470 98946 7 494 pages February 1977 £24.00/$40.65

Published by Dowden, Hutchinson & Ross Inc., and distributed by John Wiley & Sons Ltd.

IMINIUM SALTS IN ORGANIC CHEMISTRY Part 1

edited by **H. Bohme,** *Universitat Marburg, Germany,* and **H. G. Viehe,** *Université de Louvain, Belgium.*

Together, Parts 1 and 2 will describe nearly all aspects of the potential of iminium functions in synthons of nature, industry, and research. Part I covers theoretical and physical aspects, with part 2 providing more synthetically oriented chapters underlining the power of the iminium function. (Advances in Organic Chemistry)

0471 90692 1 646 pages February 1977 £32.00/$54.00

new books in
BIOCHEMISTRY

Biomedical Applications of Immobilized Enzymes and Proteins
edited by **T. M. S. Chang**
McGill University

One of the most productive new research areas in modern biochemistry has been the development and widespread application of immobilized enzymes and proteins. This outstanding two-volume work offers the first comprehensive survey of both the fundamental biochemistry and the innovative use of biologically active solid-phase materials in biology and medicine. The first volume is devoted to the basic chemical and physical properties of immobilized biochemicals, and to the multiplicity of current and future therapeutic applications, including the feasibility of immobilizing various enzymes and proteins for use in specific treatment regimes. Volume 2 discusses the applications and prospects of these substances in diagnosis and in public health as well as the techniques used in clinical and preventive medicine.

Volume 1: approx. 415 pages, illus., $53.40
Volume 2: approx. 355 pages, illus., $47.40

Immunochemistry of Proteins
edited by **M. Z. Atassi**
Mayo Graduate School of Medicine
and University of Minnesota

This outstanding new treatise reviews the major contemporary approaches to the study of the antigenic structure of native proteins, gathering together and critically evaluating for the first time the voluminous research literature on the immunochemistry of proteins. Topics covered in Volume 1 include chemical modification and cleavage reactions of proteins; effects of conformational changes and evolutionary mutations; *in vitro* immune responses; and fluorescence polarization. Volume 2 presents a thorough examination of those protein systems that have proved central to a general understanding of protein immunochemistry, including the antigenetic structure of myoglobin and lysozyme.

Volume 1: approx. 440 pages, illus., $53.40
Volume 2: approx. 415 pages, illus., $53.40

Lipid Metabolism in Mammals
edited by **Fred Snyder**
Oak Ridge Associated Universities
Medical and Health Sciences Division

This comprehensive treatise is destined to become the standard reference source on lipid metabolism in mammals. Emphasizing the uniqueness of lipid pathways in the different organs of the body, thorough and critical coverage is devoted to the comparative lipid biochemistry of each. Volume 1 explores the lipid pathways of the heart, liver and brain, as well as gastrointestinal tissues and blood cells. Volume 2 covers lipid metabolism in the lung, kidney, eye, gonadal tissue, mammary glands and skeletal muscle.

Volume 1: approx. 400 pages, illus., $51.00
Volume 2: approx. 385 pages, illus., $51.00

Alkaloid Biology and Metabolism in Plants
edited by **George R. Waller**
Oklahoma State University
and **Edmund K. Nowacki**
Institute for Biochemistry and Plant Physiology
East Polish Division of Plant, Soil, and Nutrition Science

Authoritatively written, this treatise carefully presents and evaluates all significant recent advances made in the field of alkaloid biololgy and metabolism in plants. The authors consider such topics as: biosynthesis; catabolism; genetic, chemotaxonomic, and environmental influences on alkaloid production; alkaloid formation sites; and the role of alkaloids in plant physiology. Results obtained from studies using isotopic labeling and from studies conducted with whole plants are included as well.

approx. 250 pages, illus., $27.00

Biosynthetic Products for Cancer Chemotherapy
Volume 1
by **George R. Pettit**
Arizona State University

This volume provides an up-to-date overview of cancer chemotherapy and of the development of specialized drugs of biosynthetic origin for cancer treatment. The author discusses: naturally occurring antineoplastic and cytotoxic agents; higher plant terpenoids, steroids, and lignans; quinones, flavans, and other non-nitrogenous plant products; alkaloids, amides and ansa macrolides; fungi and other lower plant biosynthetic products; and biosynthetic products from both marine invertebrates and vertebrates, as well as from other animals. An outstanding guide for the future study of chemotherapeutic agents.

Zeolite catalysis

Zeolite Chemistry and Catalysis. (ACS Monograph, 171.) Edited by J. A. Rabo. Pp. viii+796. (American Chemical Society· Washington DC, 1976.) $65.

In the preface to D. W. Breck's *Zeolite Molecular Sieves* (Wiley-Interscience, 1974), the author states that the important subject of zeolite catalysis was deliberately omitted. This serious omission has now been rectified by the publication of the only other major work in this field, edited by Jule Rabo, an associate of Dr Breck at the Union Carbide Corporation. All zeolite chemists now have two texts to keep on hand, which between them cover all the aspects of the subject and survey many important papers published up to the end of 1973.

It is a pity, however, that a book as costly as this one could not have been published more quickly, so that there is not such a wide gap in the literature. The book has, however, been carefully edited. There are only a small number of printing errors, most of which are obvious to a reasonably well-informed reader.

Six of the chapters are written by personnel from the Union Carbide Corporation, making the book somewhat biased in its outlook. This is a pity considering that much important work in this field is being carried out in European and Japanese laboratories. It is also a pity that a chapter emanating from the Mobil laboratories, where some of the most important research in this field has been carried out, could not have been included.

Despite these criticisms, this is an excellent book which will be an essential acquisition for all those working in this field. **L. V. C. Rees**

L. V. C. Rees is Senior Lecturer in Physical Chemistry in the Department of Chemistry at Imperial College, University of London, UK.

Unity of chemistry

Inorganic Aspects of Biological and Organic Chemistry. By R. P. Hanzlik. Pp. xvii+402. (Academic: New York and London, 1976.) $37; £26.25.

Although I agree whole-heartedly with the intentions expressed in the foreword to this book I am somewhat dissatisfied with the way in which they have materialised. It is true that interdisciplinary areas such as those between inorganic and organic chemistry (organometallic chemistry) and between inorganic and biochemistry (bioinorganic chemistry) provide a teaching opportunity which, if properly accepted, could show a student the unity of chemistry. The obvious danger is that, while stressing the interdisciplinary elements of the topic, the clear strengths of the disciplines themselves are lost.

The title tells us that the three disciplines we need are those of Inorganic Chemistry. Organic Chemistry and Biology. The author tackles inorganic chemistry bravely in the introductory chapter and covers the organic chemistry well in later chapters (that is, its inorganic aspects). As there are many good texts on organometallic chemistry, however, I looked for something extra which would provide the essential link with biology. Surely this must be through topics such as oxygen insertion, Grignard reagents, hydrogen activation, ester and amide synthesis, hydrolysis, and so on. I feel then that I should have been given detailed contrasts between peroxidase, cytochrome P-450 and Fenton's reagent; magnesium Grignard reagents and vitamin B_{12}; Wilkinson catalysts and hydrogenases; and between Lewis acid–base catalysts and metalloenzymes Unfortunately many of these topics receive scant treatment. The reason is I believe a lack of insight into biology, and I therefore look upon this volume as a brave and worthy attempt, rather than a great success, for I miss the special features of the discipline which is biology.

Surely the staggering feature of all biological chemistry is organisation without simple order. Even trivial compounds such as calcium carbonate have to be regarded with different eyes when they appear before us in shells, with their enormous variety of shape and form. Again, to mention cytochromes and not the organised system of catalysts of photosynthesis, or to leave out chlorophyll and its special organised function in the leaf, or to omit halogenation by peroxidases and the relation to immune systems, leaves the feeling that the inorganic aspects of *biological* chemistry are not seen in their true depth.

Dr Hanzlik has produced a good book, but there was the material here for a really wonderful one

R. J. P. Williams

R. J. P. Williams is Napier Research Professor of the Royal Society, working in the Inorganic Chemistry Laboratory, University of Oxford, UK.

A New Journal

Natural Resources Forum

Editor: Bension Varon
Associate Editor: Walter Smith

Natural Resources Forum is a journal devoted to the study of economic, scientific, technological and policy aspects of energy, minerals and water resources development This journal's aim is to aquaint policy-makers with current problems of resources and energy development; to supply accurate information written in a very readable and comprehensible style, and to provide an outlet for constructive debate on controversial issues **Natural Resources Forum** will examine ways and means of increasing supply by exploration, investment and new technologies; it will look at the possibilities of reducing demand (when desirable) through conservation and substitution

Man in his attempt to solve natural resources problems, must recognize the long-term nature of these problems and the need to base new policies upon well founded knowledge and facts It will be the objective of **Natural Resources Forum** to help in the achievement of these goals for man

Natural Resources Forum will be published quarterly on behalf of the *United Nations* by D. Reidel Publishing Company, Dordrecht, Holland.

Quarterly. Dfl. 90,– / US $34.00 per volume of four issues, including postage and handling.
Private subscription price Dfl. 45,– / US $17.00, including postage and handling.
The first issue is scheduled for Fall 1976

Circle No. 09 on Reader Enquiry Form. R 12

Insect viruses

Virus–Insect Relationships. By Kenneth M. Smith. Pp. viii+291. (Longman: London and New York, 1976.) £11.

A NEW BOOK on insect viruses is a rare and welcome event for those who work in this area, so a first reaction to it is naturally one of enthusiastic interest. This book is a well produced volume, nicely laid out and printed in a clear easily read type. There are many illustrations but most of the electron micrographs are marred by their flat grey tones. It is a pity that closer examination soon tempers this first impression. Some fears are aroused by certain comments in the preface: "This book has been written by one of the few remaining old-fashioned virologists" and "detailed accounts of the chemical nature of the viruses and their molecular biology have been omitted". Is this an apology for an incomplete or outdated treatise?

The book is divided into two parts, one giving an account of the types of virus and virus disease affecting insects, the other discussing more general aspects such as infection and replication. Although there are advantages to such a layout, it does mean that repetition occurs and narrative lacks cohesion. The further division of the chapters in the first part of the book into a general account of the virus group followed by descriptions of specific viruses was ill-advised. Both repetition and contradiction occur as a result. The general account component of each chapter decreases progressively from two and a half pages in chapter 1 to four sentences in chapter 7 so possibly the author by then had appreciated the difficulties that this approach creates. The book has other structural peculiarities. Just one example is the grouping together of parvoviruses and picornaviruses in one chapter (with a short general introductory account dealing with parvoviruses only), whereas viruses of the honey bee and *Drosophila* species are deemed worthy of a separate chapter despite the fact that most of them are small spherical RNA-containing viruses anyway.

The chapters in this first part of the book describe the various groups of insect viruses mainly from a morphological standpoint, with only spasmodic attempts to include relevant biophysical or biochemical data. More recent efforts in insect virus research, such as the definition of methods and criteria for identifying the large number of virus isolates from different insects more reliably than by naming the host insect, are given scant attention. Not only are such recent data omitted but certain accounts also seem outdated conceptually and there are several examples quoted of observations or hypotheses which would not now find great support. There are some errors also. For example, the 1.38% DNA quoted for one insect poxvirus has since been corrected to nearer 5%, and Fig. 5.6 is in fact a picture of *Wiseana cervinata* iridescent virus and not that of *Costelytra zealandica*.

In the second part of the book the chapters on serology, nucleic acids and tissue culture in particular are poorly done. Similarly the account of possible hazards in applying insect viruses as pesticides does not do justice to the amount of time and effort spent on this topic in the last three years. Surprisingly it is only in this chapter that one can find any mention of the epizootiology of insect virus diseases. I am surprised also to find staining methods for optical microscopy included as a separate chapter when little effort has been made to describe laboratory techniques elsewhere. For example, the chapter on insect cell culture gives no details of available cell lines or media (in contrast to the chapter on insect rearing where details of synthetic diets are provided) and the reader is referred to somewhat out-dated sources of information.

Two chapters are included on vectors of viruses. The one on "Insects and other arthropods as vectors of plant viruses" is a useful general account, although many plant virologists will be surprised to read that semi-persistent or circulative viruses show no latent period in the vector and do not survive after a moult. One confusing aspect of this chapter is that its subdivision by headings of different type face and size seems quite illogical. The chapter on "Insects and other arthropods as vectors of animal viruses" is of little value. It is woefully brief for a topic of this magnitude and importance, and the examples described appear to have been chosen at random. Both of these accounts seem rather out of place in the book, encroaching as they do on other major areas of virology, and they should perhaps have been given a separate section at the end.

The impression left after reading this book is that sadly it is an opportunity missed. It is quite uncritical and often strangely unbalanced in that examples of work have been selected for description, and others excluded, apparently without valid reason. Insect virology has become a more challenging and exciting subject in the last five years. The book conveys little of this to the uninformed reader. To the specialist it is a disappointment. But this book has no competitors and therefore it has some value and usefulness simply because it is a modern text on insect viruses. As such it will find a place on library shelves as a teaching aid and a reference source. We deserved better. **K. A. Harrap**

K. A. Harrap is Head of the Virology Section at the NERC Unit of Invertebrate Virology, Oxford, UK.

Iron–sulphur proteins

Iron–Sulfur Proteins. Vol. 3 : Structure and Metabolic Mechanisms Edited by W. Lovenberg. Pp. xiv+443. (Academic : New York and London, 1977.) $39.50; £28.05.

SINCE the publication of volumes 1 and 2 in this definitive series in 1973 a number of significant advances have been made in the study of iron–sulphur proteins. These are reviewed in this volume which again is a 'must' for anyone interested in the biology and chemistry of iron–sulphur proteins.

Beinert's chapter on the iron–sulphur centres of the mitochondrial electron transfer system covers "those developments of the last five years that have made the cytochromes minority constituents". The multiplicity and diversity of iron–sulphur centres makes it necessary to have an electron paramagnetic resonance apparatus to study electron transport in mitochondria. It is a pity that the iron–sulphur centres in photosynthetic membranes were not dealt with similarly.

The enzymology of nitrogenase has advanced significantly and is excellently reviewed by Orme-Johnson. The genetics of the nitrogen-fixing (*nif*) gene and the regulation of these genes is the subject of Valentine's chapter. The transfer of *nif* genes to non-nitrogen-fixing organisms is an exciting possibility for the future.

Mössbauer spectroscopy has been crucial in the understanding of the electron transfer properties of the iron–sulphur centres. Two chapters by Cammack, Dickson and Johnson, and by Debrunner *et al.* review the evidence which has been used to adduce structures of the 1Fe, 2 Fe and 4Fe centres, and help confirm X-ray evidence discussed separately by Carter.

Finally, the chapter by Holm and Ibers on synthetic analogues of the active sites of iron–sulphur proteins describes the status of their work. Holm's group has synthesised analogues of 1Fe, 2Fe and 4Fe centres. The chemical and physical properties of these centres are summarised, and make beautiful reading. **D. O. Hall**

D. O. Hall is Professor of Biology in the School of Biological Sciences at King's College, University of London, UK.

obituary

W. H. Morton

WILLIAM H. MORTON, for seven years Assistant Professor of Geology at Addis Ababa University, Ethiopia, was shot to death by Government troops in Addis Ababa on 10 March 1977, one of the many victims of the current political disturbances in Ethiopia.

Bill Morton graduated from Manchester University and served his apprenticeship with the Geological Survey of Uganda. A field geologist *par excellence,* he belonged to that select group of British geologists with detailed first-hand knowledge of the remoter parts of East Africa.

In addition to his own research publications, always the fruit of long months of painstaking geological mapping with his colleagues and students, Bill had a very real desire to share his hard-earned geological knowledge with students and teachers throughout the country. He had recently completed a handbook for non-specialists on the rocks, minerals and fossils of Ethiopia, and was awaiting the comments of his colleagues. Its publication may have to await happier times. Of more immediate value to the government of Ethiopia are the geological maps of many parts of the country, including the Addis Ababa region, which Bill and his former students produced with that attention to detail and high degree of intellectual honesty which were amongst his outstanding qualities.

The Afar Triangle has stimulated new concepts in geology which have repercussed far beyond Africa, and Bill Morton made his own contribution to the knowledge of a region that has attracted so many distinguished earth scientists. Starting with a recognition that the tilted fault-blocks bordering the Afar were the result of extension tectonics and not, as previously thought, of folding and decompressive stresses, Bill and his colleagues went on to develop a model of crustal attenuation as part of a continuous process of plate separation. His studies of Afar tectonics, of the age trends of plateau and rift margin volcanics in Ethiopia, and of crustal thinning at rift margins, some of which appeared as seminal papers in *Nature,* were always conveyed in clear and simple prose, a by-product of his experience as a teacher.

A level-headed and thoughtful person, Bill Morton was a tireless teacher, devoted to his students and immensely concerned with imparting practical and worthwhile knowledge. He was equally at home on the summit of a glaciated volcano as at the bottom of Ethiopia's deepest known pot-hole. Well loved by students and colleageus, he was highly respected by geologists from many countries. In a tragic moment, Ethiopia has lost a man who had devoted his career to her scientific advancement and welfare. His many friends and geological colleagues both inside and outside Ethiopia will remember him with love and professional admiration.

D. Adamson, F. M. Dakin and
M. A. J. Williams

Hans-Lukas Teuber

HANS-LUKAS TEUBER, Professor of Psychology at M.I.T., was lost on January 4 while swimming off the British Virgin Islands. It is thought likely that he died of heart disease; he was 60 years old. Many in Britain will share the sense of loss, not only because "Luke" (as he became known in later years as he became fully absorbed into the American culture) was an indefatigable traveller and lecturer, but also because of a memorable year as Eastman Visiting Professor at Oxford in 1971-2. His audience and influence were deservedly world-wide.

In later years he was perhaps best known as the father of a distinguished, indeed unique, centre of psychology and brain sciences at M.I.T., to which his devotion was complete and in which his pride was transparent. But it was his earlier highly penetrating and influential analyses of the problems and mechanisms of visual perception, in particular, and of brain function more generally, with which he first made his mark. His early major researches were on the psychological analysis of brain wounds in war veterans, carried out while serving with the U.S. Navy during World War II. This type of research remained a consuming interest until the end, but he contributed a unique and distinctive personal approach to a tradition that had its roots in 19th century neurology. To that tradition Teuber injected a concern for the importance of certain crucial demands that modern psychological analysis places upon the interpretation of brain function. He was, for example, one of the first to seize upon the importance of the distinction between externally imposed changes in sensory stimulation and those that result from self-initiated movement, which produces a "corollary discharge." He was quick to spot and integrate important modern developments, both technical and intellectual, but these always were seen in a historical context which he viewed with enormous erudition and reverence.

Born in Germany and educated at the French College in Berlin and at the University of Basel, he emigrated to America during the War and received his doctorate in psychology at Harvard in 1947. He claimed that he was accepted as a desirable emigré, when his ship was stopped at Gibraltar, because he was able to converse freely in Latin and Greek with the young inspecting British officer. His father was founder, for the Prussian Academy of Sciences, of a field station for the observation of chimpanzees on Tenerife, whose fame was later assured by the important work of Wolfgang Köhler (*The Mentality of Apes*) carried out there. This perhaps accounts for Teuber's early interest in problems of visual perception identified by the Gestalt psychologists, and his friendship and admiration for Köhler were life-long.

At Harvard, the story is told, he managed to fail the compulsory German translation because, as a new arrival, he did not know enough English into which to translate the German. But, if so, his command of English soon developed to lofty heights, and he could hold an audience rapt with his eloquent and gently humorous style. In 1947 he joined the faculty of the Bellevue Medical Center of New

York University, where he remained until 1961, when he became Professor of Psychology at M.I.T. His quickness of repartee was renowned. On one occasion, when chided at a symposium by an impatient participant for his frequent references to 19th century authors, Teuber replied without hesitation that he merely wanted to display his originality. And he took a quiet delight in his skill at improvisation and extemporaneous delivery. When a lecture to a large audience in a playhouse was interrupted by a power cut, he continued his lecture, without undue pause, by using his fingers in front of the emergency lamp to project his slides in the form of shadows on the screen.

His move to M.I.T. was at first somewhat turbulent, perhaps because Teuber had a clear and even uncompromising conception of the type of department of psychology he wished to develop. To it he attracted scientists of great distinction from a variety of disciplines, as well as younger persons whose promise later was fulfilled; the contributions of his colleagues were as important in neuroanatomy and neurophysiology as in experimental psychology. He worked unceasingly to attract funds for their endeavours and to promote a genuinely interdisciplinary atmosphere, warm and paternalistic, in which he and his colleagues could flourish. The M.I.T. department became an almost compulsory stopping-off point in the U.S.A. for scientists from throughout the world with interests in brain function and psychology; they were invariably greeted with great hospitality and kindness, their seminars almost always continuing at the Teubers' home late into the evening, surrounded by a formidable but enthusiastic circle of graduate students.

Ironically, his memorial service was held at M.I.T. on the day on which he was to have received an award given by the Institute to a member of its faculty for outstanding accomplishment. The citation described him as "a man who joins the instinct of a penetrating experimenter and the sympathetic experience of a true humanist with the consummate style of a gifted teacher." To these qualities may also be added his warmth, skill and dedication as a promoter of neuropsychology both at home and abroad. He was an insightful, popular, and expansive reviewer at international meetings—even as a helpful translator for foreigners, the duration of his commentaries was apt to exceed, by a considerable amount, that occupied by the original speaker. As tragic as was his death, perhaps he would have preferred it to any alternative that might have prevented him from exercising his indefatigable energies at full strength.

He is survived by his wife, Marianne, who was a devoted partner throughout his career, and by two sons, Andreas and Christopher.

A. T. Phillipson

Professor A. T. Phillipson, who died suddenly on 10 January at the age of 66, was the leading figure in the great post-war revival of interest in the function of ruminant animals. He graduated in agriculture at Cambridge, gained his MRCVS at the Royal Veterinary College, London and then returned to Cambridge to show his flair for research in a Ph.D. study of gastric motility in sheep. Subsequently, he led a small wartime group, under Sir Joseph Barcroft, FRS, at the ARC Unit of Animal Physiology, Cambridge. Between 1941 and 1947 Phillipson, with Dr R. A. McAnally, showed that the hitherto neglected volatile fatty acids are the final end products of microbial digestion of carbohydrates and that they are absorbed through the heavily keratinized epithelium of the rumen into the portal blood in quantities which provide a significant proportion of the energy requirements of the host. Such a radical conclusion was not accepted without controversy, yet attempts by others to find an alternative explanation only reinforced the evidence in its favour. In fact in the last thirty years the conclusions made by this small group have formed the basis for much of the subsequent work on ruminant digestion throughout the world and, when they were extended to other components of the diet, such as protein, completely changed our concept of ruminant nutrition and metabolism. It is salutary to remind ourselves that this major advance was based, after a preparatory period in the late 1930's for thought and observation, on a series of simple and elegant experiments carried out over the relatively short period of about four or five years.

Moving in 1947 to the Rowett Research Institute, of which he became Deputy Director in 1952, Phillipson consolidated the advances made at Cambridge. The years at Aberdeen were marked by special attention to the techniques required for the quantitative assessment of the ruminant digestive processes. Techniques ranging from microbiology to radiography were brought to bear on microbial fermentation and synthesis, ruminal absorption and metabolism of volatile fatty acids, movements of the forestomachs and the propulsion of food to the intestine. He was one of the first to emphasise and measure the extent to which urea may be secreted into the rumen to provide a substrate for microbial protein synthesis. In a prophetic mood in 1947 (*Vet. Rec.* **58**(8), 81–85) he had stressed the importance of measuring the amounts of protein and polysaccharide received by the animal in microbia form, of knowing how much starch and protein escapes degradation in the rumen and of assessing the amounts of volatile fatty acids absorbed. In 1977 we are beginning to use such information in evaluating diets.

In addition to his important research, Phillipson wrote a number of lucid reviews outlining the state of knowledge of rumen function, always with exact attributions and a minimum of extrapolation, and pointing the way to further essential investigation. These were required reading for a new generation of animal scientists and must have directed many to the fascination of the rumen. A remarkably high proportion of the active post-war workers in this field spent time with Phillipson, some to experiment, some just to discuss, but all to be welcomed, involved in his interests and influenced for the future. He travelled a good deal and those he met were also much influenced. In such benign ways, Andrew Phillipson has left a permanent mark on rumen studies. His hallmarks were enthusiasm, wide background knowledge, a preference for direct approaches, accuracy and a habit of being right.

Returning to Cambridge in 1963, Phillipson took the Chair of Veterinary Clinical Studies. Administration and teaching then restricted his opportunities for research, but in these activities he preserved the high standards characteristic of his earlier work. He was chairman of the organising committee of the very successful Third International Symposium on Physiology of Digestion and Metabolism in the Ruminant at Cambridge in 1969.

Phillipson was made FRSE in 1953 and his achievements were recognised by honorary degrees at Copenhagen, Ghent and Edinburgh. In England he received major prizes in agricultural and veterinary fields.

Andrew Phillipson was a charming man whose enthusiasm shone through a diffident manner; an aesthetic, person, especially fond of music, he enjoyed Cambridge and his Fellowship to the full. His family life was extremely happy and the sympathy of many friends, worldwide, will go to Mrs Rachel Phillipson and their three sons.

LIBRARY C.U.

Will the JET age ever come?

THERE is only one thing more frustrating than the well-known impossibility of learning precisely when particular European Community decisions are made. That is learning that they are not made. Last week's debacle at the Energy and Research Council meetings in Brussels was nothing if not frustrating.

Two major issues, among many others, confronted the Energy Ministers: the minimum safeguard price (msp) for oil, to protect investment in the North Sea and in alternative energies; and implementation of an agreed Euratom loans scheme for construction of nuclear power stations. The two have always been linked, with Britain refusing to sanction implementation of the loans scheme without agreement on the msp, and France preferring selective support to the msp.

Only one issue, or so it seemed, confronted the Research Ministers: where to site JET, the Community's fusion project. On that decision also hung the implementation of the four-year programme of the EEC's Joint Research Centre (JRC), agreed in principle months before. Since the JRC establishment at Ispra stood to benefit by the programme, its candidacy for JET had weakened next to Culham in Britain and Garching in West Germany, but France had pushed intensively for Cadarache.

With one European Commissioner (Guido Brunner) now handling both the Energy and Research portfolios, and growing talk of JET as an energy rather than as a research project, the idea of agreement in one council permitting agreement in the other emerged as soon as the two council meetings were set for the same day. Sure enough, progress in the Energy Council produced British concessions on the msp, and alternative schemes will now be examined. Implementation of the Euratom loans scheme was then agreed, and the hope was accordingly expressed that this would assist the Research Council.

It didn't. The Research Council could not agree on a site for JET, for the new but genuine enough reason expressed by France that critical organisational and financial details concerning the way the project would be run were not finalised. What is astonishing is that these matters had not been agreed in the interminable meetings held at all levels over the previous 18 months. What is surprising is that the Council nodded through the four-year JRC programme anyway.

Apart from the embarrassment (especially noticeable in Britain) that goes with such developments, the result is that a decision on JET is no longer contingent upon a tangled web of linked issues. That may mean an early decision if the new difficulties can be clarified, but no one is counting on it. Crazily, the only action has again been inaction.

Though this is an era of international competition and energy crisis, our worry is not whether or when a breakthrough on fusion comes, and certainly not who achieves it. Science does transcend frontiers. Our worry is the uncertainty which indecision generates. JET is an experiment, not a reactor, and its research team deserves better. Now may be an appropriate time to examine the thinking which makes international scientific projects matters of national prestige. Otherwise the Community's processes, though favouring compromise and calculated not to alienate, run the risk of doing the opposite by too faithfully serving governments rather than people. ☐

Science as a profession

THE founding fathers of the Royal Institute of Chemistry, which was last week celebrating its centenary, envisaged a body which would act for chemists rather as the Royal Colleges do for medical men or as the Inns of Court do for lawyers. In spite of a distinguished record in many respects, the Institute has in that aim been totally unsuccessful Neither chemists, nor indeed any group of professional scientists, form a comparable profession. Scientists and engineers are neither as secure nor as confident nor as well remunerated as doctors or lawyers. Society may view this favourably; scientists find it uncomfortable.

The difference must in part be because most scientists are neither self-employed nor fee-earning, and may consequently find themselves out of work in a recession. Sir Harold Wilson, in praising chemists at the centenary celebrations, cited the case of his own father, a dye chemist, who became Winston Churchill's election agent while out of work for two years—perhaps persuading the infant Wilson of the surer future available in Parliament. Yet, although not as secure as members of the other liberal professions, professional scientists are expected to have similar standards of ethics and behaviour. In addition to integrity in research and loyalty to an employer, particularly as regards confidentiality, scientists are expected to speak out if their work throws up any environmental or health hazards, even though such revelations may damage their employing company.

Some of the disquiet scientists feel towards government was expressed last week by the President of the Royal Institute of Chemistry when, in reply to the former Prime Minister, he voiced the irritation at the currently fashionable expression "the two sides of industry". The point is, research scientists in industrial laboratories do not see themselves as being on either side. They feel their views are not being sought, much less heard or heeded, on major issues. When British opinion is being moulded to support wealth creation, they believe that as major wealth creators they are not beneficiaries of that support.

Crucially, scientists see the innovations of research and development as the source of profit of leading companies—failures to exploit science (as with the loss of patents on antibiotics or jet engines) not being the fault of the originators. Chemists in particular are disgruntled because they feel largely responsible for the country's thriving chemical industry and its near relatives in petrochemicals, pharmaceuticals and so on. The companies concerned do not include any of the famous lame ducks. They are almost never involved in industrial disputes. They are highly scientifically innovative. They make the profits which are taxed to support other industries unable to stand up to international competition because, in many cases, of their small research investment.

In spite of this scientific and commercial success, the people who carry the burden in research do not see themselves in a secure profession. Both output of and demand for chemists has declined during this decade and there is evidence that the quality of the newly qualified has dropped. The medical and legal professions, on the other hand, control both entry and the right to practice as well as the discipline of their professions, thus evading the cyclical imbalance in supply and demand so often felt by scientists.

Science as a profession is in a weak position. The best scientists are evenly spread over the country and not concentrated in the capital with day to day access to Whitehall. Salary structures are strongly influenced by central government because the latter is the major employer, basing its rewards on comparability with industry which in turn compares with civil service salaries. It is a small but vicious circle which depresses salaries.

If the recent Bullock proposals for worker-directors in Britain are implemented along anything like the lines suggested in the majority report, the new directors are unlikely to include research scientists. Yet scientists are a major wealth-creating source. They may not continue to provide for the community if their views are not sought or are disregarded, and certainly if they are driven overseas by the tax structure. ☐

A parable on recombination

DeWitt Stetten offers some personal thoughts on the management of hazards in recombinant DNA research

SCIENTISTS and nonscientists are currently polarised in their assessments of the hazards attached to the creation and handling of recombinant DNA molecules. Whereas the hazards are of unknown dimensions, the anxieties are clearly great: but the magnitude of the anxiety is a very imperfect measure of the magnitude of the hazard. Among the diverse views we are seeking an area of possible agreement or, better yet, an area of truth.

Truth is sometimes found in unexpected places. It may be recalled that Jonathan Swift, famed satirist and author of *Gulliver's Travels,* while serving as Dean of St Patrick's in Dublin, considered the disastrous problem of the famine among the Irish peasants which was aggravated by the high birth rate and the abundance of children. He analysed the problem in 1729 in an essay entitled 'Modest Proposal for Preventing the Children of Poor People from being a Burden to their Parents or the Country,' in which, with all pretense of reasonableness, he concluded that the entire problem could be solved if the people of Ireland ate the children. In view of the evident success of Swift's satire, I am taking the liberty of presenting here a parable which I call 'Genetic Recombination—A Modest Proposal'.

After all, recombinant DNA technology is a special case of a far more general phenomenon—that of genetic recombination itself, where genetic material from two sources is repeatedly combined within a single cell. It happens when an oncogenic virus invades a mammalian cell, or when a bacteriophage invades a bacterium. It happens when two bacteria enter into conjugation and transfer plasmid DNA from one to another. In the laboratory it can be achieved through the hybridisation of eukaryote cells from widely differing species, and it is of course the very basis of sexual reproduction.

A form of this kind of experimentation which has been popular for a very long time indeed results in the fertilisation of the human ovum. I refer to this exercise as an experiment, because it always is experimental in that the outcome is not known *a priori.* At this time we can not even foretell the sex of the offspring, much less any of the details of its anatomy or character. Yet the experiment, whereas it provides great possibilities of useful and benevolent results, does have a real hazard. Textbooks of obstetrics contain many engrossing photographs of anatomical monsters which have resulted from this process, but it seems to me that the very worst monsters, the behavioural ones, are not included. These may be divided into two classes—the societal monsters such as gangsters, typified by Al Capone, and the international monsters, exemplified by Adolf Hitler.

Clearly, some of these monsters possess a survival advantage over the rest of us. One has merely to note the direction in which the machine gun which the gangster carries is pointed to ascertain which party is in the better position to survive the encounter. Of particular interest is the experiment conducted nearly ninety years ago by the parents of Adolf Hitler. The maternal ovum may be construed in this case as the host, while the paternal sperm clearly was the vector, bearing as it did a charge of DNA which was foreign to the host. The conceptus which resulted was carefully cloned under reasonably sterile and controlled conditions, and there arose an individual who became, directly or indirectly, responsible for the premature deaths of 4×10^7 human beings in the course of about eight years. This mortality is certainly large, even in the parlance of the epidemiologist.

When scientists first began to appreciate the danger attached to the fertilisation of human ova, they directed attention to the matter and called for an immediate moratorium Since the hazard seemed to be of enormous proportions, the federal government soon became involved; and by and by, a Presidential commission was established to consider the problem and to determine its best resolution. With the moratorium still in effect, one alternative solution proposed was to sterilise all adults, male and female. It was forecast that this procedure would probably work, but it would be quite costly. For this reason, the General Accounting Office, which has the responsibility of surveying costly federal projects, gave its attention to the matter and pointed out that sterilising of either the male or the female population would probably achieve the same desired effect at half the cost. To decide whether to sterilise all males or all females, a special panel of the Equal Employment Opportunity Commission was convened which, with Solomonic wisdom, recommended that since there were approximately equal numbers of males and females in the population at risk, it would appear appropriate to sterilise half of the males and half of the females.

A small experiment was conducted on normal volunteers to test the effectiveness of this procedure, and it was found, for reasons which are still unclear, that this procedure would not yield the desired result. After considerable deliberation, the commission recommended that experiments in human impregnation might proceed with caution in certain designated centres, provided steps were taken to preclude pollution of the environment. It was determined that experiments could be conducted under P4 physical containment with all the manipulations to be carried out in class III safety cabinets which, in the usual fashion, would have their entry and exit ports protected either by autoclaves or by incinerators. Only in this way could the public be assured that no monsters would escape to pollute the environment and damage the ecology. The econiche which we so comfortably occupy would not be threatened by another generation which predictably would perform less nobly than we had done. ☐

NASA's Space Shuttle

'Re-usability' is the catchword

Having generated plenty of controversy, the Shuttle is now being proven. **Colin Norman** reports

IF you have a piece of hardware weighing up to 65,000 pounds that you would like to put into Earth orbit after 1980, the National Aeronautics and Space Administration (NASA) would be only too pleased to rent you the Space Shuttle for $20 million. Or if your requirements are more modest —a 200-pound experimental package which doesn't need special handling, for example—NASA would be glad to take it aloft for as little as $3,000. Although some advance notice and a small deposit would be required, it shouldn't be too difficult to make a booking because there is likely to be considerable spare room in the Shuttle when it eventually flies.

With three years to go before the Shuttle is scheduled to begin full service, NASA is starting to drum up business. A list of fees to be charged to such users as the Department of Defense, foreign governments, commercial operations, and individual researchers has recently been drawn up, and NASA officials have developed an ambitious flight plan calling for as many as 60 shuttle launches a year in the late 1980s.

The flight plan indicates that NASA has not changed its basic thinking on the Shuttle since it won approval for the programme after a bitter fight in the early 1970s. NASA officials are still confident, in short, that the Shuttle will revolutionise space activities by sharply reducing the cost of launching payloads and providing routine access to space. If the flight plan is remotely accurate, in fact, it would represent a staggering increase in the space programme, resulting in more activity than during the height of the Apollo era. Many of those who fought the Shuttle programme in its early stages, including some prominent space scientists, remain sceptical of NASA's projections, however.

The design of the Shuttle was determined in 1972, following an intense struggle between NASA and the Office of Management and Budget. NASA had originally wanted to build a fully re-usable system, consisting of an orbiter and a booster rocket, both of which would be piloted back to Earth and re-used, but in the end it had to settle for an economy model which will be only partially re-usable. It will consist of an Orbiter mounted atop an external fuel tank and strapped to two booster rockets. Soon after launch, the boosters will separate and be parachuted into the ocean for recovery, refurbishing and re-use. The external fuel tank will be discarded in the upper atmosphere where it will burn up, and the Orbiter, after completing its mission, will re-enter the atmosphere and glide to a landing like an aircraft.

Launches and landings will take place at two locations, Cape Canaveral in Florida and Vandenberg air force base in California. When launched due east from Canaveral, the Shuttle will be capable of delivering 65,000 pounds into a 185 km orbit, or 25,000 pounds into a 500 km orbit at 55 degrees. Missions requiring polar orbits will be launched from Vandenberg because such launches from Canaveral would involve flying over heavily populated areas soon after launch. The Shuttle can deliver 32,000 pounds into a 185 km polar orbit.

The Shuttle itself is capable of reaching only low Earth orbits, and thus an extra piece of gadgetry is needed to hoist communications satellites into higher orbits and to fire planetary spacecraft out of the Earth's gravitational field. Again, NASA was originally planning to develop a re-usable rocket, called a 'Space Tug', for those tasks, but it has had to settle for a cheaper, disposable system, at least for the time being. It consists of a solid-fuelled rocket, called the Interim Upper Stage (IUS), which will be launched from a Shuttle in orbit; the IUS is being developed by the Air Force. Though NASA officials claim that they still hope to build the Space Tug someday, there is some doubt about whether that day will ever come.

Costs go up

When the Office of Management and Budget finally approved NASA's plan in 1972, the estimated cost of developing the Shuttle was about $5,200 million. The latest projections put the total research and development costs at about $6,800 million, of which about $4,500 million will have been spent by the end of this year. Virtually all the increase is accounted for by inflation. In addition, NASA reckons that it will cost about $2,500 million to produce five orbiters and associated boosters and fuel tanks, bringing the total research, development and production costs to some $9,300 million.

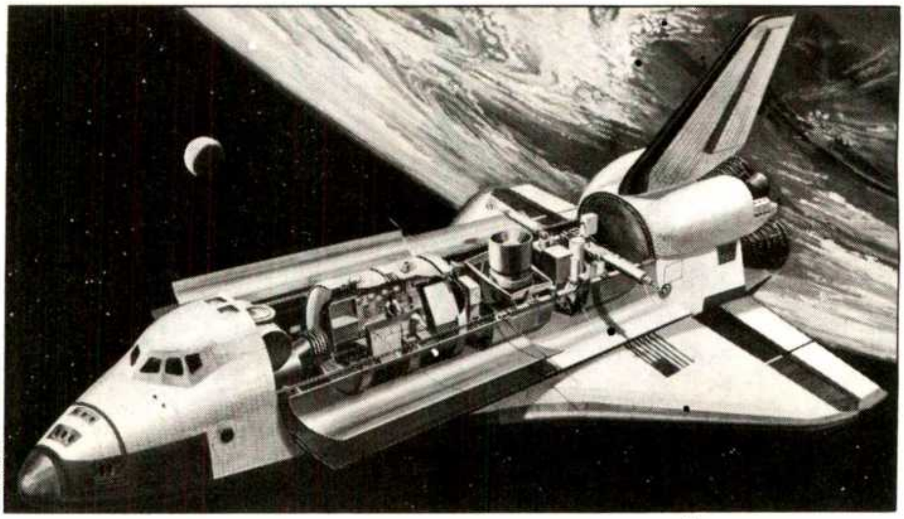
NASA

Shuttle: take-off to recovery

So far, development of the Shuttle is proceeding on schedule and no major snags have been encountered, which is an impressive record for such a mammoth undertaking. The first Orbiter was unveiled last September and, thanks to a massive mail campaign from *Star Trek* fans, it was named the Enterprise. It is now being flight tested in the atmosphere, riding piggyback on a Boeing 747, and in July or August it will be cast loose at 22,000 feet to glide on its own to a landing at Canaveral. The first orbital test flight is scheduled for March 1979, and if all goes according to plan, it will be ready for full operation in the spring of 1980. Development of the IUS is also proceeding apace, and it is also supposed to be ready by 1980.

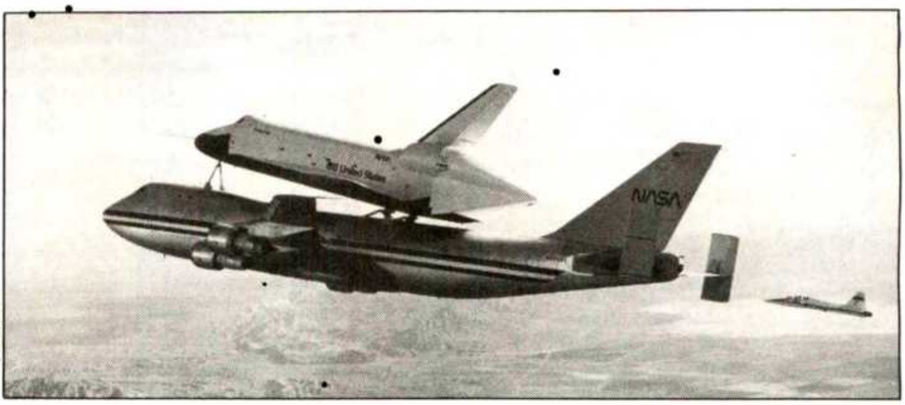
After the Office of Management and Budget gave its approval to the Shuttle in 1972, the real battle began. NASA's cost estimates and projected savings for the system were subjected to severe criticism by a group of Senators led by Walter Mondale, now Vice President, who took their cues from a number of prominent space scientists and systems analysts. They included Thomas Gold, Professor of Astrophysics at Cornell, James van Allen, Professor of Physics at the University of Iowa, George Rathjens, Professor of Political Science at MIT, and Brian O'Leary, a former astronaut.

The nub of the debate was this. NASA claimed that the Shuttle would more than pay for itself over its projected 12-year lifetime because it would be able to deliver payloads into orbit much cheaper than expendable rockets could. Critics of the system argued, however, that NASA was assuming an unrealistically high launch rate with the Shuttle, and that the cost comparisons didn't properly take into account the research and development costs of the system. Another objection was that the costs of developing and building the Shuttle would soak up so



NASA

The Shuttle's Spacelab configuration



NASA

Shuttle takes a trip, March 1977

much of NASA's budget that many space science and applications projects would get squeezed out. The debate raged for about a year, but died down when Congress finally sided with NASA and voted the money to begin developing the system.

At least one of the critics' complaints has already proven correct. While NASA's budget has remained approximately constant in real terms since 1971, spending on the Shuttle has climbed from less than $100 million to more than $1,300 million a year. As a result, there have been very few new space science projects started: some have been scrapped (such as the grand tour of the outer planets), others (such as the High Energy Astronomy Observatory) have been pared, and still others (such as the Large Space Telescope) have been deferred. As O'Leary noted last week, "Our dire scenario has been played out".

Nevertheless, since the project got under way in earnest, NASA officials have been working out a flight plan for the Shuttle based on an assumption that NASA's budget will stay roughly constant in terms of purchasing power over the next 10–15 years, and they have come up with a flight plan very similar to the one which was used to justify the Shuttle in the first place. It should be noted that the plan doesn't represent firm commitments to develop or build a set number of satellites; it is simply a planning document.

NASA calculates that there will be about 560 separate Shuttle flights between 1980 and 1991, with an average of about 60 flights a year between 1985 and 1991. With the massive payload capability of the Shuttle, that represents a very large increase in space activities. According to the flight plan, the breakdown between users will be NASA, 267; other US government agencies, 28; US commercial operations, 60; foreign organisations, 65; Department of Defense, 109. When broken down by type of mission, the plan calls for 229 Spacelab flights, 35 launches of large structures, 168 launches involving upper stages, and 97 launches of free-flying satellites.

Defense's satellites

Aside from the very considerable size of the programme represented by the flight plan, the number of launches envisaged by the Department of Defense is interesting. Though the nature of the defence missions is classified, some two-thirds of them would require use of upper stages, indicating that they are communications satellites or other satellites in geosynchronous orbits. It has also been speculated that the Shuttle's ability to manoeuvre in space will give it the capability of studying, or even capturing, enemy satellites in low orbits.

As for the fees to be charged to users, NASA has recently circulated for comments a proposal which would allow NASA to recoup the operating costs for the Shuttle. The fees would not, however, include payment for a share of the research, development and production costs. Briefly, NASA has proposed that a fee of $20 million would be charged for chartering the entire Shuttle for a single launch. The Department of Defense and foreign governments which have contributed to the Shuttle development would get a discount, as would US commercial operations. Users who require only a part of the Shuttle capacity would pay on a pro-rated basis with the smallest experimental packages which require no manual attention getting in for only $3,000 apiece.

NASA reckons that those fees represent about a 40% discount in launch costs when compared with the use of expandable rockets. Asked whether commercial organisations are showing any interest in booking space on the Shuttle, one NASA official said that he has noticed a recent awakening of interest on the part of payload manufacturers. "At one time they were between lukewarm and disinterested in the Shuttle", he said, "but I have seen a definite reversal in attitude".

As for space scientists, the Shuttle seems to have generated some resentment because of the fact that its development squeezed out a number of scientific missions. Nevertheless, several former critics of the Shuttle contacted last week all agreed that, with nearly $500 million already spent it would be folly to seek to cancel the programme at this stage. And the Space Science Board of the National Academy of Sciences said in a report published in 1974 that the Shuttle "can be an important asset to scientific research in and beyond the 1980s".

At least one former critic of the Shuttle has also recently been converted into a supporter. Brian O'Leary said last week that although he still believes that NASA's justification of the project is seriously flawed, the Shuttle "by good luck" would be a useful transport vehicle for the possible establishment of space manufacturing systems using lunar materials, to construct space habitats and solar power stations. O'Leary, who is now working with Dr Gerard O'Neill at Princeton exploring the concept of space habitats, said that he now supports the Shuttle for that reason. ☐

ESA's Spacelab

Research is the watchword

Spacelab offers scientists unique conditions for future research. **Stuart Sharrock** describes how

THE pioneer phase of manned spaceflight is now over and plans are well advanced for the exploitation era due to begin in 1980. NASA's Space Shuttle will reduce transportation costs and expand the potential applications of space technology by removing many of the constraints imposed by conventional launch vehicles. Spacelab is intended to capitalise on these principles.

A re-usable manned space laboratory with comparatively low operating costs for applications-oriented and scientific experiments, Spacelab is being developed by the European Space Agency (ESA) as a joint European endeavour and will be launched into near-earth orbit in the cargo bay of the Orbiter section of the Shuttle. Thus Europe is for the first time embarking on a new phase of space technology simultaneously with the United States.

The emphasis of the ESA's programme is on satellites for telecommunications, meteorology, Earth resources surveying and air and maritime traffic control. Scientific research is an important but by no means dominant component; the scientific satellite programme concentrates on upper atmosphere and magnetosphere research and astronomy, particularly in the X-ray and γ-ray regions. Spacelab complements these programmes to provide a balanced package of scientific research, but though maintaining the balance, not all future projects under consideration by ESA are likely to be funded. Areas of research will inevitably suffer as the emphasis shifts towards usage of major facilities, but the dwindling national programmes in Europe might be steered to help cover the gaps.

Where Spacelab fits

The Orbiter section of the Shuttle can be launched into near-Earth orbits of various inclinations with an altitude range of 200 to 900 km and a flight time of from 7 to 30 days. Equipment may be placed in orbit or returned for servicing and evaluation after the Orbiter has returned by landing like a conventional aeroplane. The Shuttle concept can be used for launching and servicing satellites, but the accessible range of orbits is limited and conventional 'throw away' launch vehicles will remain necessary unless the inter-orbit 'Space Tug' under consideration by NASA becomes a reality.

Spacelab is a particular unit that slots into the cargo bay of the Orbiter. It is of modular design with two basic building blocks: a pressurised module providing a 'shirt-sleeved' environment for a manned laboratory connected to the living quarters of the Shuttle by a crawl-tube; and an unpressurised pallet on which instruments can be mounted and exposed directly to space. Various combinations of module and pallet are possible, providing a versatile manned space laboratory with a typical experiment payload of 5 tonnes. Up to four instrument operators can be carried (two are planned for the first flight); they will need a scientific background but do not have to submit to astronaut training—the standards required will be similar to those of commercial airline flight engineers.

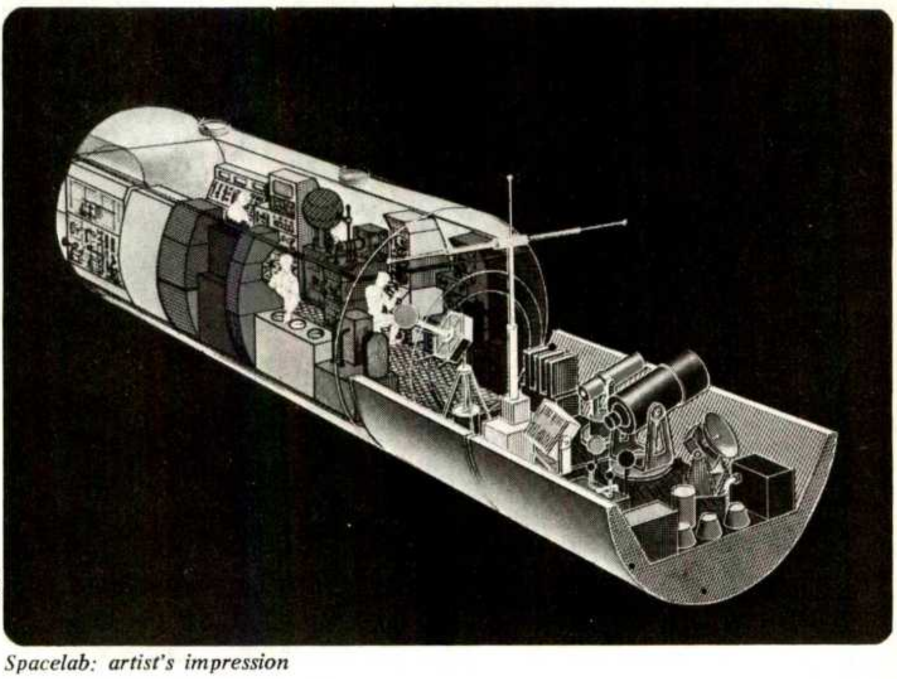
The immediate advantages of this arrangement are that the stringent requirements on weight and volume that bedevil satellite experiments are relaxed, although the problems are to some extent transferred to the strict safety regulations necessary to protect the instrument operators. Existing requirements based on astronaut protection are unnecessarily severe for Spacelab, though some amelioration remains possible. Previous manned spaceflights which have shown the advantages of having operators for some classes of experiments have mainly involved man either as an experimental subject or in his capacity as a dexterous machine; the decision-making capabilities of man in connection with an experiment have yet to be fully exploited. Re-usability is an important new facility: equipment can then be flown many times rather than abandoned at the end of each mission. Perhaps of greater significance is the ability to return materials processed or separated in a space environment and the means of collecting large volumes of data, stored for example on film, beyond the capability of feasible data transmission systems.

Cost immense

Clearly the cost of such an enterprise is immense; the design, development and delivery of one engineering model and one Spacelab flight unit is estimated at around $500 million at mid-1975 prices. Currently the cost of the Spacelab project is under review and, according to ESA, "severe cuts in the deliverable hardware will be necessary in order to accomplish the development project within the established funding ceiling"—not an unusual problem in these times of high inflation.

Value for money is possible if frequent use is made of the facilities. Spacelab is intended to be carried on around 40% of the Shuttle flights and is designed for a minimum of 50 seven-day flights, or about 10 years of operation. This schedule allows the lead time for experiments to be much reduced from the present position with satellite projects. The advantages are clear; the realisation depends largely on funding and management.

Such a large international venture can easily become constipated by its own administration. The Spacelab concept can only be a success if flexibility is maintained for much longer than in



ESA

Spacelab: artist's impression

earlier space projects, but the organisational and management structure have at the same time to cope with an unprecedented mixture of political, financial, technical and scheduling constraints. Major efforts are being made to provide a structure capable of reacting sensibly to these problems.

Experience from previous manned space missions has been invaluable. It is generally agreed, for example, that insufficient thought and preparation went into many experiments conducted aboard Skylab, and a far greater degree of control is being exerted over Spacelab proposals. A simulated Spacelab mission was conducted in 1975 to test out the role of the instrument operators on board Spacelab and the suitability of the proposed management procedures. Short lead times for experiments were demonstrated to be practical, results being obtained from experiments executed only 16 months after proposals were requested, but the mission highlighted the need for greater integration of the instrument operators with the evolution of experiments, and a second more realistic simulation mission is planned for May 1977.

Spacelab research

Areas of research in which Spacelab will provide a valuable addition to satellite facilities include astronomy, atmospheric and solar physics and earth observation. Long continuous periods of observation are often required in these fields and Spacelab is seen as an intermediate step towards mannable orbital systems containing heavy and complicated astronomical equipment that would require regular maintenance; these 'Free-Flyers' would be serviced via the Shuttle.

The use of Spacelab simultaneously for astronomical and Earth observations clearly presents problems, and future Spacelab flights will be dedicated to specific areas of research. The flight profile is not really suited to investigation into the magnetosphere and certain atmospheric phenomena, and in these fields of research Spacelab will be used primarily as a satellite launcher, particularly as the Shuttle is liable to pollute the environment. Measurement of this pollution in terms of emitted gases and magnetic fields is one of the primary aims of the initial Spacelab flight.

For the life sciences and materials science Spacelab will provide a new opportunity for the study of fundamental problems in an environment unattainable on Earth. Additional benefits for the life sciences are the availability of a wide spectrum of high energy particle radiations, whereas materials science and plasma physics welcome the ready attainment of a vacuum over large volumes and the possibility of studying processes under containerless conditions.

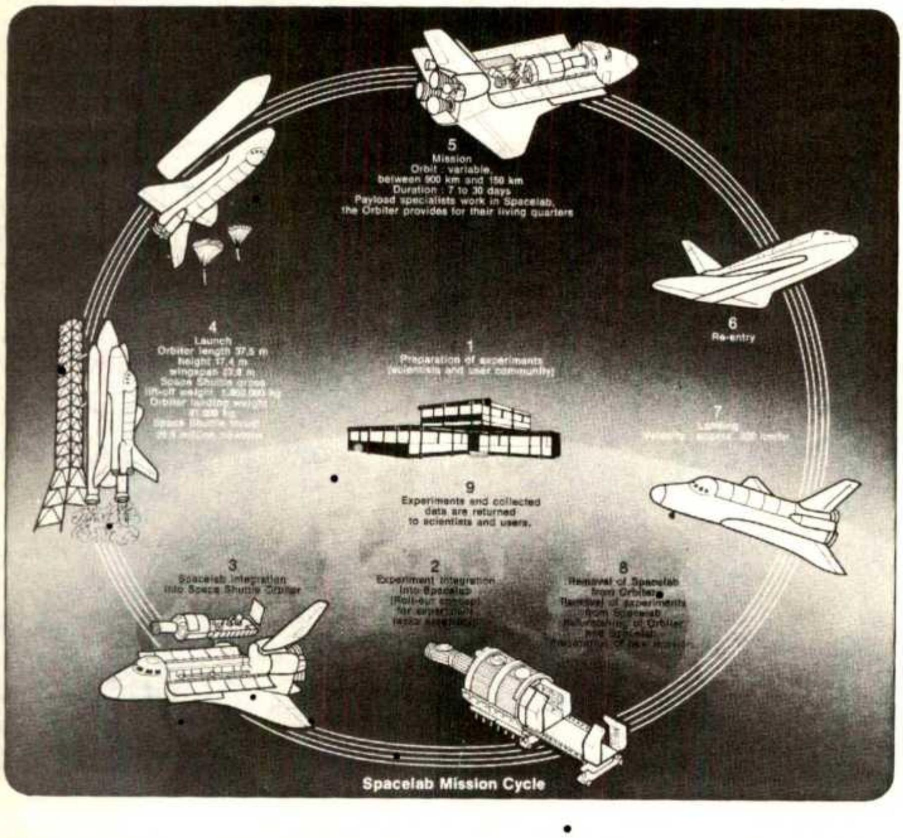
The effects of weightlessness and radiation on biological systems are the major areas of interest in biomedicine on Spacelab, and the first payload will include a Space Sled facility for studying the effects of acceleration on astronauts under weightless conditions. Materials science experiments require steady conditions which preclude the use of the Sled and spacecraft manoeuvres—luckily the majority of these experiments are of short duration.

Commercially the field of materials science offers immense potential and this is reflected in the set of experiments recently chosen as the payload for the first Spacelab flight where materials science experiments outnumber those in all other disciplines. The effective absence of gravity ($<10^{-4}$ g) removes convection and buoyancy effects, so enabling fundamental physical and chemical processes to be studied in the absence of otherwise maskings phenomena and allowing the production of novel and improved materials.

In ESA jargon Spacelab is a 'Special Project'—a programme in which participation by all member states is not mandatory. Countries participating in the finance of the project get a proportionate share of the contracts and use of experimental facilities. The major contributors to Spacelab are Germany (53%), Italy (18%) and France (10%). The initial Spacelab flight in mid-1980 is a joint ESA/NASA mission in which the available facilities are shared equally between Europe and America. The primary objective of the first flight is to demonstrate the capability of Spacelab for space research and to check out all the support systems. Experiments therefore receive second priority, although 100 man-hours have been allocated to them and the necessary test programme restricts the power available to experiments to around 30% of that ultimately to be provided.

In spite of the limited experimental facilities available on the first test flight, the response to the call for experimental proposals has been high. Of over 2,000 applicants, a total of 222 have been accepted, providing 77 experiments from 16 countries. Some proposals were no doubt motivated by the feeling that previous Spacelab experience will carry weight in proposals for future flights; others sprang from uncertainties concerning the funding of these future flights, although these fears will be groundless if Spacelab can be used with its planned frequency.

NASA will charge around $10 million to launch each subsequent Spacelab mission. Details of how this cost will be distributed between participating states within ESA and the experimenters have yet to be worked out. This cost is small compared with the investment, and it will be a pity if details over funding jeopardise the exploitation of Spacelab. It will be a disaster if ESA's future proposals for a balanced scientific programme are affected. ☐



Spacelab Mission Cycle

ESA

USSR

● The need for a closer connection between research and the requirements of the national economy is a constant theme in Soviet planning. Last autumn, the Far Eastern Science Centre was criticised by the Party for having failed to direct its research towards local needs. More recently, the prestigious Siberian Branch of the Academy of Sciences of the USSR came under similar censure. A statement from the Central Committee of the Party, while praising the Siberian Branch for its work in fundamental research, finds "insufficiencies and unresolved problems" in its activity; work on "the complex use of the natural wealth of the eastern regions of the country" is going too slowly; the Presidium of the Branch is paying too little attention to the work of certain centres; and filials, scientific forces and material resources are not being concentrated on "the most important lines of science connected with the acceleration of scientific and technical progress". In particular, insufficient attention has been paid to the problems of the Kansk–Achinsk coal basin, the Norilsk mining and metallurgical combine, and the route of the Baikal–Amur Mainline (BAM) railway.

Instead of admitting these faults and promising amendment, however, Academician Gurii Marchuk, the Chairman of the Siberian Branch, issued a statement extolling the work of the Branch, and softening the rebuke of the Central Committee to a gentle directive showing "ways of improving the quality and efficiency of scientific research". Marchuk stressed that during the 20 years of the Branch's existence, science centres, in addition to its main centre at Novosibirsk, have been established in many cities including Irkutsk, Ulan-Ude, and Krasnoyarsk. The Siberian Branch now includes 48 research and design organisations, representing practically every field of the natural and social sciences. Marchuk himself envisaged the future of Siberian science as "a growing effective force, transforming huge tracts of land along the Leninist path and exerting an increasing influence on many sides of the life of Soviet society".

Within a week, the critical tone of the Central Committee had been de-emphasised even further. Addressing the Moscow meeting of the heads of Academies of Science of the Comecon block, Mr Brezhnev held up the Siberian Branch and the Ukrainian Academy as examples for emulation. "The Siberian Branch is carrying out a very interesting experiment", he said. "The Institutes of this Branch are directly connected to many sections of the national economy, with many major [industrial] enterprises. They have worked out long-term programmes of scientific–technical cooperation and are gradually implementing them."

Since the Brezhnev speech, articles have appeared in the Central press commending the work of individual Institutes of the Branch in the service of the economy—the Hydrodynamics Institute, has been commended for surveying the line for the BAM and the Institute of Atmospheric Optics for weather-forecasting. Marchuk's defence of his Branch seems to have been successful and its present shortcomings have been accepted as temporary deficiencies rather than a failure to understand the fundamental task of the Branch.

● Although the Soviet lunar research programme has so far been confined to unmanned probes and lunokhod rovers, biophysicists at the Siberian Branch of the Academy of Sciences are already working on the possibility of farming in lunar conditions. Experiments with wheat, carrot, beetroot and turnip seedlings suggest that plants could be grown under suitable transparent domes using the natural lunar illumination cycle. The plants were kept at a temperature of 3–4 °C during the 'night' periods, and were grown hydroponically, using common tap water as the nutrient medium. In spite of the lack of minerals, especially nitrogen, and th [illegible]tic illumination cycle, all the plants produced roots with the "normal biochemical composition", and during the second lunar 'day' the wheat produced ears. The team stresses that if plants can be grown successfully by natural sunlight, the energy problem of settlements on the moon would be much easier.

● The current difficulties with international fishing limits have evoked considerable rethinking of Soviet fisheries policy; in contrast to the old theory of large catches and the overfulfilment of targets, the new line stresses that since catches are limited, the entire quota must be suitable for food. The new policy is to be implemented in various ways: Latvia is to use refrigerated factory ships in the Baltic to reduce wastage; and the Deep Sea Fishing Flotilla, operating in the Sea of Okhotsk, has been instructed not to catch Okhotsk grenadier (which accounts for up to 50% of all catches in the area) since the experts have decided that grenadier is unmarketable.

Following a recent order from the Ministry of Fisheries, likely lakes and reservoirs for fish-farming are being appraised, and existing fish-farms are being extended. An experimental trout-farm is already in operation in the out-fall of the Kola atomic power station in the Arctic. The use of fish wastes is also being investigated. According to an official of the Sevryba (Northern Fisheries) organisation, the fishing industry has for some time been able to collect and deliver heads, tails, and gut to shore enterprises for further processing. These waste products, he stressed, contain 30% fat, 8–12% protein and a "considerable quantity" of the B vitamins. At present such wastes are used for animal food, but research is underway on their possible use for human consumption—a project more likely to appeal to the planners than to the average consumer.

● The RATAN-600 radio-telescope, the largest in the world, is at last officially in operation. The telescope, sited at Zelenchuk in the Stavropol' district, was constructed jointly by the Academy of Sciences of the USSR, Moscow University, the Ministry of Power and Electrification, and the Ministry of Power Plant Construction. Mr Brezhnev's formal message of congratulation was issued on 20 March, 1977.

Each of the four sections of the telescope can operate autonomously and part of the Ratan-600 has been receiving signals since 1974. A number of research projects are already in hand including studies of the fine radio-structure of the sun, the moons of Jupiter, and the galactic nucleus.

correspondence

Travel rights

SIR,—I was very sorry to hear of the incident involving Academician Malek's passport reported by Frantisek Janouch (6 January, page 10). Ivan Malek has been a personal friend of mine for many years and I have learned to respect his wise and humane views. Personally I feel it is a tragedy that present circumstances make it very difficult for him to play the part in building up a strong, forward looking and socially concerned science in his country for which his talents so clearly qualify him.

There can be no doubt about the attitude of the World Federation of Scientific Workers toward the travel rights of scientists. I am sure Dr Janouch knows that ever since its foundation 30 years ago our Federation has worked actively for the maximum level of contacts between scientists in different countries. We fully support the UNESCO Recommendation on the Status of Scientific Researchers (1974), Article 26 of which says:

> Member states should actively promote the interplay of ideas and information among scientific researchers throughout the world, which is vital to the healthy development of science and technology; and to this end should take all measures necessary to ensure that scientific researchers are enabled, throughout their careers, to participate in international scientific and technological gatherings and to travel abroad.

Following the decision of our 11th General Assembly held in London last September, the WFSW set up a subcommittee to make these recommendations more widely known and to work actively for their practical implementation. If Dr Janouch will supply detailed, and if possible, documentary information about the incident to which he refers I am sure our subcommittee will examine it and suggest what appropriate steps, if any, the Federation should take.

E. H. S. BURHOP

World Federation of Scientific Workers,

Toxic levels

SIR,—It is not clear what are the areas of expertise of your correspondent Thomas H. Jukes (10 February, page 491). It is clear however, that one of his areas of ignorance is chemical carcinogenesis.

How does he know that "substances that are toxic at high doses are sufficiently harmless in the amounts actually present that they offer no finite hazard to health"? This is the key to the argument about carcinogenic chemicals in the environment. They give rise to tumours in significant number when tested in small groups of experimental animals for a maximum of two years. How do we extrapolate such findings to tens of millions of people whose susceptibility is unknown but might have a wide range, both above and below that of our experimental animals, and who live for 60 or 70 years?

If we reduce the doses given to our experimental animals we reach a dose at which one or two animals in a group of 100, say, will have a tumour not seen in a group of 100 untreated controls. Although this is 1 or 2% of our population of animals (equal to 2 or 4 million of the US population), we would say that this incidence of tumours is not statistically significant, and some would claim that this dose is 'safe'. I would not. In practice, we need an incidence of tumours exceeding 5 out of 100 to be sure of statistical significance. So, because the effects of carcinogens are cumulative, we cannot establish a safe dose for any carcinogen, because we don't know how. Similarly, in our animal experiments in which we usually test single compounds we cannot take account of the probable additive or synergistic effects of several carcinogens at low doses, as we must experience them in daily life. That is why we must be wary of any carcinogen when we discover it at any level, even at the risk of appearing to be lunatic consumerists.

Perhaps Jukes should ponder the fact that there is a lot of cancer around and hundreds of thousands of people die of cancer every year, almost always of unknown cause. It is my contention that part of this cause is the carcinogenesis test which chemical manufacturers and food processors, together with Nature herself, are conducting in us, presumably with Jukes' approval.

WILLIAM LIJINSKY

Frederick Cancer Research Center, USA

Thomas Jukes replies: Lijinsky misquotes me: my statment was " . . . food contains substances that are toxic at high levels but are sufficiently harmless in the amounts actually present that they offer no finite hazard to health". With this misquotation corrected, the basis for his peroration disappears. My statement was essentially a reference to the basic principle of toxicology first enunciated by Paracelsus[1].

There are numerous examples of such substances, such as solanine (potatoes), cyanide (lima beans), goitrogens (cabbage), estrogens (soybeans, wheat germ), and selenium (marine fish). I am glad that Lijinsky included Nature in his list of providers of carcinogens. His discussion of the "safe dosage" of carcinogens alleges that "some would claim that this dose" (that is a dose that would produce tumours in "2 or 4 million of the US population") "is safe". I can think of no one who would make such a claim; certainly I would not. Various authors, including myself, have discussed the problem of reaching adequately low levels of dietary carcinogens[2-6].

It is certainly possible to postulate levels that pose a risk of less than one case per year in the US population, or that will not be effective unless we live for more than 200 years. However, it is not possible to devise a diet of natural foods that is free of "carcinogens", no matter whether they are "additive or synergistic" (as Lijinsky says), or even antagonistic (which he does not mention).

In his final sentence, Lijinsky incorrectly assumes that I approve of carcinogenic food additives. I favour bans on Reds No. 2 and No. 4, but I pointed out that many consumers apparently wanted to go on eating red maraschino cherries despite the findings on the dye. Many also seem to want cyclamates, saccharin and cigarettes. The current protest by consumers against banning saccharin is an effective but an unexpected support for the point I made. Consumerists wish to decide which carcinogens should be banned. Lijinsky often warns against bacon, but not against barbecueing of steaks, despite his own demonstration that this produces carcinogens[6], and not against tobacco, which smoked or chewed supplies nitrosamines.

A list of my publications related to cancer is being forwarded to Lijinsky.

Antibody production made easier

from K. I. Welsh

THE latest paper from the laboratory of César Milstein (this issue of *Nature* page 550) reporting the construction by cell fusion techniques of a line of hybrid cells secreting antibody against rat major histocompatibility antigens, promises to be an important step forward in tackling some of the many clinical and biological problems concerned with the histocompatibility system which require a reliable and standard supply of anti-histocompatibility antigen antibodies for their solution.

Tissue matching for skin, cornea, bone marrow and kidney transplants depends to a large extent on stocks of reasonable titre monospecific typing antibodies against the major histocompatibility antigens. These precious sera, obtained from immunised volunteers, multiparous women, transplant recipients or primates take months or even years of laborious work to produce, test and become acepted as standard reagents. Antibodies, over 200 in all, are tested for lysis of recipient cells and potential donor cells; identical reaction patterns indicate identical recipient and donor histocompatibility type at the HLA–A, B, C and D locus. Commercial reagents are expensive, yet the use of antisera against histocompatibility products in the analysis of the association of particular diseases with the major histocompatibility complex (MHC) as well as for routine tissue matching, is increasing daily. The ideal solution to these serological problems would be for sufficient supplies of standard typing reagents to be available worldwide.

The isolation and characterisation of MHC products, on a large scale and experiments designed to answer many basic questions related to the understanding of their evolutionary significance, present role and importance in tissue rejection and prevention of disease would also be made much easier with a readily available supply of standard monoclonal antibodies to the MHC antigens.

Milstein *et al.* constructed their histocompatibility antibody secreting cell line by fusing a mouse myeloma cell line with spleen cells of AO-strain rats previously immunised against DA strain antigens. Clones grown up from individual hybridisations were tested for their ability to produce anti-DA antibodies, and a clone was selected which was further characterised as producing antibody against an individual K/D specificity of the Ag-B4 haplotype, thereby identifying the first uniquely defined antigenic specificity in the rat MHC. The authors hope that characterisation of the products of other clones will lead to the identification of other specificities of the Ag-B4 haplotype.

This work illustrates the latest use of basic techniques developed in Milstein's laboratory for producing hybrid cell lines secreting antibody of defined specificity (see Köhler & Milstein *Nature* **256**, 495; 1975), a technique now being exploited in other laboratories.

At a recent discussion meeting at Cambridge K. Rajewsky and G. Hämmerling reported that they have hybridised tumour cells with a variety of antibody-producing cells to obtain lines of cells synthesising antibody against a wide range of idiotypes as well as bacterial and mammalian cell components.

Antibody production from tissue cultures of such cells requires culture facilities on a larger scale than many laboratories possess. Rajewsky *et al.* have however developed an *in vivo* culture system which brings production of experimental quantities of antibodies from hybrid cells easily within the capabilities of most laboratories. The hybrid cells are injected into a histocompatible animal where they proliferate, producing high levels of antibody which can be recovered from the animal's serum. This provides a method of obtaining experimental quantities of antibody from many fewer animals than needed with techniques now used.

At present, 100 rats are needed to produce 10^{5} lytic units of anti-Ag-B serum for example, but using the Milstein/Rajewsky approach only one rat would be needed, although perhaps 10 rats would be necessary to cover all the variants of specificity.

The commercial importance of such work is that it converts antibody production from a biological science with all its inherent variability and non-reproducibility into the realms of synthetic chemistry where any desired reagent is available off the shelf and can be assumed with reasonable confidence to be identical to the same reagent in any other laboratory. Monoclonal antibodies do have disadvantages; for example, a monoclonal anti-HLA-B7 reagent might only react with 10% of the HLA-B7 individuals defined by a polyclonal serum. Such disadvantages can be easily circumvented however, and there will be the advantage that it will be possible to identify the variants of histocompatibility specificities such as HLA-B7 so precisely that near perfect tissue matchings can be made, and the precise relationship of disease to the HLA-B7 complex defined.

The potential of cell fusion in immunology extends far beyond immunoglobulin production. It should eventually be possible to produce a range of helper, suppressor and factor-producing cell lines. The development of the Milstein technique now offers the British government a unique opportunity of extending this work by financing a centre for the production of such hybrid cell lines and for UK companies to take the commercial initiative. □

Neuroanatomy of visual acuity

from Peter Lennie

ONE of the aims of vision research is to find the structures that underly our visual capabilities; sometimes the relation between structure and function is striking. There is a regular correspondence between points on the retina and points on the primary visual cortex in man, but because the cortical projection of the fovea (the area of the retina responsible for the resolution of fine detail) is huge in relation to the projection of the peripheral retina, the map on the cortex is a distorted representation of the retinal surface. The large projection of the foveal region seems to be required for the resolution of fine detail, for there is a close relation between the "cortical magnification factor" (M)—the distance in mm on the visual cortex corresponding to an angle of one degree subtended at the eye—and visual acuity, expressed as the angle subtended at the eye by the smallest object that can be resolved. Cowey and Rolls (*Expl Brain Res.* **21**, 447; 1974) showed a high correlation between $1/M$ and the minimum angle of resolution (MAR) at different points in the visual field, which suggests that a constant amount of visual cortex is devoted to the minimum angle of resolution, whatever its value.

The much magnified cortical representation of the foveal region may originate in the distribution across the retina of the ganglion cells whose axons project to the lateral geniculate nucleus (LGN), which relays to the cortex. With the exception of the foveal region the density of ganglion cells decreases regularly with increasing distance from the fovea, and is found to be proportional to M^2. Thus over most of the visual field the magnification factor could be explained by assuming that, on average, each ganglion cell projects to an equal area of visual cortex. In the foveal region, where acuity is best and cortical magnification highest, the relationship between ganglion cell density and M^2 breaks down however, probably because the ganglion cells are arranged in a band around the foveal cones to which they are connected and thus are displaced from their receptive fields.

If the displacement of ganglion cell bodies causes the breakdown of the proportionality between ganglion cell density and M^2, an allowance for this displacement should extend the proportionality into the very centre of the fovea. Rolls and Cowey (*Expl Brain Res.* **10**, 298; 1970) have done this for monkeys and Drasdo (this issue of *Nature*, page 554 has now made a correction for ganglion cell displacement in man, by computing the density of ganglion cell receptive fields at different distances from the fovea. He has shown an impressive correlation between calculated receptive field density and M^2 from the fovea to points 40° in the peripheral retina, and has also formulated an equation for which he claims some generality in predicting visual performance at any point in the visual field.

These findings suggest a remarkable simplicity in the arrangement of the mechanism subserving visual acuity. However, other recent work has revealed new complexities in the structure and function of the visual system that make these simple relations rather surprising.

One of these is that retinal ganglion cells project to several areas of the brain (notably to the superior colliculus) besides the visual cortex. We cannot be clear therefore about the significance of the simple relations between visual acuity, cortical magnification and the overall density of ganglion cells until we know what fraction of cells projects to the visual cortex, and whether this fraction varies with position on the retina. The answer to this question is unclear, although recent evidence (Bunt *et al. J. comp. Neurol.* **164**, 265; 1975) suggests that in fact virtually all ganglion cells project to the cortex through the LGN and therefore that projections to other areas arise through collateral axons from the same cells.

A more intriguing problem arises from the fact that there are several different types of ganglion cell, distinguishable histologically (and in the monkey also physiologically), and so we also need to know how the different cell types contribute to the population of cells that does project to the cortex. Although it is now more than 30 years since Polyak gave a thorough anatomical description of different cell types in the primate retina, only recently has much attention been given to their possible functional roles. The impetus to much of this work was the discovery in the cat's retina of several classes of ganglion cell that are physiologically and morphologically distinctive and in some cases at least have different projections in the brain (see Levick in *Nature* **254**, 659, 1975 for a review). The primate visual system also seems to contain ganglion cell types that are physiologically distinctive (De Monasterio and Gouras *J. Physiol. Lond.* **251**, 167; 1975), although these seem to be less clearly differentiated and are not so obviously related to morphology. One is therefore led to ask what different functions they subserve and whether their projections on the primary visual cortex are topographically different.

Since the physiologically different cell types are distributed differently on the retina it seems likely that they will project differently on the primary visual cortex. This being the case it is puzzling that M, which must reflect the projections of all classes of ganglion cell, should be so simply related to MAR, which one supposes might be mediated by a single cell type. Perhaps this class is predominant, and cells of other types, even if they differ in their distribution on the retina and their projections on the cortex, occur in numbers too small to upset the simple relation between cortical magnification and minimum angle of resolution.

We might obtain some clearer idea of the functions of the putative minor classes of cell if a variety of tasks were used to examine different forms of visual acuity in relation to position in the visual field. At all events, the heterogeneity of ganglion cells argues for caution in interpreting relations between the gross structure and function of the visual pathway. □

Historical ichthyology

from a Correspondent

TAXONOMISTS are forced by the disciplines of their calling to be continually aware of the past history of their field of study. At a basic level they are obliged to refer to the earliest description or published name for an animal or plant, and possibly more than in most sciences the constant reference back to the early literature is part of the taxonomist's way of life; to a large extent the early literature is as significant as later syntheses. In this context it is not surprising that traditional taxonomists are often deeply involved with the history of their field, or with the life and work of earlier students of their subject. A recently published study of Francis Day (1829–1889) and his collections of Indian fishes by P. J. P. Whitehead and P. K. Talwar (*Bull. Br. Mus. nat. Hist. (Hist. Ser.)* **5**, 1; 1976) is an excellent example of such painstaking research.

Francis Day was born in 1829 in Sussex, and qualified in medicine at St George's Hospital in London (1851). Immediately after qualifying he joined the Indian army as Assistant Surgeon and between 1852 and 1863 worked in the medical service in India, broken only by a year's sick leave in England in 1857. Until about 1863 his career was largely medical but then he increasingly became involved in natural history studies especially those of fishes. During 1864 and 1865 he was in England, presenting his first major paper, *On the fishes of Cochin* (*Proc. zool. Soc. Lond.* **2-40**, 286; 1865), and late in 1865 publishing the *Fishes of Malabar* (Quaritch, London) a major work on Indian fishes. In 1866 he returned to India accompanying a consignment of trout eggs in an (eventually unsuccessful) attempt to establish this fish in the Neilgherry Hills. From then until 1869, although nominally still employed in the medical service of the army, Day became increasingly involved in fishery surveys and the study of fishes. In 1871 he was appointed Inspector-General of Fisheries, and commenced a series of active surveys in various parts of India. In 1874 he returned to England to begin writing *The Fishes of India* (published in four parts between 1875 and 1878, with a supplement in 1888). This book is still the only reference work on the fishes of the subcontinent as a whole, and, although many revisionary studies of groups of Asiatic fishes have been published since, reference to *The Fishes of India* is still obligatory for the student of Indian fishes.

In his later years Francis Day turned his attention to European fishes, and his *Fishes of Great Britain and Ireland* (1880–1884) and *British and Irish Salmonidae* (1887) were for many years classics in their field. They are now highly priced by the antiquarian book trade, as are his other books, which perhaps still indicates their value. Francis Day died in 1889 at Cheltenham, Gloucestershire.

These are the bare bones of Francis Day's career as surgeon and ichthyologist, and they correctly suggest a man of remarkable energy and achievement. Whitehead and Talwar provide far more detail and have produced a rounded study of the man (despite their modest statement that there is "As yet, . . . no full biography of Francis Day"), and the difficulties that he had to face with unsympathetic superiors in India, and the criticisms and obstructiveness of Albert Günther, the British Museum zoologist. Their assessment of Francis Day is that he "was one of the outstanding figures in that phase of ichthyology which called for comprehensive works on the fishes of particular regions".

Beyond the themes of biography and assessment of Day's work, Whitehead and Talwar concentrate on the distribution of Day's superlative collection of fishes. Although his collection was brought to England when he was writing *The Fishes of India*, less than half of it found its way to the British Museum. No fewer than fourteen museums received parts of his collection either by gift or sale, and his personal library and many manuscripts passed to his daughter and thence to Cheltenham Public Library. Major collections were sent to the Indian Museum, Calcutta, the Australian Museum, Sydney, the Naturhistorisches Museum, Vienna, and the British Museum (Natural History). These four collections between them hold most of the type material of species described by Day, and Whitehead and Talwar present a tabulation of all the syntypic material of Day's species in eleven museum collections. Their painstaking listing of extant specimens and the route which each lot followed to the appropriate museum, with Day's indication of their importance, is a major contribution for later taxonomists working on Indian fishes.

That so little of Day's collection (and that, in general, the less important material) was to be found in the Natural History Departments of the British Museum, later (1880) to become the British Museum (Natural History), was due to the acrimonious relationship between Day and Albert Gunther. Whitehead and Talwar deal with the beginnings of this bitter episode and its continuance until just before Day's death. The quarrel has also been touched upon recently by Günther's grandson, A. E. Gunther (*A Century of Zoology at the British Museum . . .*, Dawsons, London; 1975), but now that both sides of the story can be compared it is clear that Günther was particularly unjust in his relationship with Day. The immediate result was that the most important portion of Day's collection was sent abroad and not, as would have been expected at that time, lodged in London.

Although Whitehead and Talwar recount this episode of nineteenth century zoological in-fighting in detail, and one must admit it makes fascinating reading, their study of the history of Day's collection is a fundamentally important contribution to furthering the study of the taxonomy of Indian fishes. □

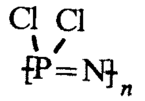
Polyphosphazenes: tailored polymers

from Paul Calvert

The polyphosphazenes are a versatile group of polymers based on an alternating phosphorus and nitrogen chain, which are potentially useful as low temperature, solvent resistant elastomers and may also have a number of applications in medicine. Recently published calculations of conformational energies shed light on the origin of their rubber-like behaviour and nicely illustrate both the gap between calculable and observable quantities and the benefits which could be gained by closing the gap.

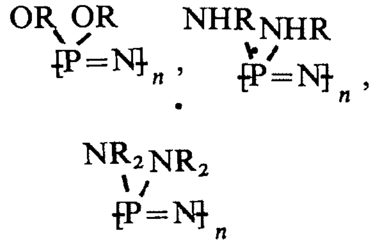
Inorganic polymers have been a subject of interest for many years, partly in the hope of finding materials which would be resistant to temperatures above 350 °C where most organic polymers start to oxidise and partly, one suspects, to allow inorganic chemists to make themselves useful. The effort has not been a great success, to a large extent because many of the polymers produced are thermally stable but very vulnerable to hydrolysis. The only important group of commercial inorganic polymers is the silicone rubbers which are used as low temperature, chemical and solvent resistant elastomers (glass transition temperature 150 K). Their main drawback is that they are mechanically weak.

The polyphosphazenes have the greatest promise of the remaining inorganic polymers. The simplest example is poly(dichlorophosphazene) produced



$$\left[\overset{\mathrm{Cl}\ \mathrm{Cl}}{\mathrm{P}}{=}\mathrm{N}\right]_n$$

by polymerisation of the trimer hexachlorocyclophosphazene which is the product of reaction between ammonium chloride and phosphorus pentachloride. This polymer readily hydrolyses starting at the chlorine–phosphorus bond but the trick to producing stable polymers found by Allcock and coworkers in 1965 is to replace the chlorine with organic groups linked to the chain by either an oxygen or nitrogen atom. This is done by reacting the chlorinated polymer directly with the appropriate amine or sodium alkoxide.



$$[\mathrm{P(OR)_2{=}N}]_n, \quad [\mathrm{P(NHR)_2{=}N}]_n, \quad [\mathrm{P(NR_2)_2{=}N}]_n$$

Since then Allcock's group at Pennsylvania State University have published about 30 papers describing the synthesis and properties of a large number of these polymers (see *Science* **193**, 1214, 1976; and *Chemtech* 553, September 1975). The interest of these polymers lies in this versatility, an indefinite number of side groups can easily be added to produce a wide range of properties without having to perform a new polymerisation each time. The low temperature flexibility of some of these materials can also be applied.

Low temperature elasticity is necessary not only to make rubber grommets for use in cold climates but also in the pumping and handling of cold liquids. A necessary condition for this is believed to be chain flexibility, that is, unhindered rotation about the chain backbone bonds. In the polyphosphazenes and silicone rubbers this arises by the alteration of an unsubstituted chain atom (the nitrogen) with one carrying only small substitutes (the phosphorus) so that internal rotation can occur without the side groups colliding. Allcock, Allen and Meister (*Macromolecules* **9**, 950, 956; 1976) have made a start toward quantifying this by calculating the potential energy as a function of conformation for a series of halo- and organo-substituted polyphosphazenes. These calculations assume a Lennard-Jones interatomic potential and then evaluate the potential energy due to neighbouring groups on the chain as a function of the bond angles. However the chain does have a conjugated double bond structure which might also hinder rotation, although Allcock asserts that it does not on the basis that the orbitals will be symmetric about the bond axis. The exact nature of the P–N double bond is still a matter for debate and they may have to be taken into account (Allcock *Phosphorus–Nitrogen Compounds* Academic, London–New York, 1972). The potential energy barrier to bond rotation calculated in this way is directly related to the chain flexibility and can be compared with the polymer glass transition temperature which varies from 180 K for the difluoro polymer to 265 K for poly(diphenoxyphosphazene). The calculated barrier heights correlate well with the observed glass transition temperatures for the halo- and organo-substituted polymers separately but poorly when the two groups are compared, the organo compounds having larger barriers to rotation for similar glass transition temperatures. Clearly some other factor must be taken into account.

This question should really be taken further as there has been relatively little advance since the theory of Gibbs and DiMarzio in 1962 stressed the importance of chain flexibility for the glass transition. The polyphosphazenes provide a good system on which to relate properly the calculated conformational energies to the glass transition temperatures since the ease with which substituents can be changed on the same backbone should allow the isolation of factors such as polarity, side group flexibility and copolymer composition.

The proposed uses for the polyphosphazenes also reflect the effect of side groups on the polymer properties. Small side groups give a low glass transition temperature and resistance to swelling by hydrocarbons, desirable for gaskets and O-rings. Crystallisation is prevented by the use of mixed substituents so that the polymer is rubbery With some subtlety it should be possible to produce a rubber which crystallises only on stretching. This would give good strength properties comparable to natural rubber rather than to silicone rubber which cannot crystallise and is weak. By adding fluorinated substituents polymers can be produced with a low surface energy which could be used for water repellent coatings and for surgical implants

---

Ultraviolet windows in sunglasses

from John Walker

CAN sunglasses damage the eyes? Two American scientists have discovered that many sunglasses on sale in the United States are not effective in filtering out ultraviolet radiation; they may actually increase the possibility of eye damage in bright sunlight.

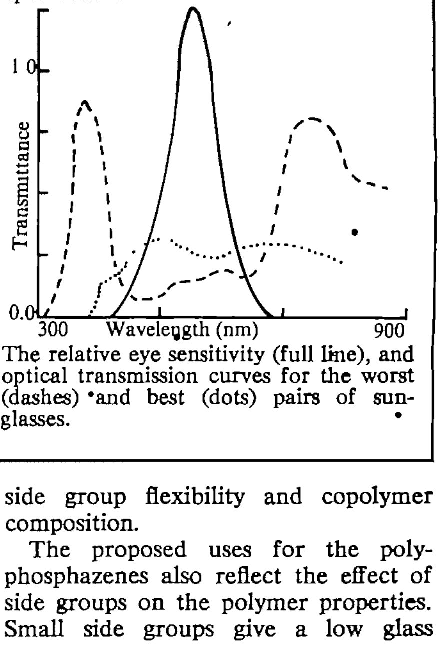
Visible light has wavelengths between 400 nm (blue/violet) and 700 nm (Fig. 1). Other wavelengths, which are at best unnecessary for vision and at worst a danger to the eyes, ought to be removed by sunglasses before reaching the eyes. Ultraviolet (300–400 nm) in particular is suspected of causing cataracts.

Anderson and Gebel (*Appl. Optics* **16**, 515; 1977) tested sunglasses they had randomly purchased in local shops and drugstores (in Ohio, USA). Many of them were optically unsatisfactory and " . . . seem to be designed more to satisfy the fashion whims of the wearer than to shield the eyes from unnecessary radiation". One-third of their selection transmitted more light in the ultraviolet than in the visible—in the worst case 70% transmission at 360 nm compared with 20% at 550 nm (Fig. 1). This may be dangerous for two reasons.

First, as the amount of visible light reaching the eye is cut down, much stronger outside light levels can be tolerated without discomfort, and so the ultraviolet exposure may be greater than if no sunglasses were worn. Alternatively, the reduced visible light intensity causes the pupil to dilate allowing more light to enter the eye. Anderson and Gebel calculate that the worst sunglasses actually double the amount of ultraviolet absorbed by the eye (Fig. 1); thus there is a greater risk of eye damage than if no sunglasses were worn.

Some sunglasses were quite satisfactory, however. Figure 1 shows the transmission spectrum of one of the better pairs—though even there it would be better if the transmission cut off at 450 nm instead of 390 nm. And unfortunately there appeared to be no correlation between ultraviolet performance, price, lens colour or manufacturer; there is no way of picking a good pair other than by measuring its transmission spectrum.

The authors conclude that their preliminary study should be extended, and should include prescription sunglasses (the only pair they tested performed very well). Furthermore "... it would be in the consumers' interest for manufacturers to indicate in some manner the transmission characteristics of their lenses over the solar spectrum".



The relative eye sensitivity (full line), and optical transmission curves for the worst (dashes) and best (dots) pairs of sunglasses.

where a low surface energy is believed to reduce the tendency of implants to cause blood clotting. The amino-substituted polymers can be made water soluble and are susceptible to hydrolysis to varying extents. Uses as resorbable sutures and slow release drug carriers are being investigated.

There are a number of groups of polymers where a wide range of properties can be produced by altering the side groups. The proteins and polysaccharides are two classes which have proved their value over the years. Vinyl polymers which range from polyethylene to polyacrylamide could also be seen as such a class Polyphosphazenes are unlikely ever to be used on a large scale but they do seem to have promise in terms of tailoring polymers for specific, small scale uses. Here the ability to add substituents without having to perform a new polymerisation is a real advantage. This approach of designing polymers for specific purposes would be real molecular engineering, something that is more often talked about than practised. The snag is that our current methods of predicting properties such as solubilities and transition temperatures are so crude as to shame most other branches of engineering. ☐

Parental care

from John Krebs

One characteristic of higher vertebrates is that they usually look after their eggs or young, a trait which is rather rare in fish, amphibians, and reptiles. The advantages of parental care in terms of survival of young may be obvious, but it is less clear why one sex rather than the other should provide the care. In birds and mammals the trend is for females to do more than males for their young, while in fish it is often the other way round.

The theory of natural selection leads one to expect that each parent should, at any time during its reproductive life, adopt the course of action which maximises the number of young produced in the remainder of its career. (It should not, of course, make the Concorde Fallacy of directing its future action on the basis of past investment (Dawkins & Carlisle *Nature* **262**, 131; 1976)). For example, if the survival of young is greatly enhanced by care from one parent, but the second parent makes rather little difference, it would pay each parent to try and leave the young in the care of its partner, to go off and mate again. On the other hand if the survival of young depends (as in most birds) on care from two parents, it will pay neither to desert.

An analysis of the theory of parental care and desertion has recently been published by J. Maynard Smith (*Anim. Behav.* **25**, 1; 1977). He considers two situations in which breeding is synchronised and seasonal: in one the factor-limiting production of young is parental care, whereas in the other, the number of eggs laid by the female is also important. In the first model, it would not pay the female to produce extra eggs since they would not survive without additional care. The first model applies to most birds. Birds are usually monogamous and both parents care for the young, but if one parent can look after the young (as in species with precocial young such as gallinaceous birds) and there is a reasonable chance of a second mating, it is usually the male which deserts. Although it would equally pay the female to desert, she is subject to a time constraint: she has to wait after copulation until she has laid the eggs, and this may mean that she is too late to have a chance of finding a second mate when there is synchronised seasonal breeding. The female can however encourage male fidelity by delaying tactics. If she refuses to copulate until the male has little chance of finding a second unmated female, she may force him into faithful monogamy.

In most fish, and a few birds, parental care takes the form of guarding and not feeding, so that the number of young reared by a female will depend not solely on the amount of parental care, but also on the initial production of eggs. Here the female has, so to speak, a choice of directing her reserves into parental care and laying fewer eggs, or channelling all her reserves into eggs and deserting each clutch. As long as one parent can rear the young, it will pay the female to desert, which she often does. As pointed out by Dawkins and Carlisle (*op. cit.*), an additional factor favouring male parental care in fish is external fertilisation. With external fertilisation the male has to deposit his sperm after the eggs have been laid; as a result the female has the chance to desert first, just as in species with internal fertilisation the male has first chance.

Mammals are rarely monogamous; male desertion is common because of the physiological commitment of the female to parental care, at least in the early stages. There are, however, some monogamous mammals, such as the gibbons (*Hylobates* spp.), and it is perhaps somewhat surprising that these species have not evolved more male parental care, for example in the form of male lactation. ☐

Neural systems

by Miranda Robertson

The Dahlem Conference on the Formation and Function of Neural Systems was held in Berlin on 7–11 March, 1977. The proceedings will be published and can be obtained from Dahlem Konferenzen, Delbruckstrasse 4c, D-1000 Berlin 33.

Although nominally the meeting was addressed to the function as well as the formation of neural systems, it was effectively dominated by the question of formation.

The growing contribution of genetics to the issue was divided by Peter Lawrence (MRC Cambridge) into two categories: the identification of genes which control development directly, and the identification of crucial cellular interactions through neurological mutants in which they have gone astray.

Two recent advances discussed at the meeting fall into the first category. One is the addition of isogenic locusts to the menagerie of mutants, mosaics and isogenic invertebrates on which much neurodevelopmental insight depends. A series of isogenic strains has been used by C. Goodman (in experiments described by D. R Bentley, University of California) to distinguish genetically controlled variation from epigenetic 'noise' in the determination of an identified neurone. While the position of the cell body varied only between strains (implying genetic control), the terminal branching of the axon varied between three positions, at different axonal lengths, within strains (implying epigenetic control).

Deducing the nature of the genetic control from mutants is, according to Lawrence, enormously complicated by the fact that most developmental mutations are bound to be lethal, which means that survivors are probably 'leaky' mutants and the investigator is thus faced with deducing wild-type function from the effects of its reduction rather than its total absence. The problem was well illustrated by the effects of homoeotic mutations on the nervous system of *Drosophila* (J. Palka, Washington University). Homoeotic mutations transform one entire structure into another—for example, wing into haltere; but the innervation of the mutant structures seems to bear no consistent relationship to the target tissue, since it can correspond either to that of either the wild-type or the mutant appendage, or to a mixture of the two, sometimes in conjunction with an abnormal pattern unlike either.

Genetic mosaics, which can be used to circumvent the lethal consequences of developmental mutations, can also distinguish direct from indirect effects of such mutations. Myerowitz and Kankel (as reported by F. D. Ready (Stanford University Medical School)) have found, for example, that a small group of mutant retinula cells in the eye of *Drosophila* mosaics causes a 'cascade' of abnormal projections in the first and second optic ganglia, although all the other cells involved are wild type.

A similar 'cascade' seems to characterise the visual system of the Siamese cat, in which a discrete subset of optic nerve fibres which projects ipsilaterally in normal animals instead crosses at the chiasm. This gives rise to abnormal connections in the lateral geniculate and at the cortex, where the callosal connections have now been shown to be abnormal as well (C. Shatz *J. comp Neurol.* **171**, 229; 1976). This abnormality is common to albinos of all species so far tested and is known to result from the absence of pigment rather than from the action of the albino gene itself, or the tysosinase deficiency which is its direct effect. (The incrimination of the pigment is due to numberless mink-breeders, who have produced animals synthesising pigment in varying quantities through mutations in no less than five different genes; and to R. W. Guillery, who has established that the degree of optic fibre misrouting in minks corresponds to the pigment deficiency and not to any particular gene.)

Guillery (University of Wisconsin), following up this clue to the cause of the mis-specification of the retinal fibres, has found that (in hamsters) a small group of pigment epithelium cells is born and dies at the base of the optic stalk at a time when no other pigment tissue has yet appeared, but the optic fibres are just beginning to grow out from the eye. It seems possible that those pigment cells induce the specification of the ganglion cell axons.

Another example of induction of neural function by non-neural cells is that of the induction of biochemical differentiation in superior cervical ganglion cells *in vitro*. Rat sympathetic neurones cultured on their own are adrenergic, but when grown in medium 'conditioned' by various types of non-neural cell they synthesise acetylcholine and form nicotinic cholinergic synapses (Furshpan *et al Proc. natn. Acad Sci. U.S.A.* **73**, 4225; 1976). Further experiments with these cells (P. Patterson, Harvard Medical School) have shown that all tissues seem to be able to induce cholinergic function, though to widely varying degrees which do not seem to be related to whether they normally receive cholinergic or adrenergic innervation, or any innervation at all There is evidence in the spinal cord *in vivo* that transmitter induction is determined by position (Le Douarin *et al. Devl Biol.* **41**, 162; 1974).

The question of how far neural development is dictated by other tissues arises in a more specific form in the context of synaptogenesis, which has been investigated principally at the neuromuscular junction. Do neurones, for example, recognise their target tissue by its neurotransmitter receptors? Experiments showing synaptogenesis in the face of receptor blockade imply that if they do, it is not by virtue of their transmitter binding sites (Cohen *Brain Res.* **41**, 457, 1972; Anderson *et al. Neurosci. Abstr.* **2**, 707; 1976). The possibility, fleetingly raised, that receptor clusters (hotspots) might attract innervating fibres has also been ruled out by Anderson *et al.*, who showed by fluorescence labelling of receptors during synaptogenesis that innervating fibres did not make synapses at existing hotspots but induced receptor clustering very rapidly on contact.

It is now clear that an important contribution to the pattern of synapse formation is made by the withdrawal of most of the contacts initially made by the innervating neurone. The evidence for this selective elimination comes both from physiological and anatomical investigations on the neuromuscular junction (Brown *et al. J. Physiol., Lond.* **261**, 387; 1976) and from anatomical studies on the cat visual system (Rakic *Nature*, **261**, 467; 1976, Hubel *et al. Phil Trans R. Soc.* in the press). Its mechanism is not known, but seems to reside largely in the nerve. Brown *et al.* have ruled out competition between lenses by the demonstration of withdrawal of synapses from rat soleus after 75% of the innervating axons have been cut, even when that leaves many fibres denervated. They do not however rule out some influence of the muscle itself in the selection of which fibres are to be retracted.

Investigation of this phenomenon in nerve–nerve synapses has been made possible for the first time by the discovery of J. Lichtman, reported by D. Purves (Washington University), that four out of five terminals made by guinea pig submandibular ganglion cells are withdrawn within four weeks after birth.

The broader implications of selective synaptic elimination are suggested by the proposal (D. Hubel, Harvard Medical School) that the period over which it occurs may correspond to the 'critical' period within which the development of the central nervous system can be influenced by its input. But the demonstration that the effects of monocular deprivation can be reversed during the critical period implies that fibres must be able to sprout as well as to withdraw.

So far, anatomical evidence of plasticity has been available only for the distribution of ocular dominance in the innervation of the visual cortex and anatomical data on the distribution of orientation selectivity (the nature of whose plasticity has been fiercely disputed) have been beyond neurology's technical means. Now however the anatomy of the orientation columns has become accessible through the discovery that ^{14}C-deoxyglucose can be used for the selective staining of active neurones (Kennedy *et al. Proc. natn. Acad. Sci. U.S.A.* **73**, 4230; 1976). Hubel has applied this technique to the autoradiographic mapping of the vertical orientation columns of the monkey visual cortex, confirming the indications from electrophysiological mapping that there is no regular anatomical relationship between the orientation columns and the ocular dominance columns. Whether this technique can be brought to bear on the issue of plasticity in orientation selectivity remains to be seen.

In the meantime, however, invertebrate neurophysiologists are preparing to join the fray. R. Murphey (State University of New York) reported that unilateral immobilisation of the mechanoreceptive hairs on the cerci of developing crickets raises the sound threshold of the medial giant interneurone which receives its input from the cercal mechanoreceptors on the treated side of the animal. Matsumoto and Murphey (*J. Physiol., Lond.* in the press) suggest on the basis of the directional tuning curve of the giant neurone that an increase in the activity of the crossed inhibitory input from the contralateral cercal hairs may at least partly account for their result.

While this has interesting echoes of the suggestion (Duffy *et al. Nature* **260**, 256; 1976) that in monocular deprivation, a tonic inhibitory input to the visual cortex from the non-deprived eye may explain the unresponsiveness of deprived cortical cells, there is much too much uncertainty about the precise mechanism of either the invertebrate or the vertebrate results to justify firm conclusions, let alone direct comparison, at this stage. □

Thermal evaporation of gas within galaxies by a hot intergalactic medium

Lennox L. Cowie
Princeton University Observatory, Peyton Hall, Princeton, New Jersey 08540

A. Songaila
5Q Hibben Apts., Faculty Road, Princeton, New Jersey 08540

High-temperature ($T \sim 10^8$ K) intergalactic gas interacts with cooler embedded gas within galaxies and extragalactic clouds principally by thermal evaporation. From Cowie and McKee's model for evaporation of spherical interstellar clouds, in pressure balance with a hot ambient medium, we produce solutions for oblate and prolate spheroidal symmetry. The results are applied to evaporation of gases within spiral and elliptical galaxies, and can be extended to evaporation of filamentary clouds in the interstellar medium.

THE recent discovery of Fe XXV emission lines in the spectrum of X-ray emission from the Perseus cluster[1], together with measurements of the cosmic microwave background[2], thermal bremsstrahlung spectrum fitting[3], and tailed radio galaxy measurements[4], provides convincing evidence for the existence of a hot ($T \sim 10^8$ K) intergalactic gas within the potential well of rich clusters of galaxies. It is also likely that a substantial amount of gas, residual from the galaxy formation process, lies outside the rich clusters; such gas may provide the closure density required to bind the universe gravitationally. Field[5] has summarised the observational constraints on such gas and shown that for a Hubble constant of 50 km s^{-1} Mpc^{-1}, (a critical hydrogen number density of 2.6×10^{-6} cm^{-3}), observations require only that the gas be highly ionised at $z = 2$ and at temperatures of less than 4×10^8 K at the present epoch. (For higher values of the Hubble constant, constraints imposed by the isotropic X-ray background are more severe, since the intensity is proportional to $H_0{}^3$). The most attractive evidence for the presence of such an intergalactic medium is the feature observed at 30 keV in the isotropic X-ray spectrum which may be fitted well by thermal bremsstrahlung from a gas with closure density and a present temperature of 3×10^8 K (refs 5, 6).

Several studies have been made of the thermal evaporation of gas within galaxies[7–9], and of the ionisation by the metagalactic ultraviolet radiation which dominates at lower temperatures[10]. De Young[7] and Bergeron and Gunn[8], analysed the evaporation as direct particle heating by penetrating particles (ions and electrons) from the intergalactic medium, neglecting the dynamics of the evaporation process. An analytical model for evaporation has been developed by Cowie and McKee[11], who derived time-independent evaporative mass loss rates for a spherical cloud embedded in an infinite hot gas with asymptotic density n_f and temperature T_f by finding simultaneous eigenvalues of the mass and energy conservation equations

$$\nabla.(\rho \mathbf{w}) = 0 \qquad (1A)$$

$$\nabla.\rho\mathbf{w}\,(\tfrac{1}{2}\mathbf{w}^2 + 5/2\,c^2) + \nabla.\mathbf{q} = 0 \qquad (1B)$$

where ρ is the mass density, w the velocity of outflow, c the isothermal sound speed and q the electron heat flux.

In the case in which the heat flux can be written as

$$\mathbf{q} = -\kappa\nabla T \qquad (2A)$$

where κ is the classical thermal conductivity

$$\kappa \equiv k_0 T^{5/2} = (1.84\times10^{-5}\,T^{5/2})/(\ln\Lambda \text{ erg s}^{-1}\text{ deg}^{-1}\text{ cm}^{-1}) \qquad (2B)$$

($\ln\Lambda$ is the Coulomb logarithm, ref. 10) the pressure is approximately constant throughout the interface and the flow subsonic; since the condition $M^2 \ll 1$ is satisfied, equations (1A and 1B) are approximately separable in a number of coordinate systems. (The equations cease to be separable when the term $(\mathbf{w}.\nabla)\,\mathbf{w}$ in the momentum conservation equation becomes important.)

Here we shall describe the solutions for both oblate and prolate spheroidal symmetry. The analysis closely follows that in Cowie and McKee[11]; in particular, oblate (prolate) spheroidal surfaces of constant u replace surfaces of radius r (the notation is that of Arfken)[13]. Thus the boundary conditions become $T = 0$ at the surface of the cloud ($u = u_0$) and $T \rightarrow T_f$ as $u \rightarrow \infty$. In terms of u_0 the mass loss rates from the clouds are

$$\text{Oblate: } \dot{M} = 8\pi a\mu k_0\, T_f{}^{5/2}/25\, k_B(\pi/4 - \theta_0) \qquad (3A)$$

$$\text{Prolate: } \dot{M} = 16\pi a\mu k_0\, T_f{}^{5/2}/25\, k_B\, |\gamma_0| \qquad (3B)$$

Here μ is the mean mass per particle, k_B the Boltzmann Constant, while

$$\theta_0 = \tan^{-1}(\tanh\tfrac{1}{2}u_0) \qquad (4A)$$

$$\gamma_0 = \ln(\tanh\tfrac{1}{2}u_0), \qquad (4B)$$

where a is related to the semi-major (l) and semi-minor (b) axes of the ellipsoid of constant u by

$$l = a\cosh u \qquad (5A)$$

$$b = a\sinh u \qquad (5B)$$

In the limit as the surface $u_0 \rightarrow 0$ (oblate spheroid → disk, prolate spheroid → needle), the result for the oblate case is a factor of $2/\pi$ times the mass loss rate from the surface of a sphere of radius a; however, in the prolate case, the mass loss rate tends to zero as the surface area of the cloud vanishes. Both mass loss rates drive clouds towards sphericity on timescales comparable with the evaporation time.

We have also evaluated the temperature distributions as

Oblate
$$(T/T_f)^{5/2} = \frac{\theta_o - \theta}{\theta_o - \pi/4} \quad (6a)$$

Prolate
$$(T/T_f)^{5/2} = \frac{\gamma_o - \gamma}{\gamma_o} \quad (6b)$$

where θ and γ refer to the surface of constant u at which the temperature is evaluated. These may be used to evaluate the column density of a given ion in the evaporative interface (see Section III of McKee and Cowie[14] for details). For example, along the axis $\nu = \pi/2$ of the oblate spheroid (the axis of rotational symmetry), we obtain for the column densities of OVI, assuming cosmic abundances[15] and steady-state ionisation equilibrium[16]

$$N_{\mathrm{OVI}} = 2.04 \times 10^{-4}\, a n_f (3 \times 10^5\ \mathrm{K}/T_f)^{3/2} \quad (7)$$

Emission measures may also be calculated in terms of the external density and temperature (n_f, T_f) and the dimension a.

The mass loss rates calculated above may overestimate the mass loss if the heat flux given by the classical formula of equation (1) exceeds the maximum heat flux which may be carried by the electrons. This was estimated by Cowie and McKee to be $5\varphi_s \rho c^3$, where φ_s is a factor of order unity. In the spherical case the mass loss rate may be calculated exactly even in this limit (compare Cowie and McKee) [11]; however, in the geometries considered, saturation of the conductivity is a symmetry breaking effect which precludes an analytic solution, while, as we have discussed above, the hydrodynamic equations are no longer separable.

Thus we note that, in the oblate spheroidal geometry, saturation of the conductivity occurs initially along the $\nu = 0$ axis, where temperature gradients are a maximum. In terms of the parameter

$$\sigma_o = \frac{2\kappa_f T_f}{25\varphi_s \rho_f c_f^3 a} \simeq \left(\frac{T_f}{1.54 \times 10^7}\right)^2 a_{\mathrm{pc}}^{-1} n_f^{-1} \quad (8)$$

which measures the ratio of the electron mean free path to the characteristic dimension of the system, this occurs when

$$\sigma_o \sim 5.7\, u_o^{4/5},\ u_o \ll 1 \quad (9)$$

or substantially earlier than would be the case for a sphere of radius a where saturation occurs at $\sigma_o \sim 1$. Initially the effect is confirmed to a very narrow range of ν and has little effect on the mass loss rates. As $\sigma_o \to 2.5$ the heat flux saturates throughout the interface; beyond this range we would expect the mass loss rates to approximate those found by Cowie and McKee[11] for spherical clouds of radius a, because the energy flow is governed by the outer regions of the saturated zone which is approximately spherically symmetric.

For clouds of a given column density, the effects of radiation on the evaporation depend only on the external temperature[14]; numerical integration shows that the results of McKee and Cowie for the radius of spherical clouds at which radiation dominates the conductive heat flux and clouds condense are approximately applicable to the oblate spheroidal geometry, if the dimension a is substituted for the spherical cloud radius. For temperatures $>10^6$ K, the condition for radiation to be unimportant is that the factor σ_o exceeds 0.027. We have also assumed in the above discussion that the effects of magnetic field structure do not substantially inhibit the thermal evaporation. Cowie and McKee suggest that this approximation is reasonable if the magnetic fields of the cloud and intercloud are well connected, a condition that will be self consistently satisfied if evaporation is important. For the present purposes it may be considered as an extreme assumption, providing an upper bound to the mass loss rate by evaporation.

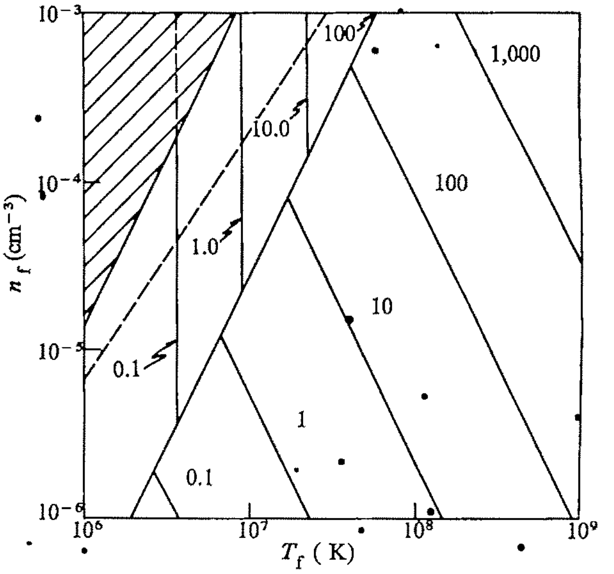

Fig. 1 Evaporative mass loss rates (in $M_\odot$ yr^{-1}) from a spiral galaxy of radius 15 kpc as a function of the local intergalactic temperature and density. The diagram is divided into three zones; in the shaded region radiation from the interface is important and galactic material condenses on to the galaxy, in the central region classical mass loss rates are applicable, while to the right of the solid line flux limiting effects are important (see text). We also show (— — — — —) the value of the external parameters for which absorption lines in the interface may be detectable ($N_{\mathrm{OVI}} = 10^{13}$ cm^{-2}).

We note finally that the evaporation rates given above for clouds in pressure equilibrium with the ambient gas should also be applicable to the evaporation of gas within galaxies, because, if the external temperature of the gas is large by comparison with the velocity dispersion of the galaxy, temperatures in the interface rise too rapidly for the gravitational field of the galaxy to be important.

In Fig. 1 we show the mass loss rate from a spiral galaxy of disk radius 15 kpc and thickness 200 pc for a wide range of intergalactic temperatures and densities. For $\sigma_o > 1$ (shown by the dashed line), we have used the spherically symmetrical results of Cowie and McKee; the discontinuity across this surface reflects the uncertainty in the mass loss rates. To within the factor of $2/\pi$ introduced by the geometry, the results may also be applied to galaxies of arbitrary ellipticity.

The mass loss rates are a sensitive function of the local temperature, but somewhat less sensitive to the local density. The existence of cool gas within galaxies therefore provides an upper bound to the local temperature of the intergalactic gas which is a weak function of the intergalactic density. The most sensitive probe is provided by the observations of column densities of 2–3×10^{19} cm^{-2} (0.18–0.27$M_\odot$pc^{-2}), of neutral hydrogen by Roberts and Whitehurst[22] at 30 kpc from the centre of M31, where the surface density of material inferred from the rotation curve is 30$M_\odot$pc^{-2}. The column density of ionised shielding slabs is unlikely to greatly exceed this value[24]. In the absence of replenishment by the stellar population, the evaporation time for the neutral hydrogen alone equals the Hubble time at a local temperature of 3×10^6 K and is independent of the density for $n \geq 2 \times 10^{-6}$ cm^{-3}. This value is comparable to that obtained by Cowie and McKee[9] from consideration of extragalactic clouds. The present results, however, are significantly more uncertain, as the possibility of substantial mass loss from a stellar population cannot be excluded. De Young[7] estimates that if the 30$M_\odot$pc^{-2} is composed of 0.1$M_\odot$ M type dwarves losing mass at a rate of $10^{-12} M_\odot$ yr^{-1} comparable with the solar value, an upper bound to the mass loss rate is $3 \times 10^{-10} M_\odot$ yr^{-1} pc^{-2}. This would result in the weaker condition $T \leq 10^7$ K for $n = 3 \times 10^{-6}$ cm^{-3}.

It must be stressed, however, that these values refer only to the temperature of intergalactic gas within local groups. We emphasise that the average temperature of the intergalactic gas may be substantially higher, though temperatures as high as 3×10^8 K, required to explain the isotropic X-ray background, seem to be ruled out by the upper bounds on cooler material within groups, provided by soft X-ray measurements (compare Cowie and McKee[9]). The values of the mass loss rates from the galaxies are sufficiently large that evaporative stripping could clear material from galaxies in regions where intergalactic gas temperatures are high, and could account for the absence of gas within field SO galaxies.

We note that for local intergalactic densities of order 3×10^{-6} cm^{-3} neither emission nor absorption in the interface will be detectable, irrespective of the ambient temperature. If lower temperature, higher density gas does exist within the local cluster, the interface might be detectable in absorption (Fig. 1).

We may apply similar arguments to galaxies which are members of rich clusters. The parameters of the intracluster medium in the central regions of the cluster, based on the thermal bremsstrahlung interpretation of the X-ray emission from the Coma cluster[18] are $n \sim 3\times10^{-3}$ cm^{-3} ($\Omega \sim 1{,}000$), and $T = 10^8$ K. The ratio of the mass loss rate by thermal evaporation to the stellar mass injection is maximised if the cool gas is confined to the nucleus of the galaxy. The evaporation from the nucleus however, is $1.4\times10^{-4}\ R_p{}^{1.625}\ M_\odot\ \mathrm{yr}^{-1}$ (Fig. 1), where R_p is the core radius of the galaxy in pc; for $R_p = 100$ the mass loss rate is $0.25 M_\odot\ \mathrm{yr}^{-1}$. Thus even in the most favourable case for retaining gas, the evaporation rate exceeds the probable mass injection rate by stars inside the nucleus for all but the most massive galaxies.

We suggest that this effect rather than ram pressure stripping is responsible for the absence of the OII λ3727 line in elliptical galaxies within rich clusters, because, as Gisler[23] has pointed out, ram pressure stripping is ineffective in removing pre-existing gas from the nuclei of galaxies. In a sample of 100 galaxies within the Coma cluster by Sargent and Gunn (quoted in ref. 19) this line was detected only in the giant central galaxies NGC4889 and NGC4874, which is consistent with the present results.

Finally, we may note that comparison of the critical radius for radiative stabilisation with characteristic scales of the galaxies (Fig. 1) indicates that radiation is never important, even for the giant central galaxies. The results indicate that the cD galaxies are not now growing by conductive condensation of hot intracluster gas, as has been suggested[19], although radiative cooling of the central intracluster gas on scale lengths large compared with the radii of these galaxies may ultimately result in gravitational accretion of material on to these galaxies[21,25].

We thank Drs C. F. McKee and G. B. Field for helpful discussions. L. L. C. thanks the Center for Astrophysics for its hospitality and support. This work was supported in part by Princeton University, under a NASA Grant.

Geochemical evolution during fractional crystallisation of a periodically refilled magma chamber

M. J. O'Hara

Grant Institute of Geology, Edinburgh University, West Mains Road, Edinburgh, UK

A realistic model of volcanic plumbing predicts that most of the established major, trace and isotopic chemical features of the common basalts could have been imposed during magma evolution in high-level magma chambers, for which process there is extensive independent field and phase equilibria evidence. These effects must be quantified before chemical features of lavas are ascribed to the nature of the underlying upper mantle.

THE changes in the chemistry of basaltic liquids which occur during a variety of partial melting processes have been explored in mathematical models[1,2]. Extensive variations in the concentrations of those incompatible trace elements which are strongly concentrated into the liquid are observed to occur with little accompanying change of the concentrations of the major elements (notably Fe, Mg, Na, Ca), particularly where the percentage of partial melt is small. Similar results can be produced by interaction of basalt magma with a peridotite wall rock in a process akin to zone refining[3]. General geological constraints suggest that both partial melting and zone refining processes have been restricted to relatively high pressure environments in the Earth.

The argument outlined here is developed in the particular context of basaltic magmas but the model presented is equally applicable to any magma, because it is a mathematical formulation of the effects which will follow from a particular style of plumbing in a volcano.

Basaltic liquids which are isolated from their upper mantle source regions may undergo crystallisation either while full equilibrium is maintained between the residual liquid and the crystals which have formed, or in such a way that all crystals formed are immediately removed from contact with the liquid. The changes in the chemistry of the liquids during these processes differ strikingly from those produced in partial melting processes. Large variations in the concentrations of the incompatible trace elements can occur, but only at the expense

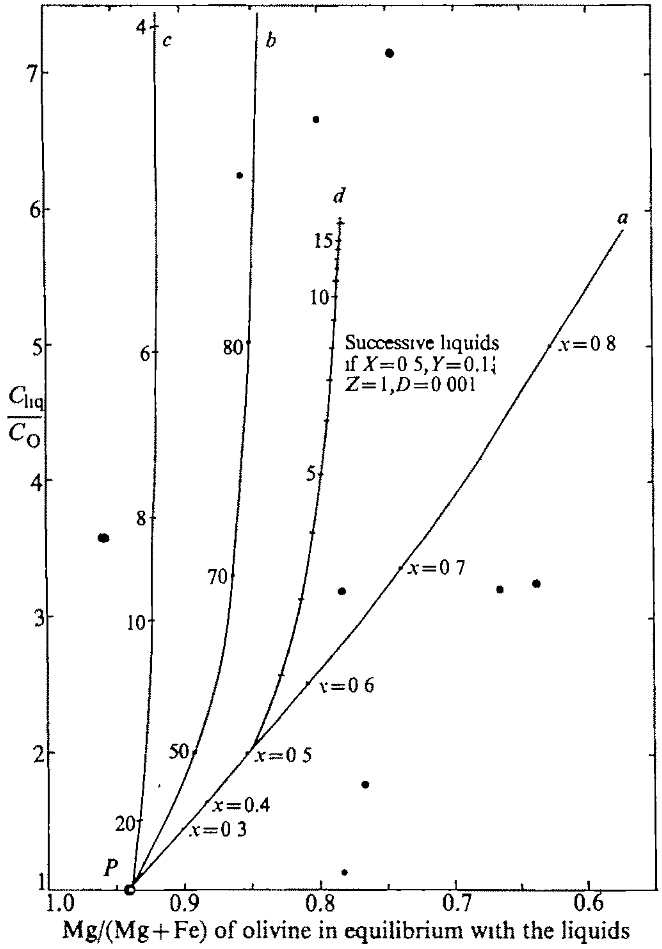

Fig. 1 How the relative concentration of an incompatible trace element: ($D = \frac{\text{conc. element in crystals}}{\text{conc. element in liquid}} = 0.001$) will vary in the liquid fraction during a variety of processes which may lead to the development of a liquid P, and a further group of processes which may act on a liquid such as P. The change of concentration of the incompatible trace element relative to its concentration in liquid P is plotted as a function of the ratio of two major, relatively compatible elements, exemplified by Fe, Mg for which it has been assumed that $D = 0.7, 2.1$, respectively. The scale is, however, translated into one showing the composition of the olivine which would coexist with these liquids, assuming

$$K_D = 0.33 = \left(\frac{\text{Fe}}{\text{Mg}}\right)_{\text{ol}} \left(\frac{\text{Mg}}{\text{Fe}}\right)_{\text{lq}}$$

It has been assumed that liquid P is in equilibrium with olivine of composition Fo_{94}. Further discussion is in the text.

of producing large volumes of crystal cumulates, and extensive increases in the ratios of major elements such as Fe/Mg, Na/Ca. General geological constraints suggest that such processes occur extensively at low pressures, and are probably important at high pressures also.

The differences between the chemistry of the liquid products of the partial melting, equilibrium and fractional crystallisation processes are illustrated in Fig. 1, curves *a*, *b*, *c*. Curve *a* shows the evolution of the residual liquid composition during closed system perfect fractional crystallisation (with percentage crystallisation marked). Curve *b* shows the evolution of the intercrystalline liquid during perfect equilibrium crystallisation (with percentage crystallisation marked). Curve *c* shows the variation during an equilibrium partial melting process which would yield P as a 30% melt of the source region (with intermediate compositions and the percentages of melt then formed indicated).

None of the processes so far considered are effective in causing a variation in the ratio of two elements which are both strongly concentrated into the liquid relative to the crystals.

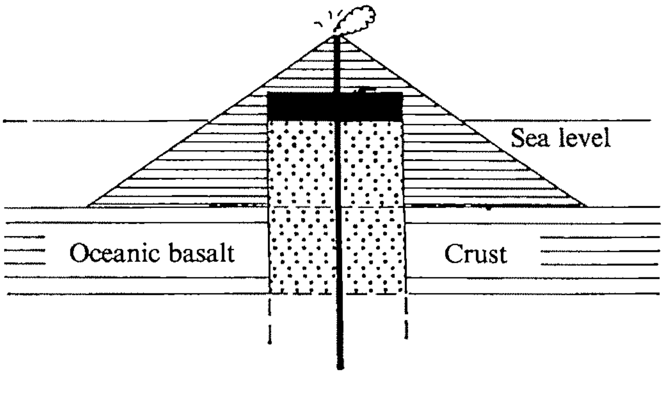
These considerations have led to the development of two criteria of widespread application in studies of basalt genesis and upper mantle motions. If the concentrations of incompatible elements vary greatly in a series of basalts of comparable major element composition, this variation reflects differences in the extent of partial melting at the source region which gave rise to each magma batch. If the ratio of the concentrations of two incompatible trace elements differs between two series of basalts, they have been derived from two different source regions of distinctive chemistry (partly characterised by the ratios of the incompatible trace elements).

These criteria have been critical in underpinning the hypothesis of the existence of hot fertile plumes of upper mantle material rising beneath volcanic 'hot spots'[4]. Their application carries with it the implicit assumption that there has been little fractional crystallisation of the basalts near the surface, and that little chemical change, particularly of the trace element ratios, can have occurred in those near-surface processes. This view apparently conflicts with a wealth of observational and experimental data which indicate that most erupted basalts have been thoroughly modified in composition during near-surface processes[5–9].

The evolution of basaltic magmas by equilibrium or fractional crystallisation in closed systems provides only one model of what could occur in near-surface magma chambers. A slightly more sophisticated model has recently been explored in which the magma in a high-level chamber undergoes continuous fractional crystallisation, but is periodically fed with a new batch of the parental magma from depth. In this model, the arrival of this new magma batch is assumed to displace a sample of the residual liquid from the chamber as a lava flow. The rest of the residual liquid and the new batch of parental magma then mix, and the fractionation process continues.

Many central volcanoes seem to have a core of gabbroic cumulates extending to great depth[10–17]. In the case of oceanic island volcanoes it is manifest that much of what is now plutonic gabbro must have replaced what was previously basalt which had erupted into and had the opportunity to react with seawater. A thick portion of the oceanic crust formed at the ridges is composed of gabbro which may largely have replaced previously erupted basalts. As a refinement to the simplest model, provision has been made to consider the possible effects which are due to the digestion of previously erupted basalts

Fig. 2 Model of the evolution of an oceanic island volcano. The active magma column and differentiating chamber are shown in black. The advancing magma chamber has digested all the previously erupted basalts in the stippled column, replacing them with cumulates. Incorporation of basalts altered by contact with seawater has contaminated the isotopic ratios of later erupted basalts. Because the cumulate pile is built up below the active and advancing magma chamber, this may be a relatively thin sheet of liquid at the cumulate–roof interface. There need never have been a magma chamber of the size of the ultimate gabbro pile.



(Fig. 2). This adds a process akin to zone refining on to the other effects. (This zone refining, however, operates within the fertile ground of previously erupted basalt rather than in the less promising ground of upper mantle peridotites).

Let X = mass fraction of cumulate formed from the magma in each cycle
Let Y = mass fraction of the original liquid before this fractionation which is extracted as a lava flow at the end of each cycle
Let Z = mass of parental magma added in each cycle (expressed as an absolute quantity relative to the initial size of the magma chamber)
Let C_0 = the initial concentration of an element in the parental liquid
Let $C_B{}^S$ = concentration of element in the residual liquid of the fractionation cycle, in the steady state.
Let $D = \dfrac{\text{concentration of element in crystal extract}}{\text{concentration of element in liquid}}$
Let C_Q = concentration of element in the material digested by the magma chamber
Let q = fraction of the total cumulate X fraction, which has been precipitated in order to provide the energy necessary to digest a mass fraction Q of previously erupted basalt. It has been assumed that $Q = qX$ and that $(1-q)X$ represents fractionation caused by conductive and other energy losses.

The following relationship may then be derived. (Full details of these derivations will be given in a longer communication which is in preparation.)

The steady-state mass, M, of the magma chamber is given by $Z/(X-qX+Y)$, M and Z being expressed in any absolute or relative units.

The way in which the potential lava composition, C_B, evolves in successive cycles towards the steady-state composition, $C_B{}^S$, during successive cycles of the addition, mixing and fractionation process, is shown for just one choice of the parameters X, Y, in Fig. 1, curve d ($q = 0$). As X becomes smaller, curve d approximates more closely to c. As X/Y becomes larger, the steady-state composition ($C_B{}^S$) moves to higher values of C^{1q}/C_0.

The concentration of an element in the basalt erupted periodically when the magma has reached a steady state, relative to its concentration in the parental magma, is then given by

$$\left(\frac{C_B{}^S}{C_0}\right) = \frac{\{X[1+q((C_Q/C_0)-1)]+Y\}(1-X)^{D-1}}{1-(1-X-Y)(1-X)^{D-1}} \qquad (1)$$

(provided Z, C_0 remain constant and assuming Rayleigh fractionation).

Figure 3 plots ($C_B{}^S/C_0$) against D for a various values of X, Y, assuming always that $q = 0$. The dotted curves a,a' show the values of D for which one incompatible element will achieve a steady-state concentration 1.5 times greater than that achieved by an element for which $D = 0.1$, 0.2 (lines b,b') for cases where $Y = 0.001$. Much larger (absolute) differences in D are necessary to produce the same effect when D lies closer to unity and separation of elements of similar D value is most effective when $X \gg Y$. When X is large relative to Y, and X, Y, D are all small, it is possible to produce large variations in the ratio of two incompatible elements without large change in the major element composition of the parental magma. The values of X, Y are critical in determining the steady-state concentrations of elements with D very different from unity.

Note that compatible element concentrations ($D \sim 0.4$–2.5) are relatively insensitive to the absolute and relative values of X, Y, especially when X, Y are small and $X > Y$ (Fig. 3).

The X/Y ratio determines the relative concentration achieved by highly incompatible elements, but the absolute values of X and Y become very important as D increases. The larger the values of X, Y, the higher $C_B{}^S/C_0$ of elements for which D $\sim$ 0.3, and the lower $C_B{}^S/C_0$ of elements for which $D > 1$. In other words, the absolute values of X, Y have little effect on $C_B{}^S/C_0$ for incompatible elements, provided X/Y is constant, but greatly influence the concentration of a highly compatible element such as nickel or chromium, the steady-state concentration remaining higher as the absolute values of X, Y decrease.

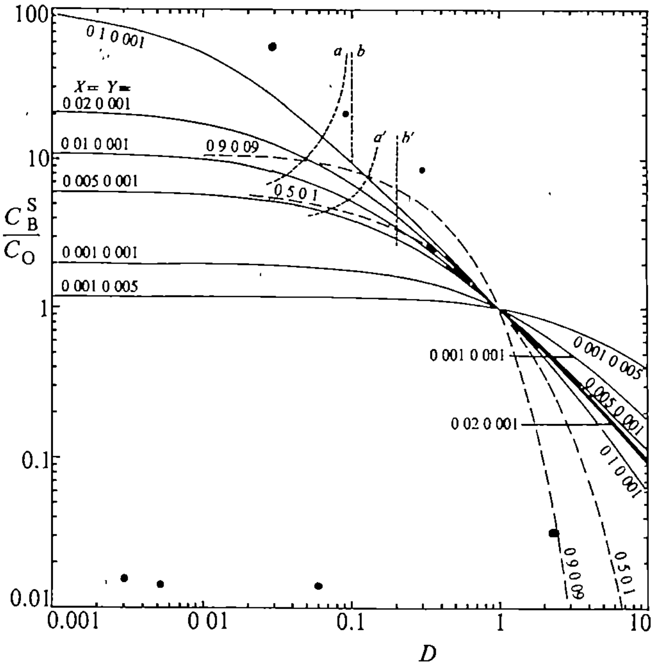


Fig. 3 Variation of the relative concentration of an element ($C_B{}^S/C_0$) as a function of D for a selection of choices of X, Y, ($q = 0$ in equation (1)). At values of D along curves a, a′, the concentration of an incompatible element is 1.5 times that at values of D given on b, b', for all curves with $Y = 0.001$.

$$\frac{C_B{}^S}{C_0} = \frac{(X+Y)(1-X)^{D-1}}{1-(1-X-Y)(1-X)^{D-1}}$$

Further discussion is in the text.

The major geochemical effects hitherto considered to be indicative of small and variable degrees of partial melting or derivation from different upper mantle source regions can also be produced during plausible high-level fractional crystallisation processes for whose operation there is so much independent evidence. This type of fractionation could be effective in exploiting small differences in D (as between isotopes of a single element) to produce small but significant differences in their relative concentrations. (These differences will not be completely removed by the normalisation procedures in standard use unless the differences in D for different isotopes vary linearly with mass.)

The concentration, $C_B{}^S$ of an element in the steady-state liquid is made up of a spectrum of partial concentrations, K_P, each arising from one previous input of parental magma, such that

$$\sum_{P=1}^{P=P} \frac{K_P}{C_B{}^S} = \sum_{P=1}^{P=P} [(1-(1-X-Y)(1-X)^{D-1})] \times$$
$$\times\ [(1-X-Y)(1-X)^{D-1}]^{P-1} \qquad (2)$$

The number of mixing and fractionation cycles, p, for which this summation is equal to 0.5 represents the average residence time (in cycles) of that particular element in the magma chamber. The smaller the values of D, X and Y, the larger p becomes. An incompatible radioactive parent element (for example, Rb) may have been effectively present in the magma for a much longer time than its more compatible decay product (for example, ^{87}Sr).

Returning to equation (1), we can consider the probable effects of the digestion of previously erupted basalts. Setting $q = 0.5$, $C_Q/C_0 = 2$, $X/Y = 1$, $C_B{}^S$ will be 1.25 times as large as it would have been had there been no digestion of basalt. If $q = 0.8$, however, $(C_Q/C_0) = 5$, $X/Y = 3$, $C_B{}^S$ becomes 3.4 times larger than it would otherwise have been, and the contribution of digestion of previously erupted baslts begins to dominate the geochemical effects.

The potential effect of the digestion of previously erupted basalts, whose isotopic ratios have been altered by interaction with seawater, to influence the isotopic ratios in the later basalts to be erupted may be seen by rewriting (1) to obtain the fractional change in the isotopic ratio, Δ, where

$$\Delta = \left\{\left(\frac{{}_1C_B{}'^S}{{}_1C_B{}^S}\right)\left(\frac{{}_2C_B{}^S}{{}_2C_B{}'^S}\right) - 1\right\}$$

and ${}_1C_B{}^S$ = steady-state concentration of isotope 1 if $q = 0$, ${}_1C'_B$ as here = steady-state concentration of isotope 1 if $q \neq 0$, and so on. Assuming no difference in D for the isotopes 1, 2, and setting the ratios of the two isotopes in the altered basalt

$$\frac{{}_1C_Q}{{}_2C_Q} = r\left(\frac{{}_1C_0}{{}_2C_0}\right)$$

then

$$\Delta = \left(\frac{X}{Y}\right)q\left(\frac{{}_2C_Q}{{}_2C_0}\right)(r-1) \bigg/ \left\{\left(\frac{X}{Y}\right)\left[1+q\left(\frac{{}_2C_Q}{{}_2C_0}-1\right)\right]+1\right\} \qquad (3)$$

Δ has been calculated for the values of q, C_Q/C_0 and X/Y discussed above. If $r = 1.0014$ (the fractional change in $^{87}Sr/^{86}Sr$ for average ocean floor basalts deduced by Spooner[18]), then $\Delta \sim 5$ to 13×10^{-4}, which is of the order of size observed between fresh ocean floor basalt and ocean floor basalt and oceanic island theoleiites[19].

Isotopic fractionation (with D values varying non-linearly with mass), larger effective residence times in the magma chamber for an incompatible parent element than for its radiogenic products, and digestion of previously erupted, isotopically altered, basalts could all contribute to changing the isotopic ratios of the basalts erupted at a later stage in the development of oceanic islands. The last of these processes apparently has the greatest potential. It could be that a substantial part of the differences in the isotopic ratios of Sr, Nd and Pb between basalts from hot spots relative to those from mid-ocean ridges may reflect the longevity and comparative geochemical fertility of seawater rather than of any underlying mantle source region.

Contamination by assimilation of crustal material could also occur during the creation of cumulate piles in central volcanoes of continental regions.

In discussing the possible effects of contamination on major or trace elements, or isotopes of elements, several relevant factors must be borne in mind. It is the local average continental crust, or isotopically altered oceanic crust (not seawater itself) which is causing the contamination and which must, therefore, be characterised. The advancing magma chamber will thermally metamorphose the assimilated materials before they are digested; there may be further isotopic exchange with expelled waters at this stage. The assimilation of basalt by basalt magma would create no dramatic change of major element chemistry of the magmas or the cumulates, but the assimilation of crustal material might well do so. The effects of this chemical contamination cannot be simply envisaged, however, because the speeds with which the added elements are removed to the cumulus pile and their steady-state concentrations in the magma are functions of the distribution coefficient for each element. Where the contamination is severe, the bulk distribution coefficients could themselves be modified due to the change in the nature or proportions of the minerals precipitating.

Thus far the effects of this model of magmatic evolution on trace elements, for which $D \sim$ constant have been treated. For the major components, D is not constant, changing progressively with crystallisation of a phase within any one equilibrium (for example, olivine + liquid) and changing abruptly

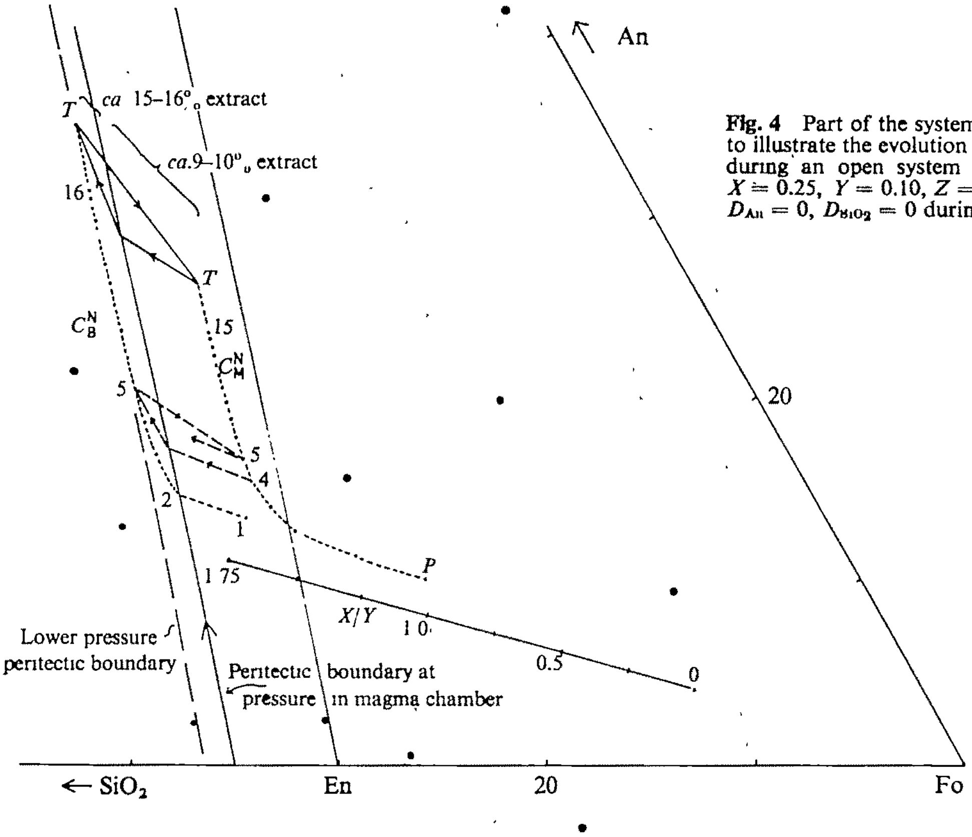

Fig. 4 Part of the system forsterite–silica–anorthite (simplified) to illustrate the evolution of the major components of the liquid during an open system fractionation process $C_0{}^N = C_0 = P$, $X = 0.25$, $Y = 0.10$, $Z = 1.0$, D_{Fo} = variable, D_{En} = variable, $D_{An} = 0$, $D_{SiO_2} = 0$ during Fo crystallisation only (discussed in the text).

whenever there is a change of equilibrium (for example, to olivine + pyroxene + liquid). The possible effects here are difficult to convert to mathematical models, but can be handled by graphical means. Figure 4 shows where the steady-state liquid composition will lie for two particular choices of parent liquid composition, and how one of them evolves during successive mixing and fractionation cycles to reach that composition.

With parental magma composition O, (Fig. 4), the steady-state liquid composition may lie anywhere along the line from forsterite through O, depending upon the ratio of X, the amount of crystals extracted, to Y, the amount of magma erupted.

With parental magma P the amount of fractionation supposed is sufficient for the residual liquids in successive cycles to evolve beyond the cotectic between pyroxene and forsterite. The evolution of the liquid towards the steady-state concentration has been traced graphically for one choice of X, Y. The actual evolution of the liquid between the fourth mixed magma (C_M), the fifth residual magma C_B, and the fifth new mixed magma (C_M) is illustrated by dashed lines. The loci (but not the path) of the evolution of liquids C_B, C_M to their steady-state compositions, T, are shown by dotted lines. The steady-state recycling by repeated fractionation and mixing is shown by a triangle of solid lines. The loci C_B, C_M approach each other as X becomes smaller. The steady-state compositions move further from O, P as X increases relative to Y.

The important general principles to be derived from Fig. 4 are that the steady-state liquid composition could be arrested within the liquidus field of a single crystalline phase (for example, olivine or pyroxene), or on a cotectic where two or more phases are precipitating together. In certain circumstances, such as those depicted in Fig. 4, which are relevant to the crystallisation of olivine from natural basalts at low pressures, steady-state residual liquid compositions are constrained to lie close to those of liquids which are in reaction relationship with olivine. This result contradicts the general rule in closed system fractional crystallisation, that residual liquids will depart in composition relatively rapidly from a peritectic relationship (see Fig. 4). To add to the possibly misleading aspects of the effect shown in Fig. 4, any drop in pressure which accompanies the eruption of a liquid from the magma chamber to the surface will expand the limits of the olivine liquidus field (Fig. 4), tending to place the locus of the peritectic liquids at low pressure even closer to the liquid compositions generated at a slightly higher pressure.

Summarising, in this open-system fractional crystallisation process, a near-surface magma chamber is fed regularly with batches of parental magma which mingle with the liquid already there. The mixed magmas undergo continuous fractional crystallization. The steady-state lavas which may be extracted from time to time will then show the following characteristics: (1) Uniformity of composition, provided the thermal insulation of the magma chamber, the rate of supply, the amount and nature of assimilation and the composition of the parental magma are maintained constant. (2) Large differences of composition between the lava and the parental magma with respect to major and trace element concentrations and ratios. (3) Strong control of liquid composition by the low pressure phase equilibria. The steady-state liquid composition may be arrested within the liquidus field of one crystalline species only (specifically, that which would be the liquidus phase in the parental magma). It is, however, more likely to be located on a cotectic where two or more crystalline species precipitate together, or very close to a peritectic where one (or more) crystalline species is in reaction relationship with the liquid while others precipitate.

Steady-state lavas developed from the same parental magma but in magma chambers with different characteristics of heat loss and supply rate may show the further characteristics:

(4) Large variations in the concentrations of incompatible elements (for example, the large-ion, lithophile elements) with litttle change in the concentrations of the more compatible major elements, and little variation in the iron: magnesium ratio.

(5) Significant variations in the ratio of two incompatible elements.

If the magma chamber advances ahead of the growing column of cumulates within the growing volcano in part by digestion of previously erupted basalts, then:

(6) Enrichment factors mentioned in (4) may be greatly enhanced in the later products of the volcano.

(7) Isotopic characteristics of the previously erupted basalts, which may have been altered by contact with sea water, will influence the isotopic characteristics of the later products of the volcano. Higher ratios of the radiogenic to non-radiogenic isotopes of Sr, Pb, Nd in the lavas erupted from large central oceanic island volcanoes than in ocean floor basalts may partly reflect the chemical characteristics of sea water. This process can explain the difference in strontium isotope ratios observed[7] between oceanic island and oceanic floor basalts quantitatively as shown above. Data are lacking at present for isotopic ratios of Pb, Nd in the average altered oceanic basalt section, hence this part of the prediction cannot yet be tested.

Provided X, Y are small,

(8) Highly compatible elements (for example, Ni, Cr) may show relatively high concentrations despite the effects noted in (2), (4).

(9) The mass of the magma chamber is large relative to the periodic batches of parental magma added to it, and the composition of the steady-state magma will be insensitive to short-term random fluctuations in the mass or composition of the added batches.

Lastly,

(10) There is no requirement for the magma chamber to be large. The whole ocean floor gabbro sequence might be laid down from a magma sheet never more than a few tens of metres thick, as might many cumulus piles in central volcanoes.

As a general comment one may note that few of these features are anticipated as a result of closed system fractional crystallisation processes.

The geochemical features noted under (1), the second sentence of (3), (4), (5), (6), (7) or (8) can therefore only be used in support of claims that particular basalts are primary, have been derived by different degrees of partial melting of some source region, or have been derived from fundamentally different source regions, if the model of volcanic plumbing discussed in this paper can be specifically excluded. Because of the feature mentioned in (2), overlooking the effects of high-level fractionation which are possible results of this model will result in misleading conclusions about the chemistry of the source regions and the processes which have affected them. The hallmark which indicates that lavas may have evolved in this type of process is set out in (3)—often the lavas will be porphyritic, but in general will be close to saturation at low pressure with two or more phenocryst species.

An oxygen-isotope climatic record from the Devon Island ice cap, arctic Canada

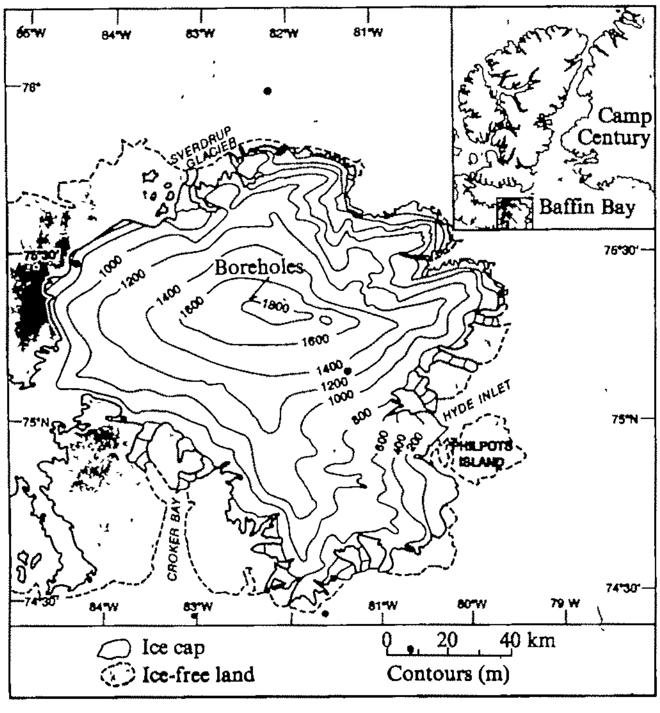
Physics Institute, University of Bern, Switzerland

Isotope measurements on two adjacent cores through the Devon Island ice cap provide a well-dated climatic record for the past 5000 yr. Fluctuations in annual values include much 'noise', and ice flow over a rough bed produces distortions in the lowest 5% of core which covers roughly 120,000 yr. Comparison with the Camp Century, Greenland, record helps to separate climatic changes from changes in ice thickness or flow pattern.

SINCE the $^{18}O/^{16}O$ ratio in polar snow depends on its temperature of formation[1], deep cores from polar ice sheets contain a record of past temperatures. Records covering all or part of the Wisconsin Glaciation have been obtained from Greenland and Antarctica[2–5]. We report here on two cores from the Devon Island ice cap, arctic Canada. These cover the same period as the Camp Century, Greenland, core, namely about 125,000 yr, but because the ice more than 10,000 yr old is compressed into a few metres near the glacier bed, the record is less detailed.

The $^{18}O/^{16}O$ ratio is expressed as the fractional difference between the ratio in the sample to the ratio in 'standard mean ocean water'. It is denoted by δ and measured in ‰. In polar snow δ is negative; the more negative, the lower the temperature. Correlations between δ and temperature must be made with caution, however, because δ will also change if the source area of precipitation changes, if the ice thickness changes with time or if the ice at depth originates upslope from the drill site[2]. Drilling near an ice divide, as in the present study, eliminates the last problem.

Fig. 1 Map showing location of boreholes on the Devon Island ice cap and its position relative to Camp Century, Greenland.



The ice cap and boreholes

Figure 1 shows the ice cap and borehole site some 600 km from Camp Century on the opposite side of Baffin Bay. The boreholes, Holes 72 and 73, are 27 m apart on the same flow line about 900 m north of the ice divide. Hole 73 is upslope from Hole 72. The holes reached bedrock at depths of 298.9 m (Hole 72) and 299.4 m (Hole 73). The ice–bedrock contact was sharp; the lowest metre of each core contained a few small dirt particles, probably of wind-blown origin, but there was no basal moraine in the ice. The temperature at the interface was −18.4 °C. Annual precipitation is 0.22 m water equivalent and the mean annual air temperature is about −23 °C. In most summers, a little surface snow melts and refreezes in the snowpack. This, combined with the relatively low precipitation rate, means that seasonal variations in δ are eliminated in a few years.

Dating the ice

For a palaeoclimatic record to be of any value, the age of the ice at each depth must be known. Age t at depth y is calculated by the formula

$$t = \int_0^y v^{-1}\,\mathrm{d}y$$

where $v(y)$ is the component of ice velocity perpendicular to the surface. In previous studies, various functional relationships between v and y have been assumed[6,7]. In the present case, v was measured at various depths in the borehole[8] and the integral evaluated numerically. Although a measured relation should be better than a theoretical one, the measured values must be assumed typical of past values. This implies that the ice cap has been in a steady state (no change in precipitation rate, ice thickness or temperature) for the time period covered by the core. This may be a reasonable approximation for a period of a few thousand years but not for one extending into the last glaciation. At any depth in a steady-state ice cap, the value of v, expressed as the distance an ice particle moves downward in 1 yr, should be equal to the thickness of an annual ice layer, a quantity that can be determined from seasonal variations in concentration of microparticles in the core[9]. Thirteen such measurements (10-yr means) in the youngest 2,100 yr of core checked satisfactorily.

The time scale was further checked by absolute dating of the ice at four points by the ^{32}Si method[10] and at another four points by ^{14}C obtained by down-borehole extraction of CO_2 from air bubbles in the ice[11].

Figure 2 shows the time scale and absolute dates. The curve is within 1 s.e. of each of the ^{32}Si dates. The discrepancies that exist may be real rather than statistical because similar differences at about the same ages have been observed in two Greenland cores. This suggests that the production rate of ^{32}Si in the atmosphere may vary with time. The curve is also within 1 s.e. of two of the four ^{14}C dates and within 2 s.e. of another. The discrepancy of the youngest date is very large, however. We conclude that this ^{14}C date is wrong, probably because the sample was contaminated by fossil CO_2. A ^{13}C/^{12}C analysis supports this idea. The standard error of the calculated ages, based on the standard error of measurement of v, is about 6% for the first 1,500 yr and increases to about 20% at 5,000 yr. The precision of the ages is probably better than this because the curve agrees with most of the absolute dates. We therefore believe that the record for the past 5,000 yr is well dated.

Comparison of adjacent cores

Having two boreholes 27 m apart enabled the variation in δ over short distances to be measured. To check the repeatability of the mass spectrometer measurements, 400 samples from one core were measured twice. The correlation coefficient between measurements was 0.991; thus instrumental inaccuracies are negligible. Next, 450 samples, each of the calculated annual layer thickness, were cut from each core. The δ values were compared in equivalent segments corresponding to 50 calculated annual layers. The correlation varied between 0.45 and 0.72. These relatively low values show that much of the variation in annual values of δ is 'noise'. Part of it probably results from variations in snow accumulation over short distances so that samples cut to the mean annual layer thickness will contain varying amounts of summer and winter snow; the remainder probably results from variations in the amount of meltwater percolation.

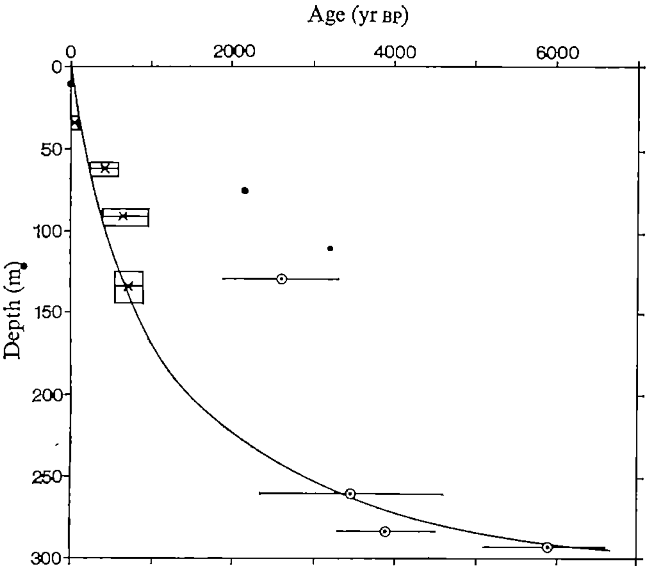


Fig. 2 Time scale for the core, based on measured vertical velocity, and absolute dates. The vertical lines beside the ^{32}Si dates indicate the depth interval over which each sample was taken. Each ^{14}C sample covers a depth of 1.5 m X, ^{32}Si date; ⊙, ^{14}C date. Bars are 1 s.e on each side of mean.

The isotope profiles from the two boreholes closely resemble each other except near the base of the ice. The correlation between 50-yr mean δ values is 0.965 between the surface and 13 m above the bed, but only 0.449 between 13 and 5 m. The correlation decreases because bumps and hollows in the bedrock disturb the regular flow pattern in the ice immediately above.

Figure 3 shows the lowest 5 m of each record. Although the profiles show many of the same features, gaps in each are apparent. No gap is more than 50 mm long and construction of a composite record, described later, suggests that 25–30% of each record is missing. This assumes that no part of the record is missing from both cores, which may not be true. The extremely steep δ gradients at certain points may be additional evidence for gaps. For example, the feature at 2.6 m in both cores corresponds to a change of 9‰ in about 30 mm of core and the feature at 2.3 m in core 72 to a change of 5‰ in 10 mm. Because molecular diffusion reduces δ gradients, these values must have been greater in the past. We consider it most unlikely that such gradients represent climatic effects; a recent tectonic origin seems more probable. We emphasise that such gaps do not represent missing core sections; a complete core was recovered from each borehole. Nor can the gaps result from ablation; there is no ablation at the drill site at present and most gaps occur in the Wisconsin part of the record when temperatures were much lower than present.

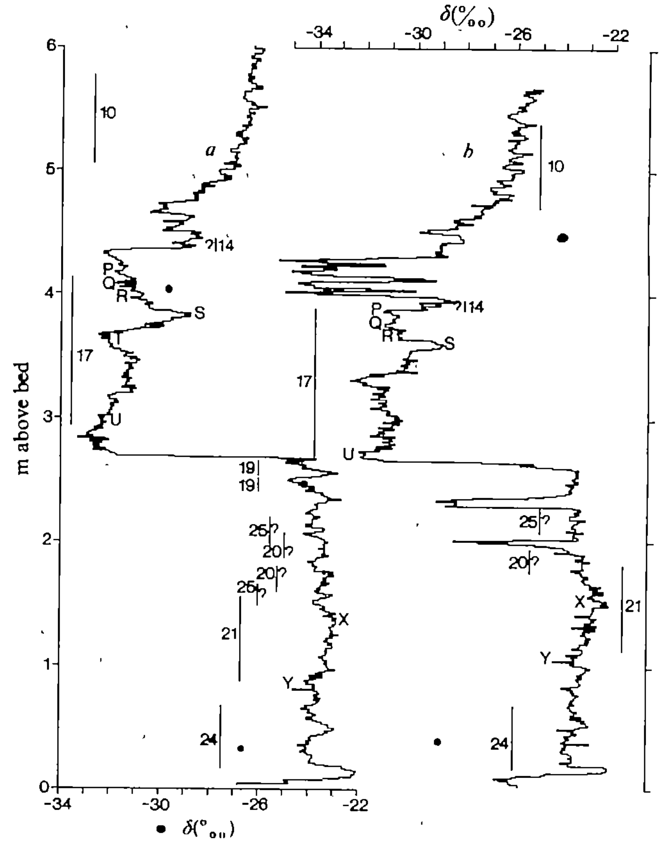

Fig. 3 Values of δ, for samples 10 mm long (*a*, core 73; *b*, core 72), against distance above bedrock for lowest few m of each core. Sections and features marked with the same number or letter are considered to be equivalent. The 'cold peak' at 2 m in Core 72 is doubtful; it may result from a sampling error. Gaps up to 50 mm long are apparent in both cores.

Variations in vertical strain rate, and thus in annual layer thickness, over short horizontal distances, can probably explain most of the disturbances in the lowest part of the record. The strain rate is expected to vary as the ice moves over an uneven bed; thinning and 'pinching out' of horizontal layers of bubbles observed in vertical sections of core, provide evidence of such variations. The apparent gaps in the record may be highly compressed regions where the isotope variations have been smoothed out by diffusion. Faulting or movement along narrow zones of intense shear provide another possible explanation of the gaps. Although these processes might occur near bedrock bumps and hollows, the cores show no definite crystallographic evidence for them. Large changes in grain size occur over short vertical distances but there are no thin bands of very fine-grained ice characteristic of shear planes. Folds might also be expected to form. These would produce inverted sections of record; segments 25 and 20 in core 73 (Fig. 3) may perhaps show this. Again, however, there is no crystallographic evidence of folding.

Climate and ice thickness changes 0–5,250 BP

The point, 13 m above the bed, dated at 5,250 BP where the correlation between the two records starts to break down corresponds closely to the limit of the accurate time scale. We therefore present the results in two parts: (a) the period 0–5,250 BP and (b) the section from 5,250 BP to the bottom of the core (dated at roughly 125,000 BP by comparison with the Camp Century record) where we do not assign dates and discuss only major features. Except for the lowest 5 m, plotted δ values are an average of the values for the two cores. The estimated standard error of an annual value in the combined record is 0.5‰.

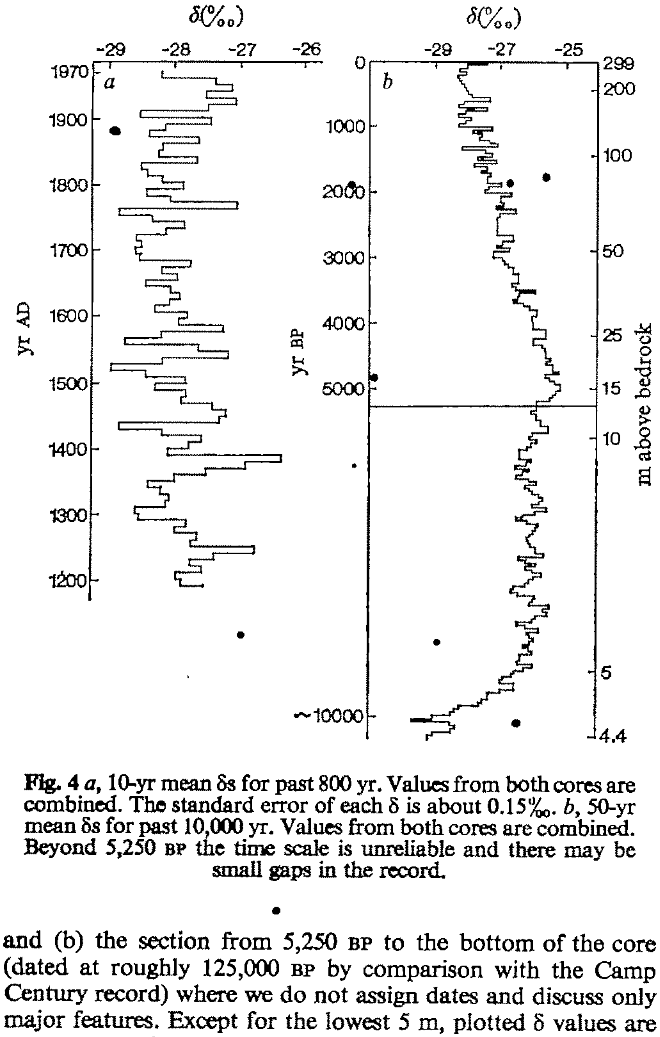

Fig. 4 *a*, 10-yr mean δs for past 800 yr. Values from both cores are combined. The standard error of each δ is about 0.15‰. *b*, 50-yr mean δs for past 10,000 yr. Values from both cores are combined. Beyond 5,250 BP the time scale is unreliable and there may be small gaps in the record.

Figure 4*a* shows 10-yr mean δ values from AD 1200 to present. Prominent features are brief warm periods with peaks at 1240 and 1380, cold peaks at 1430, 1520 and 1560, the 'Little Ice Age' continuously cold from 1680 to 1730 and with another temperature minimum at 1760, a pronounced warming at about 1910 with relatively warm temperatures until about 1960 and a marked cooling thereafter. The Camp Century record[2] also shows most of these features, although some dates are different; in particular, the coldest part of the Little Ice Age occurs at about 1660. Such differences are not surprising; the Little Ice Age does not even appear in the period 1500–1700 in the record from Crête in central Greenland[12].

Figure 4*b* shows 50-yr mean δ values for the past 10,000 yr. The warmest part of the Climatic Optimum occurred on Devon Island at about 5,000±800 BP. The date 5,000 BP is more likely to be too old than too young because a value greater than 5060 BP would be outside the limit of 2 s.e. of the ^{14}C date (3860±600 BP) at this point.

The record shows a long-term decrease in δ from 5,000 BP to present; this does not appear in the Camp Century record[2,4]. Figure 5 shows this feature. In *a*, curve 1 is the last 5,000 yr of the Camp Century record, smoothed by a 5,000-yr low-pass filter applied to the last 10,000 yr of the record. The time scale is that calculated from the Dansgaard–Johnsen flow model[6]. Curve 3 is a similar curve for Devon Island. Part of the difference between the two arises because the deeper layers in the Camp Century core were formed at higher elevations inland from the station. Curve 2 is the trend corrected for this effect, based on the present surface configuration and ice velocity at Camp Century and the assumption that a 100-m increase in elevation changes δ by −0.62‰ (ref. 13). The Devon record needs no correction because the boreholes are near the ice divide, provided that the divide has not migrated during the past 5,000 yr. Even after the flow correction is made, the change in δ at Camp Century is less than at Devon Island (0.6 compared with 2.2‰). On the other hand, the shorter-period trends in δ at the two stations seem to be of about the same size (Figs 5*b* and *c*).

Although it is possible that the long term cooling has been much greater at Devon Island than at Camp Century, changes in ice thickness provide a more likely explanation of the difference. Koerner[14] has shown that the percentage of ice layers in the Devon cores is highly correlated with the ice cap's mass balance. He concluded that accumulation balanced ablation from about AD 1300 to 1860 and that the mass balance has been slightly negative since then. Thus during the Climatic Optimum, when δ was more than 2‰ less negative than at present, the ice cap was probably smaller and thinner than it is now. The change in δ at Camp Century would correspond to a cooling of roughly 1°. The additional 1.6‰ at Devon Island would correspond to a thickness change of about 250 m. This seems excessive in view of the broad agreement between the time scale calculated from the present vertical velocity and the ^{14}C dates. Thus the cooling trend over the past 5,000 yr has probably been more than 1°. If so, it has been partly obscured in the Camp Century record by thinning of the ice there since the Climatic Optimum[15]. Other interpretations of the difference between the long term trends in δ are of course possible. Moreover, we have ignored the possibility that δ has been affected by changes in atmospheric circulation patterns.

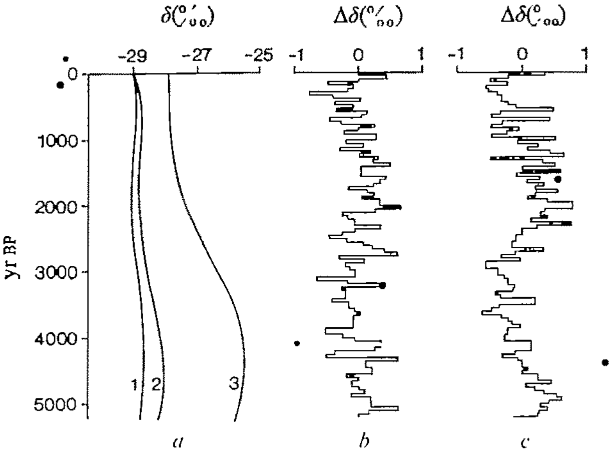

Fig. 5 *a*, Trend lines in δ for past 5,000 yr (1) for Camp Century, (2) for Camp Century corrected for ice flow from up slope, (3) for Devon Island. *b*, residual from trend for Camp Century. *c*, residual from trend for Devon Island. The Camp Century time scale is that of ref. 6.

The glaciation record

In Fig. 6*a*, the pre-Holocene record is a speculative reconstruction using the lowest few metres of both cores. The following rules were used in the construction: (1) Where segments of the two cores seem to be roughly equivalent the longer of the two is used. (2) Any repeated sections are used only once. (3) Where there is a large gap in one core, the record from the other core is used and placed in the position consistent with adjacent common equivalent segments. (4) It is assumed that no segment is missing from both cores. (As we estimate, however, that each core lacks 25–30 % of the record, it is likely that 6–9 % of the combined record is missing.) The record broadly resembles that of Camp Century (Fig. 6*b*): a cold period between about 10,000 and 65,000 BP (Camp Century dates) preceded by a warm period of roughly the same duration.

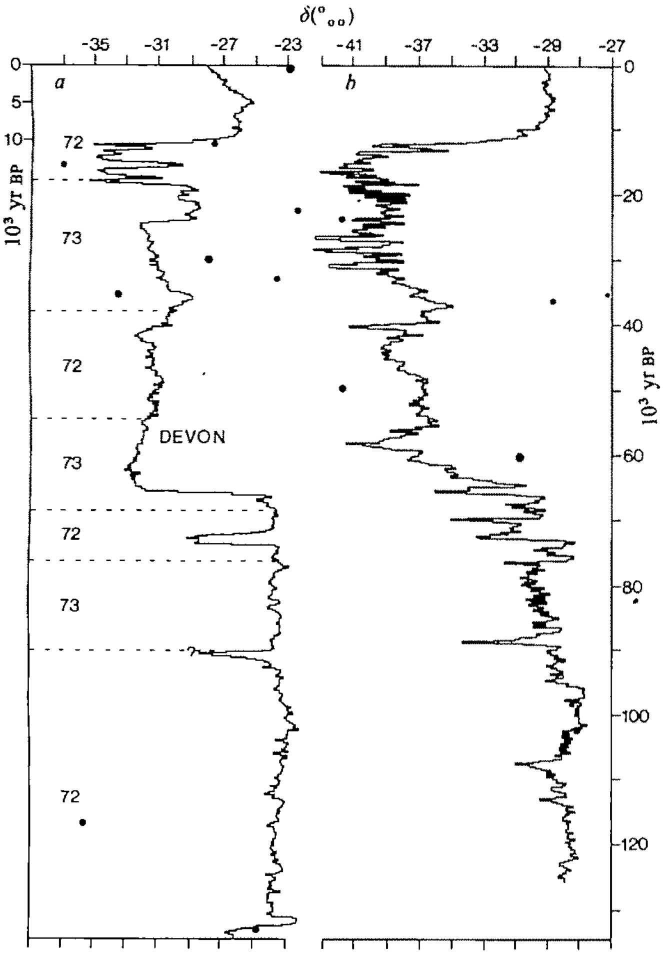

Fig. 6 *a*, Profile of δ for Devon Island. The Holocene section is that of Fig. 4*b*. The remaining section was obtained by combining the records from the lowest few metres of the two cores (See Fig. 3). While more nearly complete than either record, the combined one probably still has gaps. *b*, Profile of δ for Camp Century, Greenland[8].

A major difference between the stations is in the change in δ at the end of the Wisconsin Glaciation about 10,000 BP. The change at Camp Century is 11‰, at Devon Island 8 %, and 5 or 6‰ in Antarctica[4,5]. While the temperature change at the end of the Wisconsin may have been greater at Camp Century than elsewhere, a more likely explanation is that the Wisconsin ice in the Camp Century core originated at a much higher elevation than that of the present station. Measurements of total gas content of the ice, a quantity negatively correlated with the elevation at which the ice formed, seem to support this view and suggest that the Wisconsin ice originated at about 1,300 m higher than the Holocene ice[16]. Such a difference is more than enough to account for the exceptionally large change in δ. The most likely explanation is that the Wisconsin ice originated near the main divide of the Greenland ice sheet, whereas the Holocene ice originates within 50 km of the station[17]. The reason for such a drastic change in flow pattern is unclear; it may be related to the rise in sea level at the end of the Glaciation.

The difference of 8‰ between Wisconsin and Holocene ice at Devon Island should not be interpreted as purely a climatic effect because the ice probably thinned at the end of the Glaciation. A rough estimate of the difference in thickness, based on standard ice cap profiles and the assumption that the ice margin at the late-Wisconsin maximum was in the position shown in the map of Prest[18], is 150 m. Because this increased load would depress the bedrock, the increase in surface elevation would be 100 m which would change δ by about 0.6‰ (ref. 13). An additional change of 0.6‰ would result from the 100 m lowering of sea level during the Glaciation. Thus the climatic effect is perhaps about 7‰. During the relatively warm period in the Glaciation δ was more negative than at present. Thus this period was an interstadial rather than an interglacial.

Oldest part of record

Except for short intervals, values of δ in the lowest 3 m of the Devon record are 0.5–3‰ less negative than at the peak of the Climatic Optimum. This segment seems to correspond to the part of the Camp Century record estimated to extend from 65,000 to 120,000 BP (Fig. 6). Values of δ are less negative than in the Climatic Optimum in much of this part of the Camp Century record also. The obvious interpretation is that, during this period, temperatures were higher and the ice thinner than at present, except for relatively brief intervals in which temperatures fell to glacial values. An alternative explanation, however, of the relatively high values of δ might be that, during this period, the major source area of precipitation on the ice caps was different from the present one. Two independent lines of evidence suggest that world sea level was below present from 65,000 to 120,000 BP (refs 19,20); thus glaciation in many parts of the world must have been more extensive than it is now. Moreover, studies of pollen[21] and soil[22] in northern Europe indicate that glacial conditions began there about 110,000 BP, although there is evidence that North Atlantic water remained relatively warm until about 70,000 BP (ref. 23). For these reasons we think that the high δ values probably indicate a different source of precipitation rather than a less extensive ice cover.

Inverse Compton γ rays from Cyg X-3?

THE detection of ~100-MeV γ rays from Cyg X-3 has been reported from recently published SAS-2 data (R. C. Lamb *et al.*[17]). The γ-ray luminosity is $\sim 10^{37}$ erg s^{-1} assuming the source is ~10 kpc distant. Cyg X-3 is well known as an X-ray and infrared source, and a source of non-thermal radio outbursts[1] ($L_x \sim 10^{38}$, $L_{IR} \sim 10^{37}$, $L_{radio} \sim 10^{33}$–10^{35} erg s^{-1}). The infrared, X-ray and γ-ray fluxes all display a 4.8-h modulation in phase with one another[1], which we shall presume to be attributable to binary motion[2,3]. We note here that inverse Compton scattering of ~100 MeV relativistic electrons, in a region between the X-ray source and its companion, by the plentiful X rays, provides a mechanism for the γ-ray emission and its observed modulation.

Modulated γ rays are most efficiently produced by injecting the relativistic electrons in such a region for the following reasons. The γ rays cannot be created too close to the X-ray source ($R_x \sim 10^{10}$ cm), or they would be destroyed by pair creation in γ-ray–X-ray collisions. Creation outside the binary orbit would not allow sufficient modulation and would, if the emission is by inverse Compton scattering, be inefficient, as adiabatic losses would dominate the cooling of the relativistic electrons. It seems likely that the source of X-ray modulation is primarily electron scattering; the scattering optical depth must be of order unity to account for the observed amplitude of X-ray modulation (ref. 2 and references therein). But if the γ rays came from a region near the X-ray source (but $R_x \gtrsim 10^{10}$ cm), they could not be modulated by electron scattering because the Klein–Nishina cross section is greatly suppressed at γ-ray energies.

We thus have a picture of a close binary system with a cloud of relativistic electrons close to and on the X-ray source side of the primary. Modulation of the γ rays, generated by inverse Compton scattering, in phase with the X rays, arises naturally as γ rays will be most strongly emitted in backscattering X rays (compare ref. 4). The γ-ray power emitted towards the observer is approximately $\propto (1 - \sin i \cos \varphi)^2$, where i is the orbital inclination and φ is the observed phase ($\varphi = 0$ is X-ray minimum). Additional γ-ray modulation could come from partial eclipse of the emitting region as it is closer to the primary than the X-ray source, which is not eclipsed. The depth of γ-ray modulation depends upon the position and extent of the electron cloud.

What is the required source ($\gtrsim 10^{37}$ erg s^{-1}) of relativistic electrons? For a lower limit on the timescale for changes in the 4.8-h period of $\sim 10^5$ yr (ref. 5), it seems improbable that this energy could come from the orbit or the spin of the primary. The X rays themselves could drive winds at $v \sim v_{escape} \sim 10^3$ km s^{-1} from the primary which could be shocked, but the efficiency of thus producing relativistic particles is then necessarily high ($\gtrsim 10\%$). The only remaining energy source seems to be the spin of a neutron star/X-ray source. An attractive possibility is that the source of X rays and relativistic particles is a young pulsar as suggested by Lamb *et al.*[17]. The X rays might then exhibit a $\lesssim$30-ms pulsar period. This would obviate the need for any mass transfer.

The model may be developed a little further to account for the infrared observations. If the relativistic electrons are injected in a region magnetised to say $B \sim 500$ G, then a distribution $dn_e/dE \propto E^{-4}$ for $E \geq 100$ MeV can produce the observed infrared flux. The infrared photons would be free–free absorbed for $\lambda \gtrsim 2$ μm accounting for the rising spectrum[6]. The observed modulation[1] can be attributed to electron scattering similar to the X rays, but with smaller amplitude as the infrared source is closer to the primary. Unfortunately, Faraday rotation in the wind would probably completely depolarise this source of infrared. We may predict, however, that if the source of γ-ray and infrared emission in this model is correct, then γ-ray and infrared variability (non-binary) should be correlated. Alternatively, if the infrared comes from a circum-binary shell as proposed by Milgrom[7], such correlation may not be expected.

We also note that inverse Compton scattering by the stellar photons (which mostly come from incident X rays re-radiated in the ultraviolet band) and by the infrared photons in this model could account for the hard X-ray tail[8], which would again be modulated by electron scattering. If this is correct, then the infrared and hard X-ray fluxes should show similar 4.8-h modulation and similar variability on other timescales.

Cyg X-3 is a spectacular emitter of polarised radio waves[9–12]. If, as seems likely, the emission is synchrotron radiation, this provides independent evidence for the acceleration of relativistic electrons in this system. Radio emission is then detectable, however, at gigahertz frequencies only when the radio-emitting electron cloud has dimensions $\sim 10^{14}$ cm (ref. 11). Such a cloud cannot be closely related to the source of γ rays and infrared we have proposed. The radio cloud could hardly produce 4.8-h modulated γ rays, and the γ-ray emitting cloud could not expand to 10^{14} cm without suffering catastrophic energy losses. It is interesting, however, that the densities and field strengths ($n_e \sim 10^7$ cm^{-3}, $B \sim 0.1$ G) proposed in a shock-wave model[11] for the radio cloud are compatible with those inferred above within the orbit if the field is toroidal ($B \propto r^{-1}$) and $n \propto r^{-2}$.

Finally we note that Circinus X-1, which has an X-ray period of 16.6 d (ref. 13), is also an infrared[14,15] and non-thermal radio source[16]. Its light curve may be interpreted as an extreme example of the asymmetry present in Cyg X-3. A γ-ray study of this source would clearly be of interest.

Further γ-ray observation of Cyg X-3, and observations of Circinus X-1, to better define the 4.8-h light curve, is needed. Correlated γ-ray, hard X-ray, infrared, and radio observations will be extremely useful in defining the site(s) and source(s) of relativistic electron injection in this system.

Amplification of cosmic Cerenkov radiation

EJECTION of relativistic or ultra-relativistic electrons is used in most quasar models to explain the very high luminosities of these objects. The velocity distribution of matter is taken as[4]

$$F(r) = F_0\,\gamma_0^{-3/2} \tag{1}$$

where

$$F(r) = \frac{1}{M}\int_r^{\infty} 4\pi\rho r^2 \mathrm{d}r$$

is the mass fraction external to the radius r; $F_0 \approx 10^6$; ρ is the density and the Lorentz factor is $\gamma_0 = (1-u^2/c^2)^{-1/2}$; u and c are velocities of the particle and the light, respectively. The observed luminosities are then explained on the basis of inverse Compton scattering of synchrotron radiation to the optical frequencies. In the radio frequency range the observed emission spectrum shows polarisation and also follows the power law, suggesting a synchrotron emission mechanism supporting these models, which essentially lead to the existence of finite magnetic fields in the quasars[1,2]. In these conditions, some Cerenkov radiation is also produced[4,5]. We suggest here that this radiation is amplified, and may account for the observed luminosity of quasars.

The energy density of magnetic field $B^2/8\pi$ is taken to be greater than the energy of the relativistic particles[3–5] and the non-relativistic electron density, n_0, is $< 10^8$ cm^{-3}. The emission of synchotron radiation at 10^8-Hz frequency, requires a magnetic field of the order of 10^2 G. These parameters also satisfy conditions for Cerenkov emissions and may explain observed optical luminosities due to inverse Compton scattering[4,5]. Explanations based purely on the Cerenkov emissions, however, need linear dimensions of the order 10^{14}–10^{16} cm, which are more or less equal to quasar dimensions. Therefore, the assumptions regarding conditions for 'Cerenkov emission' in these regions are rather doubtful. Moreover, the relativistic particle distribution of the type given by equation (1) can also amplify the Cerenkov radiation, which seems to be important.

We suggest here, therefore, that the wave emitted by the relativistic particle in the Cerenkov mode might undergo amplification by Landau mechanism. It is important to point out that the Cerenkov emission and its amplification are two entirely different processes; the former is due to individual particles, whereas the latter is a collective phenomenon. Therefore, in the magnetoplasma the plasma of sharply defined energy will not amplify its own Cerenkov radiation. In the presence of a distribution of energetic particles, such processes may explain the very low frequency emission in the magnetosphere[6–8]. In the case of quasars the energetic particle distribution follows equation (1) and seems more suitable for amplification of the Cerenkov radiation, as discussed below.

A relativistic electron moving with velocity **v**, in a medium with refractive index $\mu > 1$, emits energy ε_ω[4]

$$\varepsilon_\omega = \frac{2e^2}{c^2}\omega\left(1-\frac{c^2}{\mu^2 v^2}\right)\text{erg s}^{-1}\,\text{Hz}^{-1} \tag{2}$$

in the frequency band near ω, where e is the electron charge. These waves, for propagation at angle θ to the magnetic field **B**, satisfy the dispersion relation[6]

$$\mu^2 = \frac{c^2k^2}{\omega^2} = \frac{\omega_p{}^2(\Omega_e+\omega)}{\omega\Omega_e{}^2\cos\theta} \tag{3}$$

for frequencies $\omega_p, \Omega_e > \omega \gg \Omega_i$. Following Bell and Buneman, the maximum growth rate for the instability is[6]

$$\gamma_{\max} = 0.87\left\{\omega\left(\frac{\omega_s^2(\Omega_e+\omega)\,\omega\sin\theta}{4\omega_p{}^2\Omega_e(\Omega_e\,\omega\cos\theta+\omega(\Omega)_e+2\omega)\cos\theta}\right)^{1/3}\right\}_{\omega=\mathbf{k}.\mathbf{v}}, \tag{4}$$

where $\omega = \mathbf{k}.\mathbf{v}$ is the condition for resonance; ω_s, ω_p, Ω_e, Ω_i represent, respectively, the plasma frequencies of the relativistic and non-relativistic electrons, and gyrofrequencies of the electrons and ions; **k** is the propagation vector of the wave. Equation (4) shows that there is growth of Cerenkov radiation for wave propagation at a finite angle to the magnetic field. There is no growth for the angle $\theta = 0$ and 180° because for these angles there is no electric field in the direction of the wave propagation. In the case of the magnetosphere, there is not sufficient amplification of Cerenkov radiation for nearly parallel propagation because the region of amplification is very small. For quasars, however, the region of amplification can be as large as 10^{13} cm and, therefore, waves propagating nearly parallel can be efficiently amplified. The maximum growth rate for the Cerenkov radiation at frequency $\omega \approx \Omega_e$ is

$$\gamma_{\max} = 0.87\Omega_e\left(\frac{\omega_s{}^2}{16\omega_p{}^2}\frac{\sin^2\theta}{\cos\theta}\right)^{1/2} \tag{5}$$

If we represent the amplification factor by

$$\eta = \frac{1}{2\gamma_{\max}}\exp(2\gamma_{\max}R/V_g)$$

where V_g is the group velocity, which can be shown to be

$$\frac{2\sqrt{2}}{3}\frac{\Omega_e}{\omega_p}c(\cos\theta)^{1/2}$$

(from equation 3) and R is the region of amplification. For a typical optical luminosity of a quasar of 10^{46} erg s^{-1} (3C 273)[4], we obtain the relation $R^3 = 10^{37}\eta$. For an angle of propagation to the magnetic field < 5° and a typical value of $\gamma_{\max} = 4$, the amplification can be as high as 10^3 in the region $R = 10^{10}$ cm, which is much smaller than 10^{14}–10^{16} cm (refs 4, 5). It is therefore possible that the optical luminosity of quasars may be due to the amplification of Cerenkov radiation.

The amplification mechanism discussed here is based on the particles having free streaming along magnetic field lines. Such particles can be scattered, however, due to hydromagnetic waves as has been discussed in the case of the galactic cosmic rays[10]. As this scattering affects the amplification of the Cerenkov radiation, we must include an appropriate modification in our mechanism. Detailed calculations of the characteristics of Cerenkov emission and an estimate of its role in quasar luminosities are needed. It is especially important to use the Cerenkov amplification effect correctly to account for the high luminosities of quasars.

I thank A. C. Das, S. M. Bhandari and V. Satyan for helpful suggestions and discussions.

Measuring solar wind velocity with spacecraft phase scintillations

THE discovery of interplanetary scintillations (IPS) of natural radio sources[1] has been followed by extensive multiple-station or spaced-receiver IPS measurements of the solar wind velocity in regions not yet probed by direct spacecraft[2-8]. Few measurements have, however, been obtained within 40 $R_\odot$ because amplitude or intensity scintillations saturate when they are strong as is the case near the Sun. This is unfortunate because the scarcity of wind velocity measurements in the acceleration region close to the Sun is one of the reasons why the construction of a unique picture of solar wind dynamics has not yet been possible, despite numerous theoretical studies and direct spacecraft observations farther out[9,10]. The demonstration of the measurement of spacecraft phase scintillations with a coherent dual-frequency radio system[11] paves the way for making solar wind velocity measurements with multiple-station phase scintillations. Although similar in principle to the IPS technique, several factors make this new tool a more powerful and promising one.

Because phase scintillations do not saturate when they are strong, observations can be carried out closer to the Sun than with amplitude scintillations. Spectral broadening has this same property[12] and we have obtained measurements at 2.3 GHz as close as 1.7 $R_\odot$ with the Helios spacecraft. Extensive phase scintillation observations in the accleration region of the solar wind are, therefore, possible using a dual-frequency S- and X-band coherent radio link[11].

For multiple-station observations the baselines are restricted to distances shorter than the correlation distance of the observed scintillations. For amplitude scintillations, the correlation distance is of the order of the size of the first Fresnel zone[13], which is roughly 140 km at 2.3 GHz. On the other hand, since the correlation distance for phase scintillations is at least 10^6 km (refs 11, 13), a much wider range of baselines is possible. Particularly suited for these measurements are the three 64-m S- and X-band tracking antennae of NASA's Deep Space Net located at Goldstone (California), Canberra and Madrid. These antennae can be used for two-station observations with baselines of the order of 10^4 km.

Because the slowly varying phase scintillations are considerably stronger than the faster varying amplitude scintillations[13], the signal–noise ratio (SNR) needed for long baseline phase measurements is much lower than that needed for short baseline amplitude measurements. The frequency spectrum of the phase scintillations[11,13] indiates that if the baseline distance is increased by a factor of 10 the SNR can be reduced by at least 20 dB. The choice of observing antennae for phase scintillations is, therefore, flexible, since a wide range of antenna sizes and receiver noise temperatures can be considered, in addition to the wide range of baseline distances. This is especially important since it would be desirable to add observing antennae to the group of NASA 64-m antennae to permit three-station measurements. Also, for a given SNR, slowly varying phase scintillations yield measurements at larger solar elongations than faster amplitude scintillations.

We have discussed some of the important advantages of measuring solar wind velocity with multiple-station phase scintillations. Current and future NASA deep space missions equipped with the coherent S/X radio system include Viking, Pioneer Venus and Mariner Jupiter/Saturn. Extensive observations using this new technique during the numerous superior conjunctions of these spacecraft will provide much needed velocity measurements in the acceleration region of the solar wind. These proposed observations will complement the large number of measurements that have been and are still being made with natural radio sources and will lead to a better understanding of the dynamics and driving mechanisms of the solar wind.

Tidal acceleration of the moon deduced from observations of artificial satellites

DOUGLAS *et al.*[1] demonstrated the existence of an apparent latitude dependence of tidal friction by determining disparate values of the second degree Love number (k_2) from perturbations of the inclinations of the GEOS-1 and GEOS-2 satellites. Lambeck *et al.*[2] correctly explained this phenomenon as being due to neglect of ocean tide perturbations. Parameter values for some ocean tide components have been obtained from several satellites[3], but parameter values for the M_2 tide, the dominant (85%) effect of the oceans on the tidal acceleration of the Moon, have not been published. Using an improved method for computing mean elements, we[4] obtained an observation equation for the M_2 tide from the satellite 1967-92A. Applying this technique to the satellite GEOS-3, we now obtain an additional observation equation for the M_2 tide. As shown in ref. 2, solid and fluid tide effects on satellites cannot be separated, requiring assumption of the solid tide amplitude and phase parameters for a fluid tide solution. Assuming $k_2 = 0.30, \delta_2 = 0°$, and using the values of Lambeck[5] for the minor O_1 and N_2 contributions to n_t, our fluid tide parameters for the M_2 ocean tide yield the value of the tidal acceleration $n_t = -27.4 \pm 3$ arc s (100 yr)$^{-2}$, in excellent agreement with the value $n_t = -27.2 \pm 1.7$ arc s (100 yr)$^{-2}$ obtained by Muller[6] from a combination of ancient and modern observations. These two values are lower than the value $n_t = -35 \pm 4$ arc s (100 yr)$^{-2}$ obtained from numerical ocean tide models[5]. Our assumption of a negligible solid tide phase angle is supported by a recent determination by J. T. Kuo (personal communication) that the phase angle obtained from a transcontinental network of tidal gravimetric stations is < 1°. Changes $\leqslant 0.5°$ in solid tide phase angle change our result for the combined solid/fluid $\dot{n}_t$ by no more than 1 arc s per (100 yr) (ref. 2).

Cosmic spherules as rounded bodies in space

COSMIC spherules obtained from deep-sea sediments have generally been accepted as extraterrestrial; but their mode of formation has been uncertain. On chemico-mineralogical evidence and the study of polished sections, it is difficult to refute the assumption that the spherules are merely the droplets shed from the fusion crust of a meteorite as it ablates in the atmosphere. We are now re-examining a new spherule collection (diameter > 50 μm) from surface red clay samples used previously[1]; that is, Atlantic A2 (24°30′ N, 64°47′ W, 5949-m depth) and Pacific (22°07′ S, 115°10′ W, 3,060–3,200-m depth). Scanning electron microscopy of 40 'stony' spherules and 25 'irons' has led us to consider a new hypothesis—that the cosmic spherule is a round body in space and those that we find suffer only slight alteration during their grazing flight through the atmosphere. Interesting surface features exist on many of the spherules, both stones and irons, which make it difficult to believe that they have been sprayed from a meteorite. If our hypothesis can be substantiated, then cosmic spherules become important objects in their own right, a cometary origin beingas distinct possibility. We now show some of these surface featur e and mention other supporting evidence. From the surface appearance we can classify the spherules into different types and forms, and all forms occur with similar relative frequency in Atlantic and Pacific oceans.

The 'stony' spherule type appears either as a vuggy form or an organised (near single crystal) form in about equal numbers. A vuggy form (Fig. 1), gives smooth lines of olivine and magnetite on X-ray powder photographs. The holes are suggestive of outgassing of some volatile substance during a warm stage. This example shows no sign of a fusion crust; under the optical microscope the surface is dark grey. We conclude (note the well-faceted crystals) that this spherule did not reach its melting point in atmospheric flight and was not attacked by seawater. From this and other examples, it seems that seawater has not affected our stones, collected from surface sediments. Stony spherules do erode, however; they are not found in the deeper sections of red clay cores.

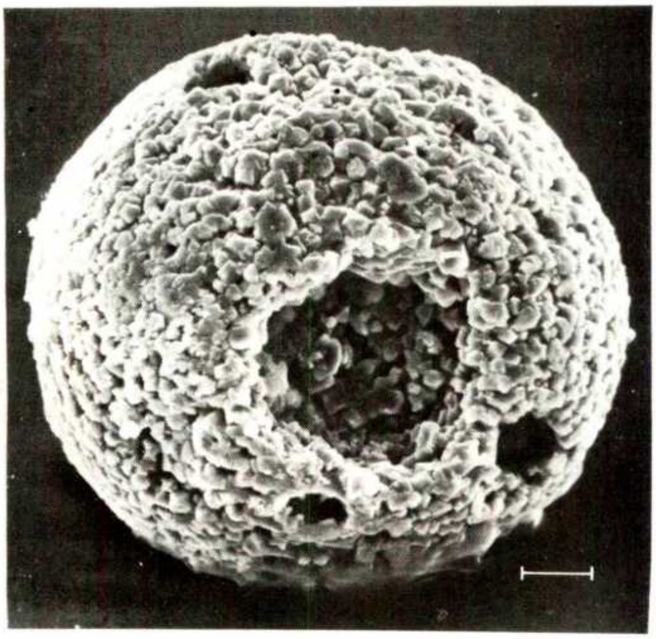

Fig. 1 A vuggy spherule. X-ray diffraction (all lines fairly smooth) gave magnetite lattice $a = 8.330$ Å, Fe/(Mg+Fe) = 22% for the atomic ratio of the olivine. On other vuggy spherules the crystal faces show interesting growth or etch features. Scale bar, 10 μm.

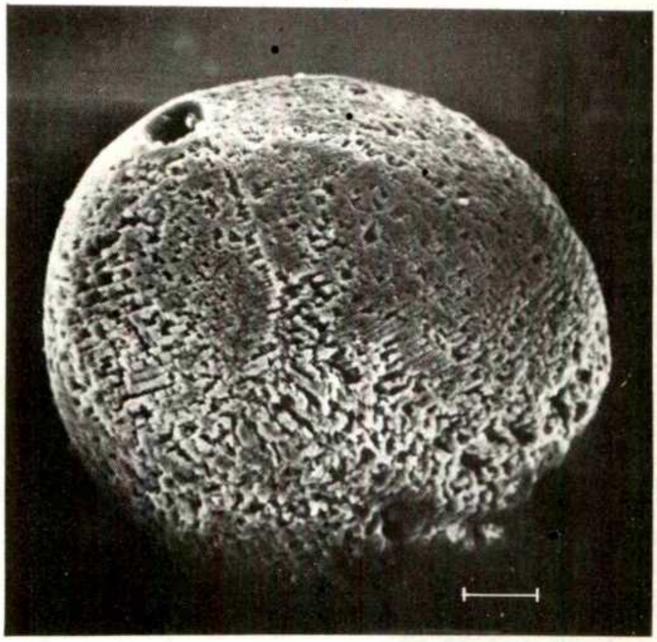

Fig. 2 An egg-shaped organised stone, uncommon because of the 'glassy' lined cupule found on the sharper pole. The spherule was polished to a diametral plane, including the cupule. The olivine crystals lie normal to the polar axis and no voids can be seen. Spot analyses of sub-micron areas gave: a somewhat variable Mg/Fe ratio; an erratic Ni distribution, which when present was ~0.1 Fe; and traces of Ca, Ti, Cr, Mn. X-ray diffraction (all lines very spotty) gave magnetite lattice $a = 8.356$ Å, and Fe/(Mg+Fe) = 20% for the olivine. From the spot analyses no large magnetite crystals were found in the interior. Part of the Ni seems to be in the olivine as well as in the magnetite. Ni in the stony phase of meteorites is < 300 p.p.m. (ref. 7). Scale bar, 20 μm.

Other vuggy spherules, sometimes found to be broken, show dark smoothish fusion crusts in patches. The interior is whitish and usually there is a large spherical hollow. In the unbroken state these vugs were thick-walled bubbles, with irregular-shaped holes scattered throughout the wall. X-ray microprobe analysis suggests that the magnetite is concentrated in the fusion crust. Fragile 'creamy-centred' spherules have already been described[1].

Fusion crusts on stony meteorites[2–4] are about 100 μm thick, vesicular and very opaque. In fact there is little or no glass present (private communication). Apparently magnetite is exsolved from the melt and the melt recrystallises into an olivine with a composition poorer in Fe than the parent material. For example, a pure olivine sample ablated in a plasma jet showed a 50% decrease of Fe[4]. In some respects both vugs and organised stones are similar to fusion crustal material. We find only olivine and magnetite (also sometimes wüstite). There is a lack of glass and the vugs are vesicular. However, the distribution of Fe/(Fe+Mg) for the olivine in our spherules agrees with that occurring in the interior of the chondrites[2]. If the spherules were ablation products, then the Fe content of the parent body would be greater than that commonly observed, a carbonaceous chondritic composition being more likely. But it is difficult, however, to see how vugs with whitish interiors could come from dark opaque material typical of a meteorite's crust. They seem more like micrometeorites, superficially fused or merely discoloured by moderate heating.

An organised form (Fig. 2) shows spotty olivine and magnetite X-ray lines. The texture is typical, but the presence of the 'glassy' lined cupule is very rare. In fact vesicles seem generally absent in the organised forms. The particle shown is slightly egg-shaped with the cupule near the sharp pole. We have found one stony spherule with a globule protruding about ⅓ of the way out of the surface. We mention this rare particle because it may provide the clue for explaining the cupule (Fig. 2). Perhaps during the molten stage, a magnetite globule was formed within the silicate melt and, assuming the melt was spinning, centrifugal forces would cause the globule to emerge at the sharper pole. Freezing may then flick the globule free. It could be argued that such a spinning process should occur at the moment of spraying from a meteorite's surface; and so egg-shapes, dumb-bells and even tear-drops would be a common occurrence. These forms are not found—all the spherules are near spheres.

Like the vugs, organised stones can be smooth in places. A thin fusion crust barely disguises the laminar or rod-like interior. The lack of a crust on the particle in Fig. 2 implies that it suffered little or no damage in its flight through the atmosphere. Again, seawater is unlikely to have removed a fusion crust, as the cupule is perfectly preserved. An SEM photograph in ref. 3 shows a 20-μm diameter spherule embedded in the fusion crust of Murchison. This is thought to have been sprayed off the surface of an 'upwind' piece of the shower and by chance to have been captured by the piece under investigation. This genuine ablation spherule shows a 'glassy' smooth surface. We have never found a stony cosmic spherule with such a smooth appearance, that is, having been thoroughly molten. The 'fusion' crusts on stony spherules seem very superficial. In some spherules parts of the crust have cracked away under thermal shock; in others the smoothing is only on one hemisphere and for these there is sometimes a 'brushed' appearance, strongly suggesting aligned flight through the atmosphere. Finally, the magnetite in the stones has a low lattice parameter, ranging around 8.352 Å; in the irons it ranges about a mean of 8.391 Å. Furthermore, we have never observed pyroxene in the spherules.

The 'iron' spherule type appears in two forms; those with a Ni-rich metal globule (or its oxidised remains) visible at the surface of a Ni-free magnetite–wüstite shell, and those without the metal—the oxide being only magnetite or magnetite–wüstite. A remarkable example of a metal form is shown in Fig. 3. It is the appearance of this particle that prompts us to view all our spherules as micrometeorites. It seems to us that in space the particle was already spherical, and flight through the atmosphere must have been steady, with the heavy globule forward. The frontal hemisphere is polished, as if a film of low melting point wüstite spread from the slightly dished taenite globule. Other particles show a spectrum of damage, ranging from metallic globules that are perfect, then dished (as in Fig. 3) to markedly cupped.

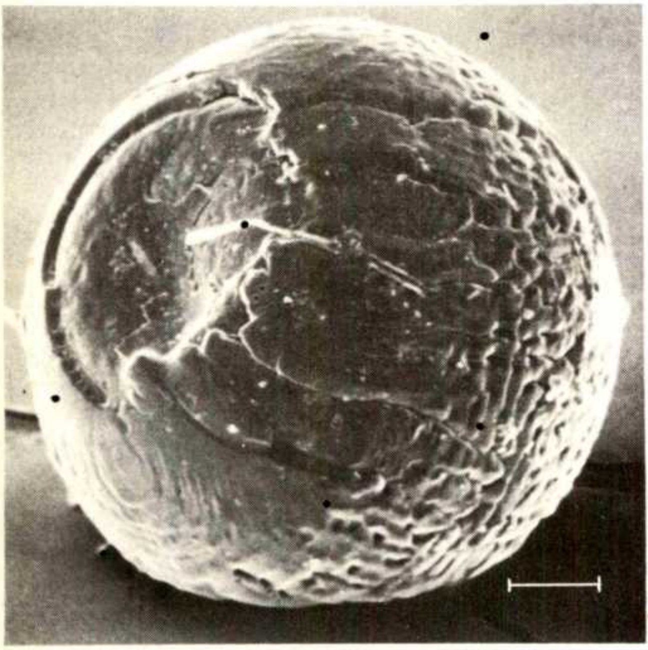

Fig. 3 A partly smooth ring structured iron—'Lucky Strike'. A polished section through the ring showed that the globule came right to the surface and had a diameter ~⅔ that of the whole. Note the shallow depression in the centre and the fractured edges of the ring. X-ray diffraction (all lines spotty) magnetite lattice a = 8.385 Å, wüstite lattice a = 4.286 Å, alloy lattice a = 3.573 Å suggesting 61% Ni. Scale bar, 10 μm.

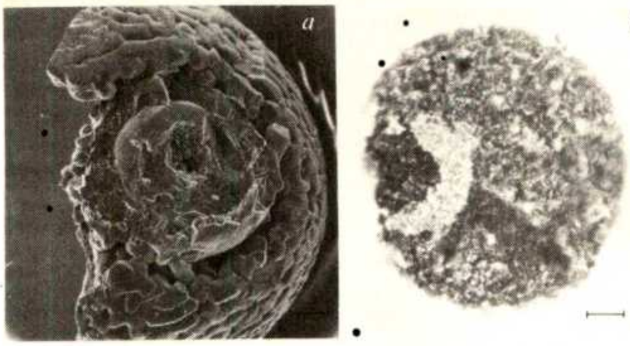

Fig. 4 A 'ballooned-iron' found as a hemisphere. *a*, the cracked-off outer part of the ballooned oxide and the small central void. Scale bar, 10 μm. *b*, An optical photograph of a polished section through the ring structure. Scale bar, 10 μm. A probe analysis for Ni gave ~1% in the magnetite shell, ~80% in metallic crescent and ~30% in the ballooned oxide. There is 4% Co in the metal, a trace in the shell but slightly more in the oxide scale. Spot analyses of sub-micrometre areas over the scale give Ni/Fe count ratios from 0.27 to 0.66, but many were constant at 0.55. This probably means that the oxide is nickel rich and contains in places some finely divided metallic nickel. X-ray diffraction gave magnetite (spotty lines) a = 8.390 Å, wüstite (spotty lines) a = 4.280 Å, alloy (smooth lines) a = 3.546 Å suggesting 82% Ni.

Other metal forms are more complex, and we call these 'ballooned-oxides'. Here a scale grows out from the globule as it oxidises. This expansion process can crack the spherule open, and a hemispherical portion is shown in Fig. 4*a*. In Fig. 4*b*, we show a polished section. All that remains of the globule is a crescent. The ballooned oxide scale within the arms of the crescent is rich in Ni, and there is little Ni in the oxide shell. This particle is similar to one found by Finkelman (Fig. 1 in ref. 5). Foley[6] reviewed the growth of non-molten scales on Ni/Fe alloys over a wide compositional range. For Ni ≳ 20% entrapment of Ni always occurs and a nickel spinel (trevoritic magnetite) forms. We now have to account for the lack of Ni in the oxide shell and the particle's general appearance. Clearly, at one time, the particle has been thoroughly molten and in this state Ni would diffuse to the metal phase. The particle then freezes. On entering the atmosphere at grazing incidence, the temperature does not reach the melting point (note the well-faceted crystals in Fig. 4*a*) but a non-molten oxide scale balloons out, thus cracking the spherule. Magnetite scales grow on metal under water, but this cannot be the case here. We have examples of ballooned forms clearly associated with melting conditions.

In the metal forms, the X-ray lines of the magnetite and wüstite phase are spotty, but the metal lines are sometimes smooth. In every case, the low lattice parameter (around 4.284 Å) for wüstite suggests that it has grown from magnetite rather than from the metal. Furthermore, the coincident positioning of the spots on the X-ray film show that wüstite and magnetite crystals are in near-parallel orientation.

The other iron form, lacking a noticeable metal phase, can give smooth X-ray lines. The surface can appear as a 'brick-work' of near-perfectly preserved crystals. In others, however, a thin film coats the crystals in places and the crystals can be large; the X-ray lines are spotty. Both the metal and non-metal forms can have very shiny surfaces, but it seems that this does not mean that the particle has been thoroughly molten. On soaking a shiny spherule in dilute nitric acid for a prolonged period, the metal globule apparently dissolved, and the shell broke into fragments on manipulation. Large and small crystals were seen in the shell material, but the shiny surface, which could not be resolved into crystals, is a distinct layer about 1 μm thick: a film which had spread roof-like across irregularities in the original surface. From the irons, we gain the impression that partial recrystallisation into larger crystals takes place during atmospheric heating, and if melting occurs it is only superficial.

We conclude that cosmic spherules seem to be most easily explained by assuming that they are already round in space. The spherules could come from the zodiacal cloud and those that we find have escaped vaporisation by entering the atmosphere at grazing incidence. Molten conditions must have existed at the time of their formation. Comets undergo violent eruptions and electric discharges may occur in their atmospheres. It is also possible that the refractory material within the comet is in droplet form as collisional heating could have occurred at the accumulation stage.

We thank Drs F. J. Hazlewood, V. D. Scott, B. McEnaney and Mr G. C. Cox for discussions, and Messrs H. R. Perrott and G. Love for operation of the SEM and electron probe. We also thank Mr K. Topp for preliminary probe analyses using energy dispersive methods, and Mr B. Chapman for X-ray diffraction work. We thank Professor F. C. Frank and Dr W. Morton for helpful general information.

Corrosion–fatigue crack initiation in metals

A DEFINITE relationship has been observed between the cyclic plastic strain-enhanced dissolution behaviour of metals in aqueous electrolytes and their corrosion–fatigue behaviour in similar conditions of environment and potential. The existence of such a relationship was first suggested in 1970[1], and the present work forms part of a wide study to examine the various effects of dynamic fatigue strains on electrode reactions at corroding metal surfaces.

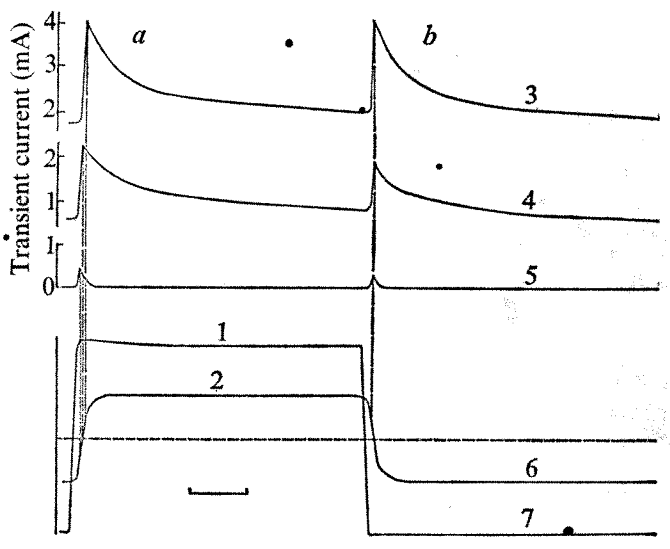

Fig. 1 Typical transients at the natural potential for mild steel in 3.5% NaCl solutions of varying *p*H. *a*, Tensile: 1, load −400 N mm^{-2}; 2, strain +0.03. *b*, Compressive: 3, *p*H 1; 4, *p*H 8.2; 5, *p*H 12; 6, strain −0.03; 7, load − 400 N mm^{-2}. Scale bar, 1 s.

The technique used involves strain cycling metal specimens under potentiostatic control in aqueous electrolytes and measuring the instantaneous electrode reaction kinetics using high-speed recording equipment. The apparatus and experimental procedure have been described in detail previously[2].

In the present tests a 'square' strain wave was used, giving strains of ±0.03 about zero at a strain rate of 0.03 s^{-1} and at a frequency of 0.1 Hz. Various metals were tested in different electrolytes over a wide potential range. Tests were carried out in conditions where corrosion–fatigue failure of the metal was known to occur and in conditions where this type of failure was not observed, so that the dissolution behaviour of the metal in 'failing' and 'non-failing' situations could be compared.

Mild steel suffers from corrosion–fatigue in aqueous sodium chloride solutions of *p*H 1–11 but is immune to corrosion–fatigue at *p*H 12. Figure 1 shows *U*–*V* recordings of the dissolution

Table 1 Corrosion–fatigue test and cyclic strain dissolution data for various systems

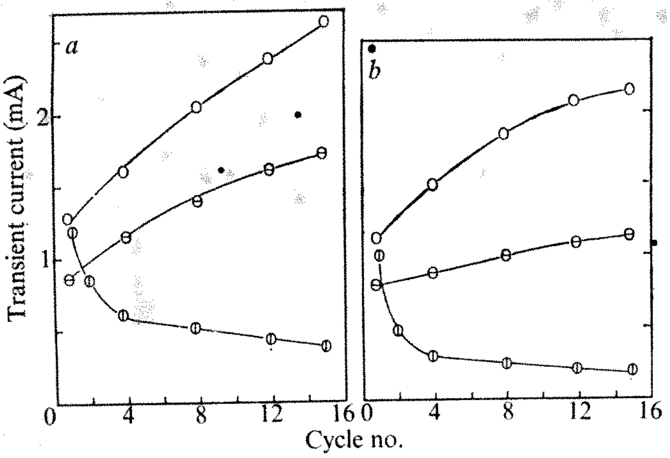

Fig. 2 The variation in the transient peak value with strain cycle number. *a*, Tensile: ○, *p*H 1; ⊖, *p*H 8.2; ⦶, *p*H 12.

transients produced by strain cycling mild steel in 3.5% NaCl solution of *p*H 1.0, 8.2 and 12.0 at the appropriate natural potentials. The transients relate to the fifteenth strain cycle. Figure 2 shows how the transient current magnitude, ΔI (defined as $I_{\mathrm{maximum}} - I_{\mathrm{initial}}$), varied with cycle number, N. ΔI, for the first strain cycle, was similar in all cases, but at *p*H 1.0 and 8.2 it increased with subsequent strain reversals whereas at *p*H 12 ΔI decreased progressively. Hence for the corrosion–fatigue failure situation $\mathrm{d}\Delta I/\mathrm{d}N$ was observed to be positive whereas for corrosion–fatigue immunity $\mathrm{d}\Delta I/\mathrm{d}N$ was negative. Other systems gave transients with similar characteristics, and the results are compared in Table 1 with the known corrosion–fatigue behaviour in similar conditions.

In all cases $\mathrm{d}\Delta I/\mathrm{d}N$ is positive when corrosion reduces fatigue life, that is when the ratio

$$\frac{\text{corrosion–fatigue endurance limit}}{\text{air fatigue endurance limit}}$$

is significantly less than one.

When the ratio equals one, $\mathrm{d}\Delta I/\mathrm{d}N$ is always negative. No exceptions to this rule have been found in the systems so far investigated.

The number of fatigue cycles to failure of stainless steel in sulphuric acid at different potentials was previously shown to be related to the magnitude of cyclic-strain-enhanced-dissolution effects[3]. It is now apparent that this principle can be successfully extended to explain the susceptibility and immunity of metals to failure by corrosion–fatigue.

Auger electron spectroscopy of wear surfaces

THE effectiveness of lubricants containing sulphur and/or chlorine compounds in preventing wear and seizure of steels is related to the chemical lability of the load-carrying element (sulphur, chlorine) contained in them[1]. This finding is consistent with the formation of surface layers of iron sulphide and chloride which prevent metal wear and seizure. Little could be deduced, however, about the nature of these protective layers. We investigate here the surface region of wear scars formed in the four-ball lubricant testing machine using Auger electron spectroscopy (AES) incorporating an argon ion sputtering technique. Here a beam of argon ions is used to etch away surface layers, and expose underlying layers for examination by AES. Using these techniques we can build up an approximate composition profile for the surface region of the sample. This was a more detailed investigation than that by Buckely[2], who used AES principally to investigate changes in the surfaces of loaded disks.

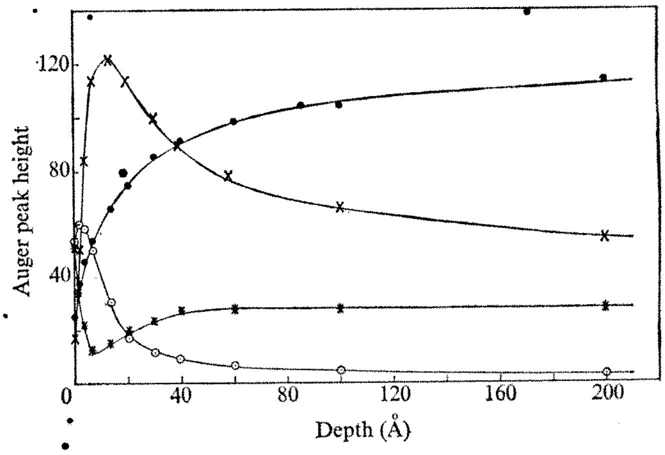

Fig. 1 Wear scar profile using dibenzyl disulphide. ●, Fe; ×, s; *, c; ⊙ O. The abscissa displays a depth scale in Ångstroms constructed on the basis of an ion beam current density of 10^{-2} (1 μA cm^{-2}) producing a sputtering rate of 1 Å min^{-1}. This conversion is arbitrary, and takes no account of differential sputtering rates of various materials. Initial results of sputtering rates determined for pure metals has shown it to be of the right order, though somewhat too conservative.

AES was carried out using a Varian cylindrical mirror analyser incorporating a 10-kV electron gun equipped with a scanning

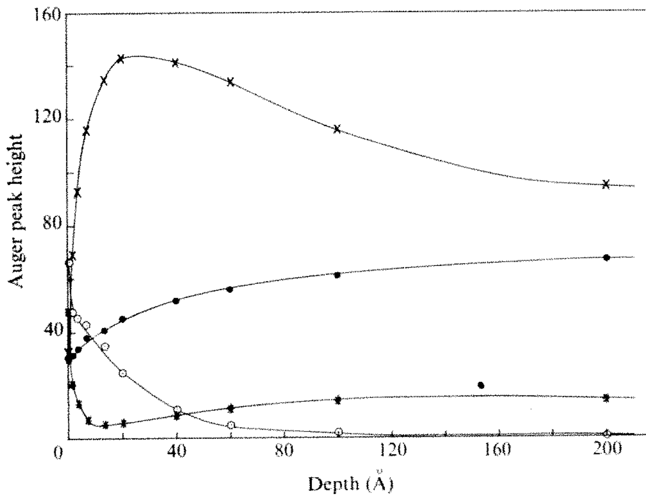

Fig. 2 Wear scar profile using di-*tert*-nonyl polysulphide. Symbols as in Fig. 1.

control for examination of areas from a few tenths of a square millimeter down to a focused spot of 2×10^{-5} mm^2. We used a 5-kV beam of 10^{-6} Å over an area of 0.1 mm^2. A large area was examined to minimise effects due to surface inhomogeneity, and the low electron current density (10 A m^{-2}) reduced beam effects. A Varian 3-kV argon ion gun in a pressure of 8×10^{-3} N m^{-2} (6×10^{-5} torr) of argon was used for argon ion sputtering. The ion beam was scanned across the surface to ensure an even ion current density which was measured using a Faraday cup. Sputtering was carried out to at least 2,000-Å depth but the most important changes occurred in the first few hundred Ångstroms, and this range is shown in the profiles (Figs 1–5).

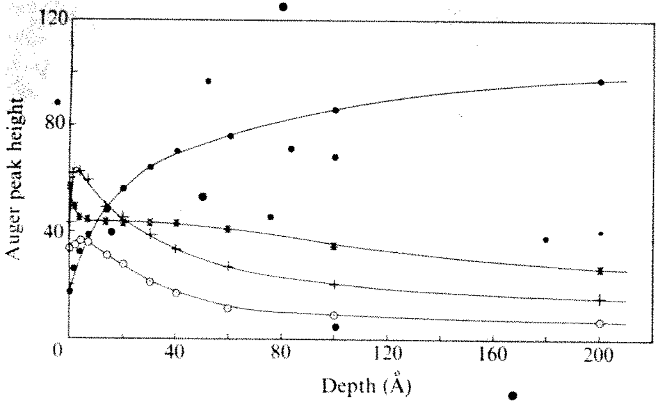

Fig. 3 Wear scar profile using Cereclor 51L. Symbols as in Fig. 1. + Cl.

We examined two sulphur-containing compounds, dibenzyl disulphide and di-*tert*-nonyl polysulphide, and two chlorine-containing compounds, Cereclor 51L (a commercial chlorinated hydrocarbon) and benzyl chloride, as lubricant additives. Blends were made up containing 15 mg-atoms of either sulphur or chlorine in 100 g of light liquid paraffin, and tested at a load of 160 kg for 1 min. The wear scars produced were washed twice in Analar toluene before examination in the Auger electron spectrometer.

The profiles obtained using the sulphur-containing oils (Figs 1 and 2) show that both oils afforded wear scars showing a high level of sulphur, presumably as iron sulphide, in the surface region. The sulphur level fell away very gradually with increasing depth, indicating considerable reaction with the metal over the first few hundred Ångstroms. High levels of carbon and oxygen were present at the surface, but were greatly reduced on etching, and can probably be ascribed to atmospheric contamination.

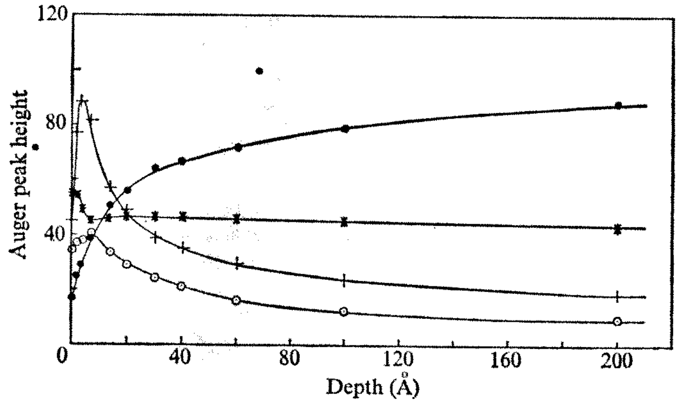

Fig. 4 Wear scar profile using benzyl chloride. Symbols as in Figs 1 and 3.

When the scars from the balls lubricated with chlorine-containing additives were examined (Figs 3 and 4), both additives showed a high chlorine level at the surface, but the level fell away sharply on etching, suggesting that only a very thin layer of iron chloride was formed. Also, a high, persistent level of carbon was found, and this was generally greater than the carbon level found with sulphur-containing oils and remaining after etching.

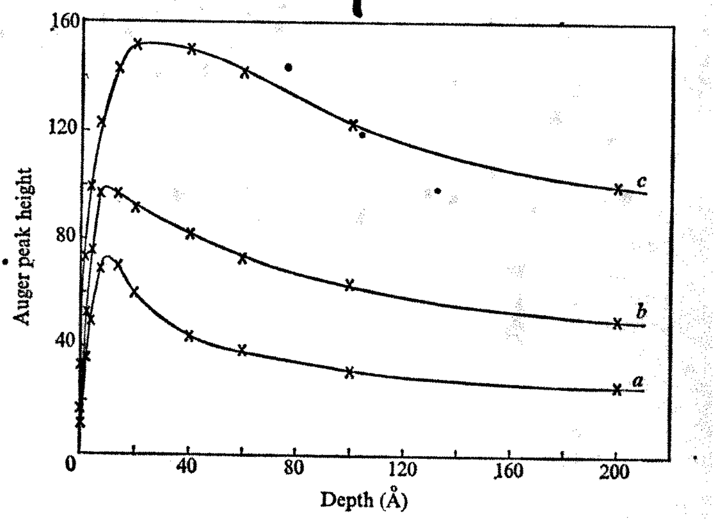

Fig. 5 Sulphur Auger profiles using di-*tert*-nonyl polysulphide at various loads. *a*, 50 kg; *b*, 100 kg; *c*, 160 kg.

Certain correlations are apparent between the wear scar profiles obtained in this work and the lubricating properties of the additives. In high load conditions, the sulphur-containing oils perform better than the chlorine-containing oils as shown by the wear scar diameters: dibenzyl disulphide, 1.54 mm; di-*tert*-nonyl polysulphide, 1.48 mm; Cereclor 51L, 2.39 mm; benzyl chloride, 2.18 mm. This effect could be linked to the production of thicker layers of iron sulphide compared with iron chloride. Furthermore, comparison of the two sulphur-containing oils revealed that di-*tert*-nonyl polysulphide gives a higher maximum concentration and deeper penetration of sulphur, and is a better extreme pressure additive than dibenzyl disulphide. The improved performance of benzyl chloride compared to Cereclor 51L is consistent with the higher chlorine level at the surface produced by the more reactive compound.

As the pressure on the bearing surfaces is one of the most critical of the parameters affecting wear, we have also examined the effect of load on film formation. The sulphur profiles (normalised to the same final iron level) obtained from wear scars formed at different loads using a blend of di-*tert*-nonyl polysulphide in liquid paraffin (Fig. 5) show that, over the range examined, both the maximum sulphur concentration and the degree of sulphur penetration increases with load. The increase in the sulphur level near the surface with increasing load is obviously related to the particularly good lubricationg properties of sulphur-containing oils in extreme conditions.

Examination of scars produced using mixtures of Cereclor 51L and the two sulphur compounds in liquid paraffin produced profiles showing the essential features of those obtained from the individual additives. A fuller account of this work will be published shortly.

Structural imperfection and morphology of crocidolite (blue asbestos)

ELECTRON microscopic studies of fibrous materials, including a range of chain silicates[1–6], synthetic polymers[7] and carbon fibres[8], have almost exclusively involved examination of the structural characteristics visible when the fibre axis is perpendicular to the electron beam. It is extremely difficult to prepare ultra-thin sections of fibrous samples such that this axis is parallel to the beam; and yet it is in this projection that the greatest insights into structural and morphological irregularities are likely to be achieved, a fact well illustrated by the high-resolution studies of Yada[9] on chrysotile asbestos which, being less brittle than crocidolite and other amphiboles, was amenable to the normal techniques of ultra-microtomy. We present here preliminary results of a successful axial study of crocidolite (blue asbestos), the fibrous form of the amphibole mineral riebeckite (idealised formula $Na_2Fe_5(Si_4O_{11})_2(OH)_2$, space group C2/*m*, $a = 0.973$, $b = 1.806$, $c = 0.533$ nm, $\beta = 103.3°$). The electron micrographs reveal several novel features.

Crocidolite from Wittenoon, W. Australia, was embedded by vacuum impregnation with Araldite (CY212) resin and thin sections (~ 2 mm) were cut across the fibre axis using a diamond saw. These sections were mechanically polished to a thickness of ~ 50 μm and finally thinned by argon-ion bombardment at a glancing angle of 12°. They were examined in Philips EM300 and Siemens Elmiskiop 102 electron microscopes using a double tilt stage that enabled the fibre axis to be set exactly parallel to the electron beam. With this orientation both x^* and y^* are normal to the electron beam so that the $(hk0)$ reflections generate lattice fringes which serve as means of identifying the precise disposition of each constituent fibril with respect to its neighbour and, in addition, of characterising planar and other structural faults.

Figure 1*a* shows a typical section, and in its schematised analogue (Fig. 1*b*) the profiles of the fibrils have been delineated and their relative degrees of rotation around the *z* axis indicated. The electron transparent regions separating the fibrils demarcate the Araldite cement, which before hardening had penetrated the fibre and separated the fibrils slightly. The overall irregularity of the fibril profiles, notwithstanding some possible artefacts due to the ion-beam thinning, is surprising, as only occasionally do the fibrillar faces exhibit crystallographic indices which coincide with the low-index cleavage faces (010) and (110), seen in optical studies[10].

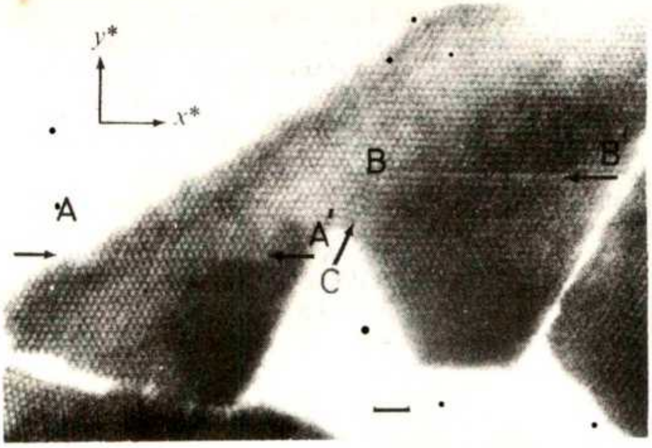

Fig. 2 Lattice image, along fibril axis, of crocidolite showing planar faults at AA′, BB′ (which coincide with (020) planes) and BC, which is the trace of (110). AA′ and BB′ are Wadsley defects consisting of triple-chains (see text). Scale bar, 5 nm.

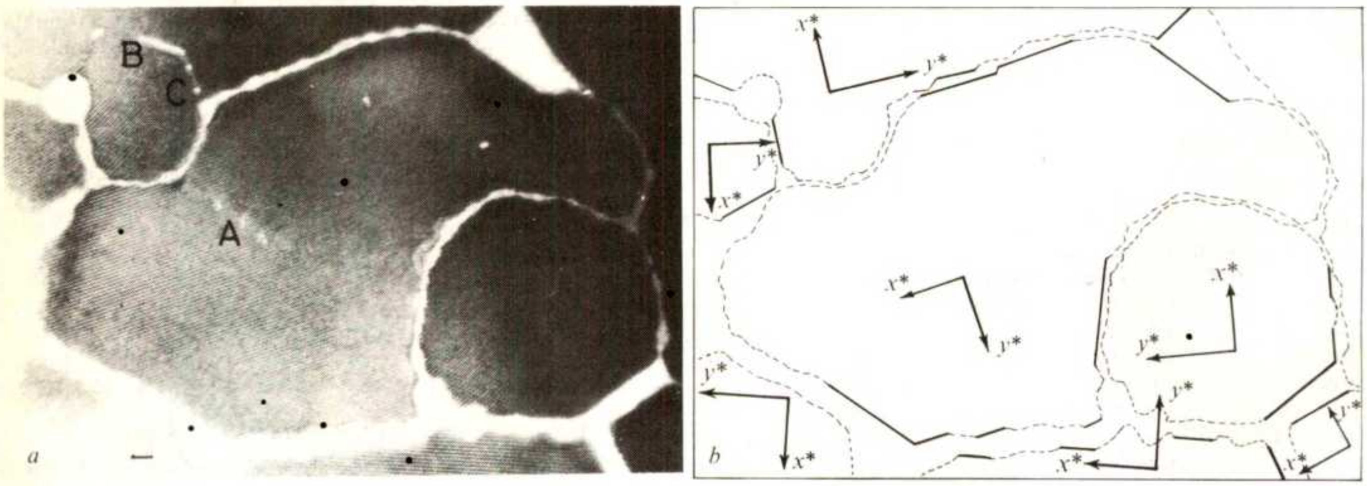
The electron-transparent regions located within the fibrils (A, B . . . in Fig. 1*a*) arise from isolated but aligned grown-in defects, which could well have been preferentially etched during ion bombardment. The possibility that they are micropores, incorporated during growth, cannot be discounted: the dimensions of the pores range from 2 nm (that is, corresponding to a unit-cell wide 'pipe') to over 10 nm in diameter. The alignments of these features could be the result of small-angle boundaries, for example, the (010) family may be interpreted either in terms of a tilt boundary composed of dislocations of the type (100)[010] or in terms of dislocations lying on (010) slip planes with Burgers vector in the direction [100].

So far as the planar faults are concerned (Fig. 2), those denoted AA′ and BB′ lie parallel to (020) and, by analogy with previous studies[3,5], it is almost certain that these correspond to triple-chain lamellae that have been incorporated into the parent double-chain matrix. They are examples of Wadsley defects[3,5] and their presence in crocidolite is demonstrated here for the first time. At such faults there is departure from the normal chemical composition of the mineral. At the triple-chain regions a reduction in number of O atoms bonded to Si is compensated by an equal increase in the number of OH

Fig. 1 *a*, High resolution lattice image of ion-thinned crocidolite with the electron beam parallel to the fibrillar (*z*) axis. *b*, Schematised form of *a*. The reciprocal lattice directions are indicated, and the random orientation of the fibrils about their axes is apparent. ——, Fibril boundaries corresponding to low-index planes. The fibrillar outlines (— — —) show a general irregularity.



groups. Planar faults on (110) are also present (BC, Fig. 2), the displacement vector of this extended defect, as measured on the micrograph, being b/4 [010]. It is noticeable that planar faults CB and BB′ intersect, and the nature of the structural rearrangement that occurs in the vicinity of region B is not yet clear.

The precise significance and full characterisation of planar faults in crocidolite (as well as in other related brittle minerals which may now be studied by the technique herein described) awaits the results of dynamical calculation of lattice images[10,11]. Such calculations are under way.

We thank the SRC and the Royal Society Exchange Scheme for support that enabled M.A.F. to work in these laboratories. We are indebted to Dr E. J. W. Whittaker for drawing our attention to this problem, and for his helpful comments on the micrographs. The technical assistance of Mr. J. L. Jenkins is also appreciated.

Pyrolysis of a polyborodiphenylsiloxane

WE have previously reported successful production of a high-strength continuous SiC fibre[1–3], a high flexural strength SiC sintered body[4] and a heat-resistant Fe–Cr alloy[5] by converting organometallic polymer polycarbosilane (PC) as the binder to an inorganic in thermal decomposition. We then found that in the thermal decomposition of organometallic polymers such as PC, an amorphous state exists before formation of the (SiC) fine particles; this SiC amorphous state is hardly possible in inorganic reactions. The process of thermal decomposition of organometallic polymers is little known. To obtain general information on the phenomenon, we have newly synthesised multi-element polyborodiphenylsiloxane containing oxygen (B, C, Si, O, H) compared with PC composed of Si, C and H, and observed the process of its thermal decomposition.

Polyborodiphenylsiloxane, (PB)p was synthesised as follows. Boric acid (0.33 mol, 20.6 g) and diphenyldichlorosilane (0.5 mol, 126.6 g) were dissolved in 200 ml of anhydrous *N*-butyl ether. The solution was then refluxed in N_2 gas atmosphere for 18 h, and heated for 1 h under reduced pressure at 300 °C, successively. 102 g of (PB)p was obtained as 92% yield. The (PB)p synthesis display is represented by the following reaction

$$3[(Ph)_2SiCl_2] + 2H_3BO_3 \rightarrow [(C_6H_5)_6Si_3B_2O_6] + 6HCl\uparrow$$

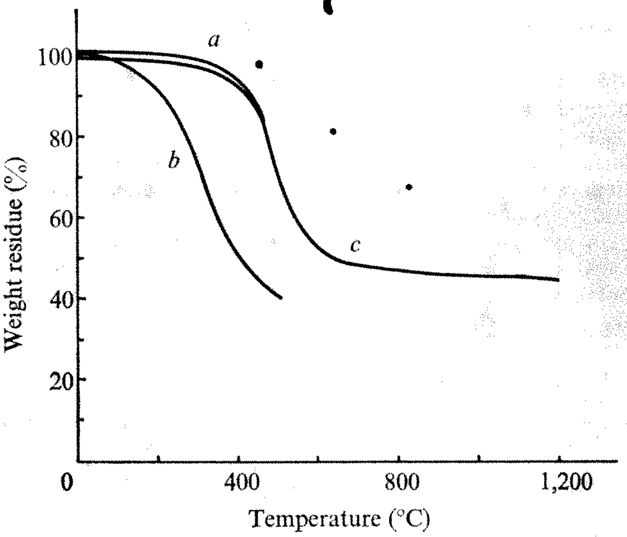

Fig. 1 Thermal analysis curves of (PB)p and (PB)m. *a* and *b*, TG curves of (PB)p and (PB)m respectively, up to 500 °C from room temperature in air. TG curve of (PB)p up to 1200 °C from room temperature in a stream of N_2 gas.

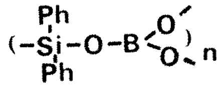
The intermediate product, $[(C_6H_5)_6Si_3B_2O_6]$, is pyrolysed at 300 °C. Microchemical analysis values of the product (PB)p are shown in Table 1, with the expected theoretical ones as $[(C_6H_5)_6Si_3B_2O_6]$. The observed analytical values of the (PB)p, C and O contents are reduced in comparison to the theoretical ones and the difference can be attributed to the pyrolysing process at 300 °C of the $[(C_6H_5)_6Si_3B_2O_6]$. The softening point is 100 °C. Its infrared spectrum shows peaks at 3600 cm^{-1} (free OH), 3500–3100 cm^{-1} (hydrogen-bonded OH), 1600 cm^{-1} (C_6H_5), 1500–1300 cm^{-1} (B–O) and 1150–1000 cm^{-1} (Si–O), respectively. The product was found to be (PB)p. It is considered to contain partial structures as follows



$$\left(-\underset{\text{Ph}}{\overset{\text{Ph}}{\text{Si}}}-\text{O}-\text{B}\begin{matrix}\text{O}\\ \text{O}\end{matrix}\right)_n$$

Of the various organometallic polymers, boron polymers are generally heat resistant but not very moisture proof[6]. Vale reported the producton of polyborodimethylsiloxane (PB)m from boric acid and dimethyldichlorosilane[7]. He improved its moisture-proof property by special means of electron irradiation. The (PB)p synthesised was found to be far more moisture proof than (PB)m. When both (PB)p and (PB)m were left in air at room temperature for 1 week, the transparence of the (PB)p was not changed, but the (PB)m was appreciably devitrified.

Simply by using diphenyldichlorosilane instead of dimethyldichlorosilane, we obtained here a superior moisture-proof characteristic of (PB)p facilitating practical handling. The thermal decomposition process of (PB)p and (PB)m was compared by means of a thermobalance. Figure 1 shows thermal

Table 1 Composition (wt%) of polyborodiphenylsiloxane, (PB)p heated 1,000 °C and (PB)p heated 1,500 °C

Sample	B	Si	C	O	H	N
(PB)p: experimental	3.68	16.23	59.1	7.8	4.9	< 0.2

Heated (1,000 °C) (PB)p	5.46	37.52	(~ 44)	12.2	0.5	< 0.2
Heated (1,500 °C) (PB)p	5.08	44.8	35.6	12.2	0.7	1.5

*The theoretical value is calculated as $[(C_6H_5)_6Si_3B_2O_6]$.

analysis curves of (PB)p and (PB)m from room temperature to 500 °C in air. TG analysis of (PB)p was examined up to 1,200 °C, in a stream of N_2 gas, and the TG curve was almost same as that of air up to 500 °C. The thermal decomposition initiation temperature of (PB)p is about 150 °C higher than that of (PB)m, indicating its superior heat resistance, and the weight loss is also smaller. (PB)p was thus greatly improved in both heat resistance and in its moisture-proof characteristic.

In pyrolysed (PB)p, the organic group is decomposed. At 1,000 °C, an amorphous phase consisting of many elements is obtained (Fig. 2*b*). Analytical values of the pyrolysed product at 1,000 °C, and 1,500 °C in N_2 gas atmosphere are shown in Table 1; and the residual as decomposition product at 1,000 °C is about 46%. The amounts of SiC of 1,500 °C sample should be at least 37 at%, based on the following assumption: all of oxygen atoms react with silicon atom and the remaining silicon atoms react with carbon and convert to silicon carbide. By further pyrolysis of the product up to 1,700 °C in Ar gas flow, phases of abundant β-SiC, glassy carbon and slight B_4C appear (Fig. 2*c*). In Fig. 2*c*, diffraction peaks (arrow) were few and weak, but they coincided with ASTM card, 6–0555 (B_4C) and the infrared spectrum of 1,700 °C (PB)p was coincided with that of a B_4C compound. The crystalline product due to the peaks is considered to be a B_4C compound.

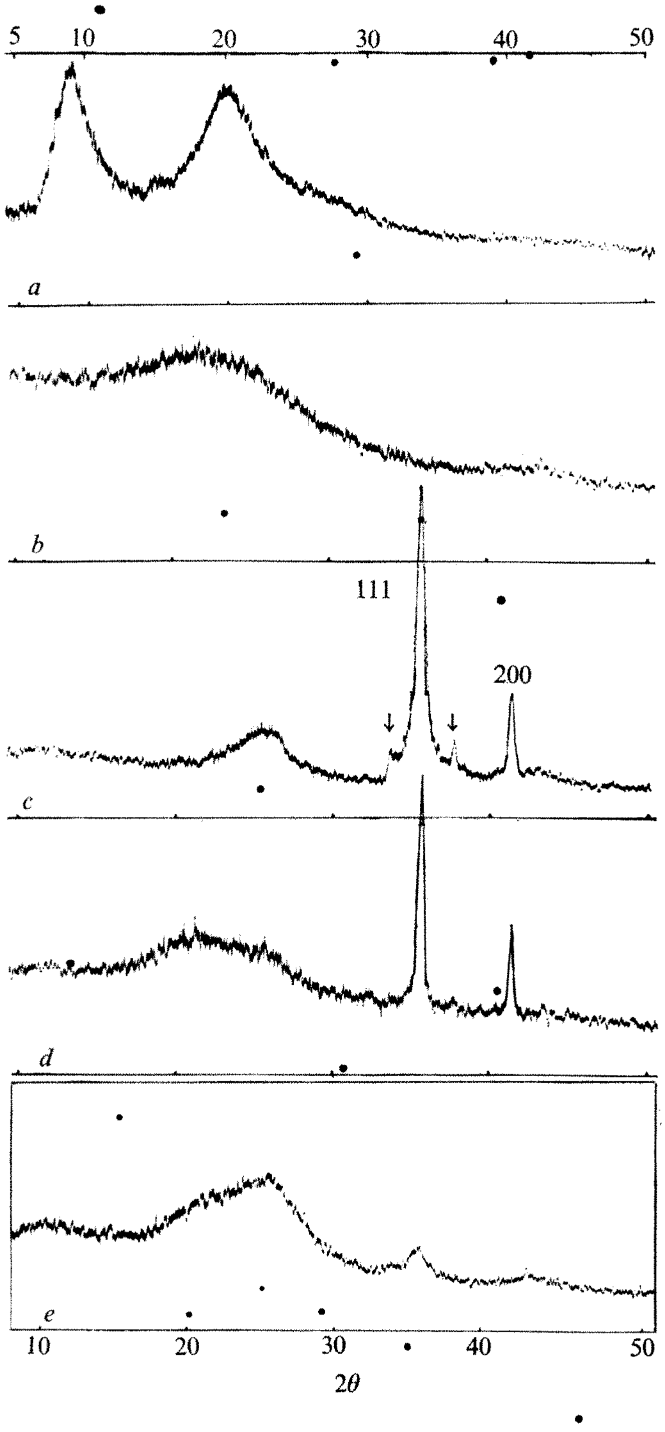

Fig. 2 X-ray diffraction patterns (CuKα) of (PB)p and the pyrolysed (PB)p products at respective temperatures. *a*, Polyborodiphenylsiloxane; *b*, 1,000 °C heat-treated (PB)p in a stream of N_2 gas; *c*, 1,000 °C product heated at 1,700 °C in Ar gas for 1 h; *d*, 1,700 °C product heated at 1,400 °C in air for 2 h; *e*, 1,000 °C product heated at 1,400 °C in air for 2 h. '111, 200': diffraction peak in β-SiC.

Though constituents of (PB)p are many (including Si, B, C and O), on pyrolysis in a reducing atmosphere, its products contain mostly a β-SiC product. This phenomenon is important.

The 1,700 °C product was then burnt at 1,400 °C in air. In the X-ray diffraction, in addition to the β-SiC pattern, broader pattern than that at 1,700 °C appears between 2θ = 16° and 30° (Fig. 2*d*). The compound, B_4C is considered to be composed and converted to amorphous B_2O_3. The broad pattern is probably ascribed to the glassy phase of B_2O_3 and the amorphous (PB)p residue and glassy carbon.

On the other hand, when the product at 1,000 °C is further burned at 1,400 °C in air, amorphous-like SiC and an amorphous phase of multiple elements occurs (Fig. 2*e*).

Because pyrolysis at up to 1,700 °C produces SiC, B_4C, and so on, it is easy to convert (PB)p into a heat-resisting inorganic material. There is thus a possibility of using (PB)p as a binder in the SiC body, for example; this will be described in another report.

In conclusion, in both previously developed polycarbosilane and newly-developed polyborodiphenylsiloxane of multiple elements, there is an amorphous state during thermal decomposition to such heat-resisting inorganic compounds as SiC and B_4C. Therefore, the production of an amorphous state in the thermal decomposition of organometallic polymers to inorganics seems to be common.

SiC and Si_3N_4 sintered bodies with new borodiphenylsiloxane polymers as binder

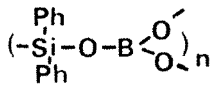
HIGH-STRENGTH SiC and Si_3N_4 sintered bodies have been studied for their application as high-temperature structural materials[1]. A high-strength SiC sintered body using an organometallic polymer as the binder has been reported[2]. A feature of this method is that polycarbosilane (PC) as the binder is converted into fine-particle inorganic β-SiC by heat-treatment, which fills the grain boundaries of the matrix SiC. In this way, with a hard-to-sinter material such as SiC or Si_3N_4, a sintered body with excellent mechanical strength can be produced at relatively low temperature

Table 1 Sintering conditions and properties of the sintered bodies

Matrix	Step	Conditions	Apparent density (g cm^{-3})	Flexural strength (MN m^{-2})	Fig.
SiC	a	Heating at 100 °C h^{-1}, keeping at 1000 °C for 1 h; N_2 gas flow	2.55	80	*a*
	b	Rapid heating, keeping at 1700 °C for 1 h; 1.8 MPa Ar	2.43	109	*b*
	c	Rapid heating, keeping at 1400 °C for 40 h; in air	2.49	182	*c*
Si_3N_4	a	Heating at 100 °C h^{-1}, keeping at 1000 °C for 1 h; N_2 gas flow	2.13	62	
	b	Rapid heating, keeping at 1500 °C for 1 h; 1.8 MPa Ar	2.06	71	
	c	Rapid heating, keeping at 1000 °C for 40 h; in air	2.18	125	

without using a hot press. We recently synthesised a particular form of polyborodiphenylsiloxane (PB)p, an organometallic polymer, which is very effective as a binder. Using this binder, SiC and Si_3N_4 sintered bodies of high mechanical strengths could be successfully obtained. These results are outlined here.

A partial structure of (PB)p used as the binder is shown as



The method of synthesis properties of (PB)p and phenomena in pyrolysing (PB)p are described elsewhere[3]. The purity and mean particle size of both the α-SiC and the β-Si_3N_4 used as the matrix materials were 99.9% and 30 μm, respectively. The procedure giving the best result in a sintered body is as follows. About 10% by weight of (PB)p is added to the SiC or Si_3N_4 powder. To this mixture, benzene is then added, to dissolve the (PB)p. The result is a uniform mixing of binder and matrix powder. The solvent is evaporated off, and a green body of size $10 \times 30 \times 4$ mm^3 is prepared by mould-pressing at 196 MPa. The subsequent sintering process, in three steps, is shown in Table 1.

The flexural strength of the sintered SiC and Si_3N_4 bodies at room temperature was measured by the method previously described[2]. The measured results and the densities are shown in Table 1. Scanning photomicrographs of the fractures after the successive steps of sintering are given in Fig. 1.

From X-ray diffraction after the successive steps of sintering of a SiC body (Table 1, Fig. 1), the following conclusions emerged. In step (a), the amorphous binder, not yet well crystallised surrounds the SiC particles. In step (b), the (PB)p binder has now been mostly converted into fine-particle β-SiC. Between 1,000 and 1,700 °C, flow of the amorphous binder would occur, resulting in good wetting of the matrix α-SiC. The flexural strength of the sintered body thus becomes larger than in step (a). X-ray diffraction at this stage showed Bragg peaks due to small amount of B_4C and amorphous carbon, as well as β-SiC. In step (c), the B_4C peaks disappear and the diffraction intensity indicating an amorphous phase increases. B_4C has thus become a glassy material by reaction with oxygen in the air. This glassy substance acts as a binder for the matrix SiC powder. Possibly because of this, the flexural strength of the sintered body is further raised. Similar results were obtained with the Si_3N_4 sintered body. Therefore, the sintered SiC and Si_3N_4 bodies using (PB)p as the binder will be safely usable at high temperatures and even in an oxidising atmosphere.

As seen in Table 1, apparent densities of the sintered bodies are relatively low. By impregnation of the sintered body with (PB)p, followed by further heat-treatment, therefore, the apparent density and the flexural strength could both be further increased. The method is similar to that described elsewhere[2]. By applying this process to the SiC and the Si_3N_4 sintered bodies following step (a), the increases in density and strength per impregnation were about 0.09 g cm^{-3} and 60 MN m^{-2}, respectively, in each case.

Compared with PC, (PB)p can be more easily synthesised and is more effective as the binder for obtaining high-strength sintered bodies.

In the SiC and Si_3N_4 sintered bodies using (PB)p as the binder, there is no dimensional change on sintering. The method of converting (PB)p to an inorganic as the binder is useful, and original, in industrial production. The sintered bodies, which are of high strength, should find many applications in various fields.

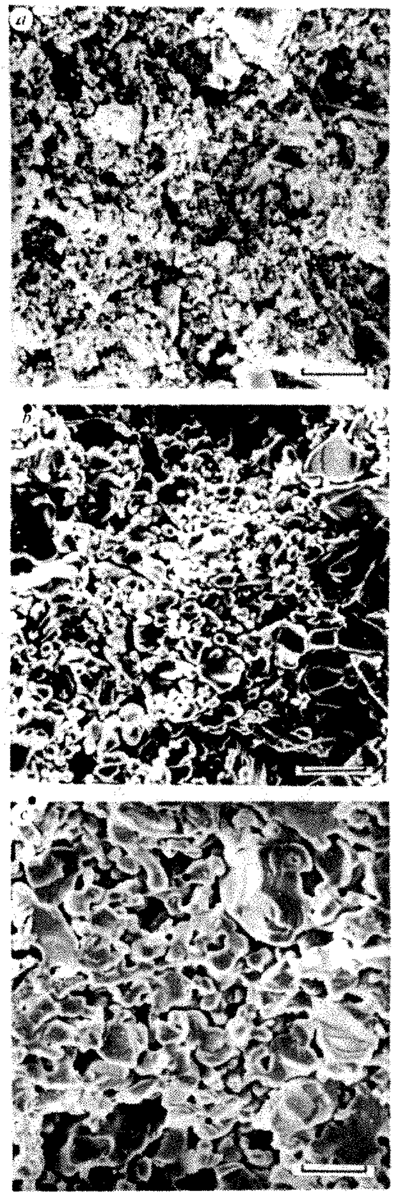


Fig. 1 Scanning photomicrographs of the fracture surfaces of SiC sintered bodies. Scale bars, 50 µm.

Production of 'prompt' nitric oxide and decomposition of hydrocarbons in flames

The pollutant nitric oxide originates in combustion systems from nitrogen in the air or the fuel. Two processes have been identified whereby atmospheric N_2 produces NO. The Zel'dovich[1] mechanism has the rate-determining step $O+N_2 \rightarrow N+NO$ and is affected by oxygen atoms having concentrations[2,3] above those for equilibrium. Fenimore's 'prompt' scheme[4] is an attack on N_2 by some hydrocarbon fragment with a lifetime of several µs in the flame's reaction zone[5]. Probable[6] primary steps are

$$CH+N_2 \rightarrow HCN+N \quad (1)$$

$$C_2+N_2 \rightarrow 2CN \quad (2)$$

The oxidation of HCN and CN to NO has been discussed elsewhere[6,7]. We have burnt premixed H_2–O_2–N_2 flames and measured the 'prompt' NO resulting from trace additions of hydrocarbons to the burner supplies. We found that 'prompt' NO yield is proportional to the number of carbon atoms in the hydrocarbon molecule. We consider that the hydrocarbons fragment into species with one carbon atom, in, or close to, the preheating region. Thus formation of 'prompt' NO, soot, ions in flames, and CH radiation from hydrocarbons all show related behaviour.

We studied flames with temperatures of 1,900–2,350 K, burnt at atmospheric pressure on a Padley–Sugden[8] burner. They have a flat reaction zone and burned gases (diameter ~15 mm; length ~0.2 m), in which the velocity, temperature and composition profiles are those for plug flow. Without additive these flames are invisible, but with, say, 0.1% (by volume) of C_2H_2, a greenish-blue reaction zone is apparent 1 mm off the burner face. In certain conditions this reaction zone of the hydrocarbon burning in the H_2–O_2–N_2 flame lifts off the burner, and to avoid this the fastest burning hydrocarbons with up to three carbon atoms, that is, CH_4, C_2H_2 or CH_3CCH, were used. The addition of 1% of a hydrocarbon and removal of a little H_2 does not affect[9] the temperature or concentrations of H, OH or O. Flames were sampled through a water-cooled quartz probe into a chemiluminescent analyser to determine [NO] along the axis of the burned gases. These flames were too hot for NO_2 to exist in them.

Using C_2H_2 as additive (Fig. 1) the NO with no hydrocarbon can only originate from the Zel'dovich process, whereas the increase in [NO] with C_2H_2 added can be unambiguously ascribed to the 'prompt' mode of production[6]. In general, with hydrocarbon present, [NO] near the reaction zone is non-zero, and well downstream in the burnt gases all the curves of Fig. 1 are parallel, with the increments in [NO] being 'prompt' NO. The dependence of this 'prompt' NO yield on $[N_2]$ has been investigated by replacing some N_2 with argon, but maintaining the temperature constant. This has established that 'prompt' NO $\propto$ $[N_2]$ in the unburnt gases. A similar investigation demonstrated that the yield of 'prompt' NO is also proportional to the quantity of hydrocarbon present (Fig. 2). The linearity held irrespective of the hydrocarbon, as well as from 1,900 to 2,350 K and for fuel-rich and fuel-lean flames. The only exception appeared with cooler fuel-rich ($T \sim 1{,}900$ K, $[H_2]/[O_2]$ in unburnt gases > 5) flames, where plots as given in Fig. 2 did show initial linearity followed by a decrease in slope for hydrocarbon additions greater than 1%, giving a maximum and a subsequent drop in 'prompt' [NO]. This suggests that hydrocarbons can destroy NO, as well as produce it.

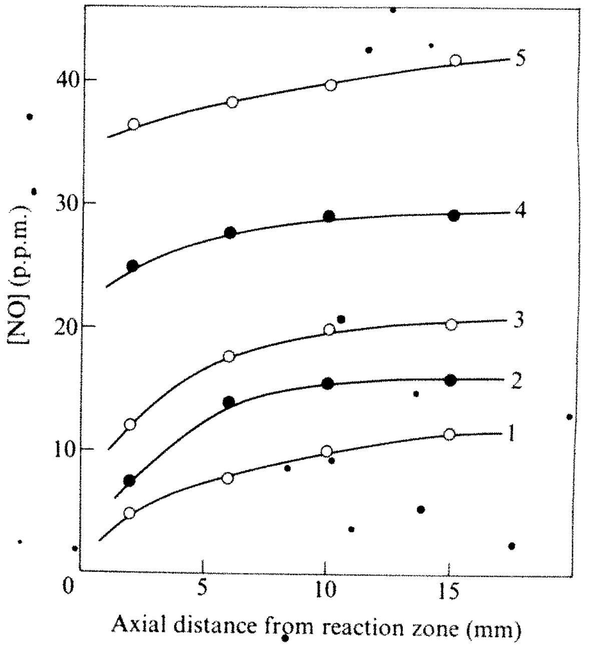

Fig. 1 Measured concentrations of NO along the axis of a flame ($[H_2]/[O_2]/[N_2] = 3.0:1.0:3.3$; temperature = 2,350 K) with various amounts of acetylene added. 1, 0%; 2, 0.98%; 3, 3.02%; 4, 4.43%; 5, 6.08%.

The efficiencies of CH_4, C_2H_2 and C_3H_4 at generating 'prompt' NO were compared (Fig. 3) for additions less than 1%. It is clear that the 'prompt' [NO] per N_2 and per hydro-

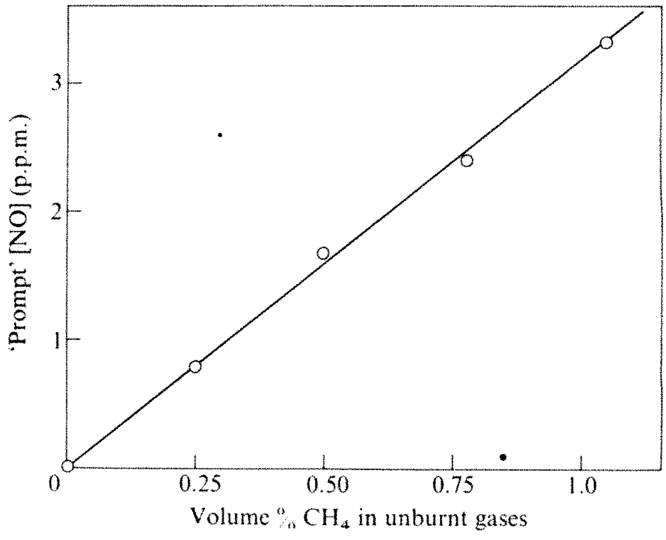

Fig. 2 Dependence of the yield of 'prompt' NO adjusted for any change in $[N_2]$ on the amount of methane added to a flame ($[H_2]/[O_2]/[N_2] = 3.0:1.0:5.7$; temperature = 1,900 K).

carbon molecule is proportional to the number of carbon atoms in a molecule of the additive. This was found to hold at different flame temperatures and compositions for fuel-rich systems. In fuel-lean flames the linearity was lost, with C_2H_2 more efficient per carbon atom than CH_4 or C_3H_4. A separate comparison between propyne and propane confirmed that both are equally effective promotors of 'prompt' NO in fuel-rich flames. Little variation of the 'prompt' NO (per carbon atom and per N_2 molecule) was detected with temperature or $[H_2]/[O_2]$ in the unburnt gases, provided the latter exceeded two. In contrast, the 'prompt' NO in O_2-rich flames decreased strongly for $[H_2]/[O_2]$ below two; when $[H_2]/[O_2] = 1$, there was always negligible 'prompt' NO. These observations establish that 'prompt' NO in fuel-rich systems is proportional to the number of carbon atoms present and independent of their origin. This rules out reaction (2), and others involving species containing two or more carbon atoms, as the primary step, because it is unlikely that say C_2 could come from CH_4 half as efficiently as from C_2H_2. Reaction (1) is apparently the most likely[6] primary step involving species with one carbon atom.

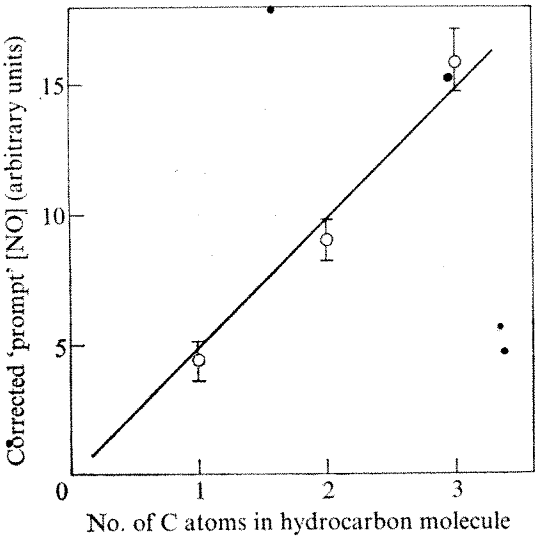

Fig. 3 The 'prompt' NO produced in a flame ($[H_2]/[O_2]/[N_2] = 3.0/1.0/3.3$; temperature = 2,350 K), per hydrocarbon molecule and per nitrogen molecule present in the burner supplies, plotted against the number of carbon atoms in the hydrocarbon.

The unburnt gases are known to pass through a pre-heating region before entering the reaction zone[5,10]. There is also an appreciable flux of hydrogen atoms into this region, because of their large concentration gradient in the reaction zone[2,9,10] and their immense diffusivity. One explanation then of the above is that CH arises from hydrocarbons undergoing a sequence of first-order decomposition reactions, with a common rate-determining step. If this holds for CH_4 and other hydrocarbons, the rate-determining step could be the conversion of CH_3 to CH_2 or CH_2 to CH. Also, since a large hydrocarbon gives as much CH per carbon atom as CH_4, the rupture of every carbon–carbon bond must occur before oxidation in the reaction zone interferes by producing stable products such as CO. A complete break-up of a hydrocarbon to CH_3 or CH_2 is possible given a significant inflow of hydrogen atoms and a pre-heating[5] of less than 1000 K. Now all the stripping reactions

$$\begin{aligned} CH_4+H &\rightarrow CH_3+H_2 \\ CH_3+H &\rightarrow CH_2+H_2 \\ CH_2+H &\rightarrow CH+H_2 \end{aligned}$$

are close to thermoneutral[11] and are exothermic if OH replaces H. Also

$$CH+H\rightarrow C+H_2$$

is exothermic by some 97 kJ mol^{-1}, so that a rate-determining step cannot be identified. In fact, the reverse of each of the above reactions is likely to be fast enough at say 800 K with the large $[H_2]$ for them to be partially equilibrated and a limited 'pooling' of CH_3, CH_2, CH and C to result. Of course, all these radicals are likely to react with O_2 rapidly enough to prevent a complete balancing of the above four reactions. As for the pyrolysis of a paraffin in the presence of H atoms, schemes are available[12] indicating that the likeliest products include CH_4, C_2H_4 and C_2H_2. Such schemes, with the sequence

$$\begin{aligned} H+RH &\rightarrow H_2+R \\ R &\rightarrow C_2H_4+R \\ H+C_2H_2 &\rightarrow C_2H_3 \\ H+C_2H_3 &\rightarrow C_2H_4 \\ H+C_2H_4 &\rightarrow C_2H_5 \\ H+C_2H_5 &\rightarrow 2CH_3 \end{aligned}$$

give the partial pool of species with one carbon atom, rapidly and first order in the hydrocarbon, before significant oxidation to CO occurs.

Since the rate constant of (1) is known[13], a crude check on the above conclusions is possible. Consider a flame with 1% of C_2H_2 and 45% of N_2 in its supplies. If 1 in 100 carbon atoms produce CH, which is taken to react in the preheating region every collision with O_2, then the 'prompt' NO is calculated to be 4.6 p.p.m. for the products of (1) going to NO. This compares with the observed 4.4 p.p.m. for 0.98% of C_2H_2 in Fig. 1. Such agreement indicates that the fragmentation of each fuel molecule into a pool of species with one carbon atom before significant CO production occurs is a real possibility.

This conclusion for fuel-rich flames is borne out by other work. Ferguson[14] concluded that soot formation is preceded by dissociation of every C–C bond. Bulewicz and Padley[15] confirmed that ions in flames originate[16] from $CH+O\rightarrow CHO^{+}+e^{-}$ with an efficiency proportional to the number of carbon atoms in a fuel molecule. Blades[17] reached the same conclusion and found the CH emission intensity to be equal on a per carbon atom basis for several hydrocarbons. Peeters *et al.*[18] also observed a first order dependence for the CH emission from various hydrocarbons including CH_4.

Lower Cretaceous Lepidoptera

LEPIDOPTERA are rare in the fossil record and, until relatively recently, most fossil butterflies and moths had been found in Tertiary deposits. Records of Lepidoptera from earlier in the fossil record have been discounted[1]. The first evidence of a Cretaceous lepidopteran was Mackay's description[2] of the head of a caterpillar in amber (about 72 Myr BP). Kühne described micropterigid scales from Cretaceous resin (about 100 Myr BP) from West France[3], and several lepidopterous specimens have been found in Canadian and Siberian ambers of Cretaceous age (personal communication from A. Mutuura and A. Skalski). There is doubt about a much earlier record reported by Riek[4], who described two insects from Triassic beds in South Africa and placed them in the Paratrichoptera, which he considered a suborder of the Lepidoptera. (Evidence to suggest that this material is not lepidopterous will be published elsewhere.) Thus the four moths described here, which were found in Lebanese amber dating from at least 100 Myr BP, are the earliest indisputable lepidopterous specimens.

The amber was received from Professor Aftim Acra in Beirut. It was considered Aptian[5] or Neocomian[6] but must be at least 100 Myr BP, and Schlüter[7] has suggested an absolute age of 130 Myr BP. The moths (Fig. 1) have a wingspan of about 10 mm and have proved to be similar to extant species of Micropterigidae (Lepidoptera, Zeugloptera). They have been compared with recent species of Zeugloptera and with the primitive Dacnonypha, Agathiphagidae. The fossil moths have similarly shaped wings and wing scales, with abundant microtrichia on the wing membrane, comparable with recent micropterigids such as *Sabatinca* and *Micropterix*. The mouthparts have mandibles but no proboscis, and maxillary and labial palps similar to those of *Sabatinca* and *Micropterix*. Differences between the fossil and living species include the lack of ocelli and the apparent absence from the fossil forewing of a branch of the subcostal vein. The fossil moths have scales and an epiphysis on the foretibia, both of which are typical lepidopterous characters. Although the jugum cannot be seen in the fossils there is a small frenulum with four bristles similar to that of recent *Sabatinca*. A study of recent micropterigids shows that the fossil species is close to *Sabatinca* with which it has more characters in common than with *Micropterix*.

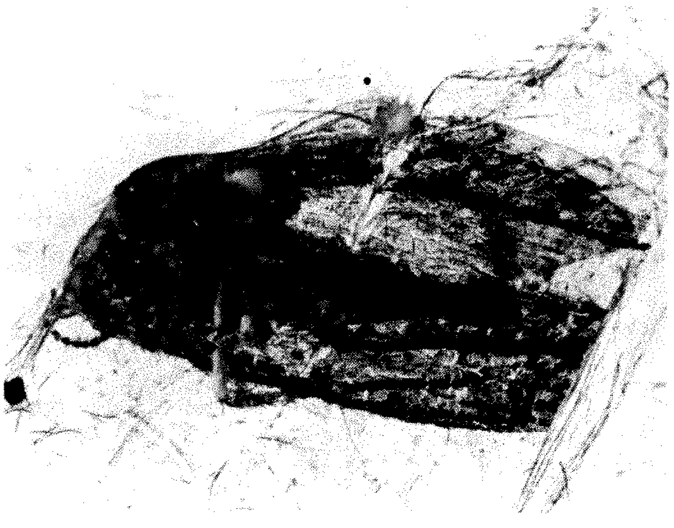

Fig. 1 Lower Cretaceous resin with lepidopterous inclusion. (Photo: British Museum Natural History.)

Re-examination of the holotype of *Micropterix pervetus* Cockerell[8] from Burmese amber of Miocene age (about 7 Myr BP) shows that this species should be transferred to *Sabatinca*. Similarly *Micropterix proavitella* Rebel[9], described from Baltic amber (Eocene/Oligocene, about 40 Myr BP) should also be transferred to *Sabatinca*. The genus *Sabatinca* has extant species in Australia, New Zealand and New Caledonia and its former distribution and origins can now be traced back through Burma in the Miocene, Northern Europe in the Eocene/Oligocene to probable origins in the Lower Cretaceous in the Lebanon. The Australasian species of *Sabatinca* are relicts of a former much wider distribution.

The newly discovered fossil provides evidence of Lepidoptera in the Lower Cretaceous but, because of its relatively specialised morphology, I propose an earlier date for the separation of the Lepidoptera from the Trichoptera–Lepidoptera stem-group than the Cretaceous origin suggested previously. We should now be looking for fossil evidence of Lepidoptera in the Jurassic. A fuller account of the morphology and relationship of these Lower Cretaceous fossil moths will be published elsewhere.

Photoperiodic termination of diapause in spider mites

TERMINATION of diapause in the spider mite *Tetranychus urticae* is considered to depend solely on a period of chilling, the so-called cold rest[1-3]. The minimal period of chilling required to reactivate a certain percentage of the overwintering population may vary between populations of different geographic origin[4]. No unambiguous relationship, however, has been established between chilling period and latitude, for there may be appreciable differences in the minimal period of cold rest between strains from close localities[5]. The situation seemed more complex after Dubynina's[6] discovery that reactivation of a Russian strain of this species increased linearly with time when mites had been induced to diapause under the influence of long days, abrupt temperature changes and severe competition for food, while reactivation was cyclical when diapause had been induced by short days and relatively low temperatures. In the latter case maximal percentages of reactivating females were obtained after diapausing mites had been kept in cold storage for 40 and 75 d. Minimal percentages were obtained after 50 and 95 d. Reactivation was complete by about the 105th day of storage. Experiments in England, however, produced no evidence for cyclical reactivation in British strains of *T. urticae*[5]. Using a Dutch strain of *T. urticae*, which has a constant photoperiodic reaction and has been reared in the laboratory for more than 15 yr (ref. 7), we have now found that termination of diapause in this species depends not only on a period of chilling but on photoperiod as well.

Female mites were induced to diapause at 18 °C in a short-day photoperiod of 10L:14D and then stored at 4 °C, in either a long-day regime of 16L:8D or a short-day regime of 10L:14D. At regular intervals samples of about 50 diapausing mites were retrieved from this cold storage and their capacity to terminate diapause was tested by placing them on fresh bean leaves at three different temperatures (Fig. 1). Females were considered to have reactivated if, within 10 d, their colour had changed from the bright orange-red of the overwintering form to the yellowish-green of the 'summer' form, and feeding and oviposition had started. Photoperiod was constant during this test; mites which had been stored in the cold in the long-day regime were reactivated in the same long days, and mites which had spent their cold rest in short days were reactivated in short days of the same length.

The results (Fig. 1) show the influence of temperature on reactivation. With increasing temperatures during reactivation, the duration of the cold rest necessary to terminate diapause in a certain percentage of the test population becomes progressively shorter. Comparison of Fig. 1*a* with Fig. 1*b*, however, shows that at least during the first 2.5 months of diapause photoperiod had a far greater influence on reactivation than did temperature. For example, at 17 °C 50% of the mites terminated diapause in long-day conditions after a cold rest of only 8 d, but in short-day conditions termination of diapause in 50% of the test population was achieved only after a cold rest of 54 d. This difference in duration of cold rest, required to terminate diapause in 50% of the mites in the two photoperiodic regimes, is still 34 d at 20 °C and 28 d at 23 °C (Fig. 1). About 2.5 months after the beginning of diapause the photoperiodic sensitivity of diapausing females had apparently disappeared, for reactivation of the complete population succeeded from that moment onwards in short as well as long days. Thus termination of diapause in *T. urticae* is dependent not just on temperature, but, at least during the first few months, on photoperiod as well.

These experiments suggest that sensitivity to photoperiod remains in adult females of *T. urticae*, at least during the first few months of diapause, and that in long days and relatively high temperatures diapause can be terminated in part of the population without the intervention of a cold rest of even minimal duration.

Although even in the short-day regime, at all three temperatures tested, complete reactivation was achieved after a cold storage of about 70 d, experiments in both photoperiodic regimes were prolonged up to 120 d to look for any cyclicity in the pattern of reactivation. Reactivation proved to be linear, however, in accordance with the results obtained with British strains of *T. urticae*[5], and in contrast to Dubynina's[6] results.

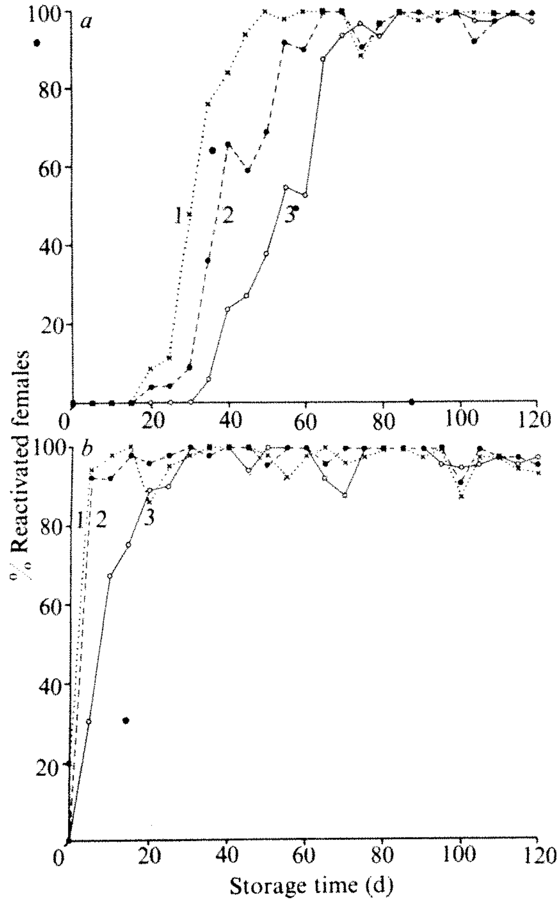

Fig. 1 Reactivation of diapause females of *T. urticae* at three different temperatures (1, 23 °C; 2, 20 °C; 3, 17 °C) in relation to the cold rest during which the mites were stored at 4 °C. *a*, Cold rest and reactivation in short days (10L:14D); *b*, cold rest and reactivation in long days (16L:8D).

Our results were obtained with a laboratory strain of *T. urticae*, and experiments with strains isolated from different localities in Europe are in progress to check the generality of the phenomenon of photoperiodic termination of diapause in this species. Some speculation, however, is possible about the ecological significance of the sensitivity of diapausing mites to photoperiod. It is conceivable that sensitivity during the early days of diapause tends to retain the diapause state during the autumn, when occasional warm days might break diapause in part of the population. According to our results the short days of autumn would prevent this breaking of diapause, while during winter diapause would be sustained and prolonged by prevailing low temperatures. In this sense, photoperiod would not function to terminate diapause when external conditions are favourable again, as in several insect species, but rather to protect the mites from becoming active again long before the season favourable for development and reproduction.

Albinism in relation to competition in bamboo *Phyllostachys bambusoides*

THE ecological consequences of albinism in plants have not been investigated, although the phenomenon has been considered by physiologists, geneticists and cytologists[1–7]. Production of albino offspring generally reduces parental reproductive value, because albinos die after seed reserves are depleted, and thus do not reproduce. This negative effect can be moderated if a recessive allele for albinism confers increased fitness in the heterozygous state[8–13]. I present here a hypothesis that, in species producing dense stands of seedlings subject to interspecific competition, albino offspring can confer a competitive advantage to photosynthetic siblings; the reduction in parental fitness due to albinism may thus be less than predicted on the basis of reduced number of offspring. A test using bamboo (*Phyllostachys bambusoides*) supports this proposal.

Production of albino offspring by a given parent at a given time could increase growth and survivorship of non-albino members of the same cohort if the albinos shade interspecific competitors, but impose less intense intraspecific competition than would the same number of photosynthetic seedlings. As albinos deplete their seed reserves and die, adjacent photosynthetic seedlings should expand their crown and root systems to fill the space. Shading of competitors is thus maintained. Decomposition of albinos will release nutrients which can be absorbed by surrounding plants. The parental investment of resources in albino seeds may therefore be regained in part by photosynthetic offspring. The amount regained will depend on intensity of interspecific competition, as well as on rate of nutrient leaching from the soil.

This hypothesis was tested experimentally on Barro Colorado Island, Panama (9°10′N latitude, 79°51′W longitude, 50 m elevation). Green and albino seedlings of *P. bambusoides* Sieb. and Zucc. (Graminae), a monocarpic bamboo introduced from Asia, were grown alone and in competition with seedlings of *Sida acuta* Burm. f. (Malvaceae), a very widely distributed pantropical weed. The bamboo occurred as a dense clone approximately 5 m wide by 10 m long, with stalks of approximately 15 m. The bamboo was located on the edge of a large

clearing. It produced abundant seed between January 1975 and July 1976, and then died. Dense stands of seedlings appeared around the clone during the wet seasons of these years (May–December). Average seedling density on 19 May 1976 was 1,549±1,089 seedlings per m^2; 25.4±3.21% of all seedlings were albino. This ratio was also demonstrated during the wet season of 1975 (Carol Augspurger, personal communication). A one-to-three ratio of albino to green seedlings suggests that albinism is determined by a recessive gene. Average leaf area per seedling on 19 May was 1.4±0.32 cm^3 for green bamboo, and 1.4±0.40 cm^2 for albinos. *Sida acuta* was the only species producing abundant seedlings of uniform size in the same habitat as *Phyllostachys* at the time of the study. It is an herbaceous perennial growing to a maximum height of approximately 2 m in clearings and on forest edges.

Seedlings of both species were excavated on 6 May 1976. Mean height of excavated seedlings was 7.2±1.15 cm for green bamboo, 6.3±1.16 cm for albinos and 1.3±0.19 cm for *Sida*. Bamboo seedlings were approximately 2 weeks old at the time of collection, and all retained connections to seeds which seemed to contain endosperm. *Sida* seedlings were in the cotyledon stage and had not yet produced mature leaves. Seedlings were transplanted with bare roots to soil-filled clay pots 15.2 cm in diameter and 12.3 cm deep. Soil was a Frijoles clay[14], collected from a site near the bamboo clone, and thoroughly mixed. Seedling densities in each treatment are given in Table 1. There were no significant between-treatment differences in height for a given type of seedling at the beginning of the experiment. Height was linearly correlated with dry weight in a series of non-experimental seedlings: for green bamboo $r = 0.81$, $P < 0.01$, $n = 44$; for albino bamboo $r = 0.88$, $P < 0.01$, $n = 44$; for *Sida* $r = 0.84$, $P < 0.01$, $n = 45$. Each experimental treatment was replicated twice. The two replicates were initiated at different times during the planting period, to avoid between-treatment differences due to time of planting. Lack of sufficient *Sida* seedlings of uniform size prevented greater replication. A carefully measured grid system was used to ensure uniform spacing of seedlings. In treatments containing more than one seedling type, seedlings were arranged in regular alternating sequences (ABAB, AABAAB, ABACABAC, and so on) determined by relative proportions of each type.

Pots were placed in a growing house with walls and roof of insect screening. A clear plastic sheet was used to eliminate rain. The growing house was in a clearing and could receive direct insulation from mid-morning until mid-afternoon. The experiment took place during the wet season, when cloudy weather was predominant. Each pot received 60 ml of untreated water from Lake Gatun every other day. Location of each pot relative to others was randomised and changed every other day to avoid position effects. All seedlings which died during the first 2 d after planting were replaced. Replacement of albino seedlings was continued for 2 weeks after planting. Initial mortality of albinos seemed to result primarily from damage to seedling-seed connections during planting and was evenly distributed among treatments. Marked albino plants in the field did not die during this period. The experiment was terminated after 37 d, when all albinos had died. Marked albinos in the field had also died by this time. Dead seedlings decayed very rapidly due to fungal attack. Seedlings were cut at ground level, dried to constant weight at 70 °C, and weighed.

Results (Table 1) are consistent with the hypothesis. Green bamboo seedlings grown in pure culture at three densities showed lowest mean dry weight per plant at highest density. This demonstrates intraspecific competition, a necessary condition for the hypothesis. Green bamboo grown at intermediate density with an equal number of albinos, however, did not differ significantly in dry weight from green bamboo in pure culture. Thus, albino and green bamboo do not seem to compete. Green bamboo grown at low and intermediate densities in the presence of *Sida* had significantly lower mean dry weight per plant than did plants grown in pure culture at the same densities, demonstrating interspecific competition. When green and albino bamboo were grown together in the presence of *Sida*, however, mean dry weight per green bamboo plant was not significantly different from that for controls. Mortality of *Sida* seedlings was much greater in the presence of a mixed green–albino population than when grown only with green bamboo or only with albino bamboo. Differences among means for *Sida* dry weight were not statistically significant. Mortality of green bamboo was too low to permit meaningful comparisons among treatments.

This experiment provides the first evidence that plants with a lethal genotype can confer a competitive advantage to siblings with non-lethal genotypes. The primary result of this competitive effect in natural populations might be a reduction in the intensity of selection against albinism; the fitnesses of parents producing partially albino cohorts could remain lower than fitnesses of parents producing entirely photosynthetic cohorts despite the competitive effect. To be of adaptive value, the benefits of improved competitive ability would have to outweigh the energetic cost of producing seeds with albino genotypes, the cost of reduced number of viable offspring, and potentially, the cost of reduced genetic variability among viable offspring due to reduced numbers. Surveys are planned to determine if the phenomenon is likely to occur in natural populations. Regardless of its importance in natural conditions, agricultural applications of this effect should be considered.

I thank Carol Augspurger for calling my attention to albinism, and Drs Egbert G. Leigh, Jr, Richard I. Yeaton, David

Janos, and Daniel H. Janzen for criticism of the manuscript. Research was supported by the Smithsonian Tropical Research Institute.

Increased homoeologeous chromosome pairing in *Hordeum vulgare* x *Triticum aestivum* hybrids

WHEAT and barley are the most important cereals in the agriculture of temperate zones. Although both genera belong to the same tribe, Triticeae, apparently successful crosses between wheat and barley have been reported recently[1,2]. I report here the production, morphology and cytology of F_1 hybrids of *Hordeum vulgare* L. cv Betzes × *Triticum aestivum* L. cv Chinese Spring.

The emasculation of barley, the maternal parent, pollination by wheat pollen, application of the gibberellin GA_3 to pollinated florets and subsequent excision and culture of hybrid embryos on a nutrient medium were performed as described before[3]. From the 372 florets pollinated, 44 embryos were obtained of which four seedlings (9.0%) survived. Examination of root-tip squashes revealed $2n=28$ chromosomes, the expected number in such hybrids. Further confirming evidence for hybridity was obtained from studies of esterase patterns of leaf tissue in the hybrids. The hybrid pattern was a combination of the differential parental bands. No hybrid bands were detected (Fig. 1*b*).

The hybrid plants were as vigorous as the parents and had foliage of characteristic light green colour. Unlike either parent with the exception of colour and plant height, which was intermediate to the parents, the phenotype was typically paternal. The wheat-like pubescent auricles were evident from the early seedling stage to maturity. The spikes differed slightly from those of wheat by being somewhat longer and more lax with awnletted lemmas (Fig. 1*a*). Pollen grains of the hybrid were empty and shrivelled, the anthers were minute and indehiscent, and the plants were completely male sterile. A small number of seeds was obtained by pollinating the hybrid with wheat pollen, indicating some degree of female fertility.

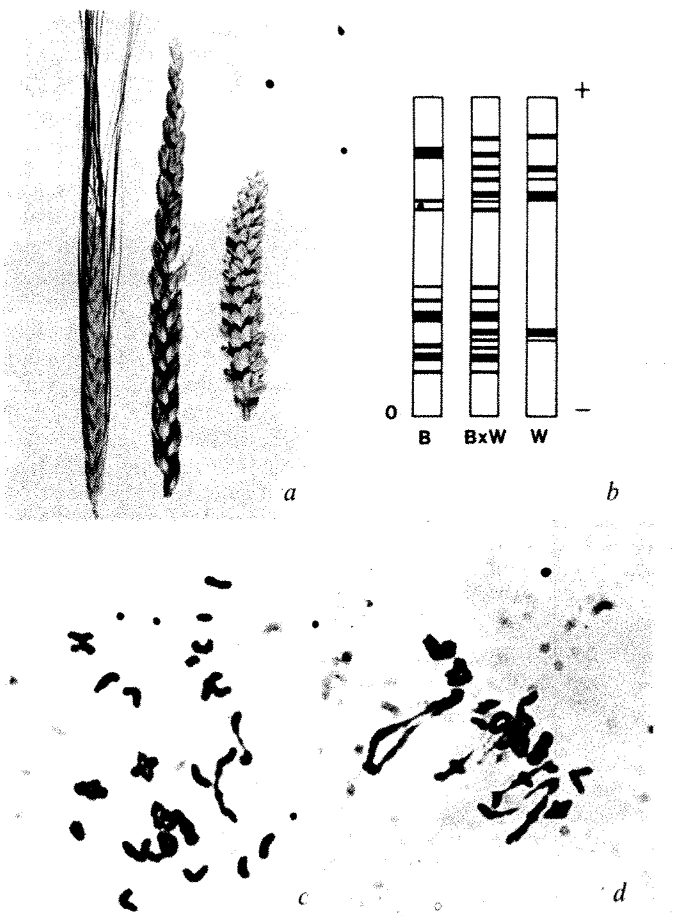

Fig. 1 *a*, Spikes of (left to right) barley; barley–wheat hybrid; wheat. *b*, Diagram of acrylamide gel electrophoresis of esteresa isozymes from leaf tissue of: barley (B); barley–wheat hybrid (B+W); wheat (W); *c*, metaphase I in barley–wheat hybrid showing one trivalent, 6 bivalents, 18 univalents (6 dyads and 12 monads) the latter indicative of equational division (×428); *d*, Metaphase I in barley-wheat hybrids showing one hexavalent, one quadrivalent, eight bivalents and two univalents (×428).

Meiotic behaviour in the four barley–wheat hybrids was similar; therefore the data were combined (Table 1). Meiotic configurations at metaphase I in individual cells ranged from 21 univalents with a considerable amount of equational division at anaphase I; to cells with five or more ring bivalents (Fig. 1*c*) or a combination of complex configurations such as quadrivalents and hexavalents (Fig. 1*d*) to give mean frequencies per cell of 19.88 univalents, 1.72 bivalents, 0.40 trivalents, 0.12 quadrivalents and 0.03 hexavalents.

A portion of the chromosome pairing in the barley–wheat hybrids would be expected to be of the autosyndetic type not unlike that observed in the haploids of both

Table 1 Mean chromosome pairing at first metaphase of meiosis in F_1 hybrids from crosses between *H. vulgare* and *T. aestivum* compared to haploids of the two species and other intergeneric hybrids

	Configurations							
Genotype	I	II	III	IV	V	VI	Xta.per cell	No. of cells
H. vulgare × *T. aestivum*	19.88	1.72	0.40	0.12	—	0.03	1.82	422
T. aestivum—haploid[4]	18.84	1.05	0.02	—	—	—	—	750
H. vulgare—haploid[5]	6.90	0.04	—	—	—	—	—	589
Sum of barley and wheat haploids	25.74	1.09	0.02	—	—	—	—	
T. aestivum × *T. longissimum*[6]	24.56	1.69	0.02	—	—	—	1.75	—
T. aestivum × *T. tripsacoides*[7]	—	—	—	—	—	—	1.51	50

species. The number of paired chromosomes in the barley–wheat hybrids, however, exceeded the sum total of paired chromosomes in haploid barley and haploid wheat (Table 1). Genotypes in diploid wheat species such as *T. tripsacoides*[7] (*Ae. mutica*) and *T. longissimum*[6] suppress the effect of diploidising genes in wheat to variable degrees. A mean chiasmata per cell of 1.82 in the barley × wheat hybrids indicates that the barley genotype may also suppress the diploidising system in Chinese Spring similar to that of the weak suppressors reported in *T. tripsacoides*[7] and *T. longissimum*[6] which showed 1.51 and 1.75 chiasmata per cell, respectively, in hybrids with Chinese Spring. The data suggest that in barley as in some diploid *Triticum* species a locus (or loci) has evolved that permits some homoeologous pairing in hybrids with unrelated species. It remains to be determined whether there are extensive intraspecific differences in the genus *Hordeum*, as there are in certain species of the genus *Triticum*, for genes that relax the suppression of homoeologous pairing of wheat chromosomes. The infrequent occurrence of a heteromorphic bivalent at metaphase I suggested that there may be some homology between chromosomes of barley and wheat, providing an alternative explanation for the increased pairing in the hybrid above the sum of the two haploids. The application of Giemsa staining techniques for meiotic chromosomes in barley–wheat hybrids could help to solve this problem.

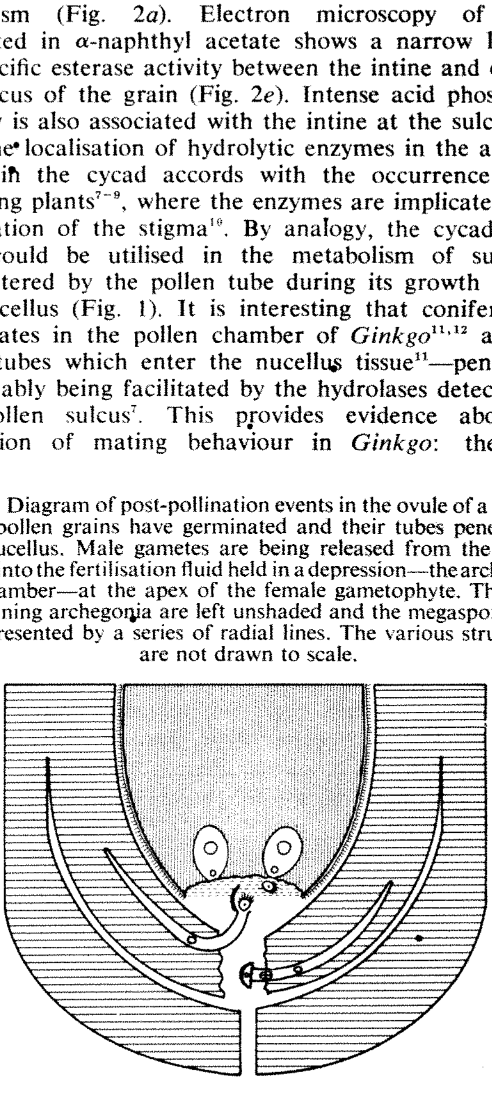
Detection in primitive gymnosperms of proteins and glycoproteins of possible significance in reproduction

THE modern cycads are the remnant of a gymnosperm group that has been in existence for at least 200 Myr[1]. Cycads are dioecious, with separate male and female plants, and fertilisation is effected by motile male gametes—so-called zooidogamous reproduction. Zooidogamy is found also in *Ginkgo*, another dioecious gymnosperm of considerable antiquity[1]. Reproduction in all other gymnosperms and in flowering plants is siphonogamous. Here fertilisation occurs through a pollen tube which conveys the non-motile male gamete to the egg. A pollen tube is produced in the zooidogamous gymnosperms, but it is not involved in gamete transfer; it simply anchors the male gametophyte to the ovule during gametogenesis (Fig. 1). The ripe male gametes are released to swim freely in a pool of fluid bathing the openings of the egg-containing archegonia (Fig. 1). It is not known how the gametes that carry out fertilisation are selected in these plants. Dioecism ensures outcrossing, but there is presumably some form of intraspecific screening. The male gametophyte or male gamete could, for example, identify itself to the parent of its prospective mate, or the male gamete to the egg cell at the threshold of syngamy. I report here the occurrence in cycads of proteins and glycoproteins at sites in the pollen grain and ovule where they might be involved in reproduction.

Nonspecific esterase activity was detected in cryostat sections of *Macrozamia reidlei* pollen slurries using 5-bromoindoxyl acetate and α-naphthyl acetate as substrates, the latter in a coupling reaction with fast blue B salt[2]. For electron microscopy, the pollen was incubated in the reaction mixture before glutaraldehyde fixation and osmium post-fixation. Controls were run without substrate in all tests. Acid phosphatase activity was localised in freeze-sectioned pollen by Gomori's lead salt method[3] and the controls were incubated in the reaction mixture containing 0.01 M sodium fluoride. Nonspecific esterase activity was localised in cryostat sections of fresh *Cycas thouarsii* ovules by the indigogenic method. Acid phosphatase was investigated in ovules in the same way as for the pollen. Concanavalin A (con A)-binding sites in the megaspore wall of *C. thouarsii* were revealed ultrastructurally in glutaraldehyde-fixed ovules by coupling with horseradish peroxidase (HRP) and diaminobenzidine (DAB)[4], and by fluorescence microscopy in fresh, frozen sections with con A labelled with fluorescein isothiocyanate (con A-FITC, L'Industrie Biologique Française). The con A in the controls for both methods contained 0.2 M α-D-methyl mannoside[5]. Homogenates of *C. siamensis* megagametophytes were prepared in buffered saline, filtered and dialysed against water. The dialysate was concentrated and the concentrate was tested for ability to agglutinate trypsinised, human O+ erythrocytes and analysed by sodium dodecyl sulphate (SDS)–polyacrylamide electrophoresis[6] after dissociation of the proteins in mercaptoethanol and SDS. The gels were stained with Coomassie blue for proteins and the periodic-acid-Schiff technique for carbohydrates.

Proteins with enzymatic properties are contained in the pollen grain wall and the cytoplasm of the male gametophyte in *M. reidlei*. The indigogenic method reveals discrete granules of nonspecific esterase activity in the tube cell cytoplasm (Fig. 2*a*). Electron microscopy of pollen incubated in α-naphthyl acetate shows a narrow layer of nonspecific esterase activity between the intine and exine at the sulcus of the grain (Fig. 2*e*). Intense acid phosphatase activity is also associated with the intine at the sulcus (Fig. 2*c*). The localisation of hydrolytic enzymes in the apertural intine in the cycad accords with the occurrence in the flowering plants[7–9], where the enzymes are implicated in the penetration of the stigma[10]. By analogy, the cycad hydrolases could be utilised in the metabolism of substrates encountered by the pollen tube during its growth through the nucellus (Fig. 1). It is interesting that conifer pollen germinates in the pollen chamber of *Ginkgo*[11,12] and produces tubes which enter the nucellus tissue[11]—penetration presumably being facilitated by the hydrolases detectable at the pollen sulcus[7]. This provides evidence about the regulation of mating behaviour in *Ginkgo*: the ovule

Fig. 1 Diagram of post-pollination events in the ovule of a cycad. Two pollen grains have germinated and their tubes penetrated the nucellus. Male gametes are being released from the lower grain into the fertilisation fluid held in a depression—the archegonial chamber—at the apex of the female gametophyte. The egg-containing archegonia are left unshaded and the megaspore wall is represented by a series of radial lines. The various structures are not drawn to scale.



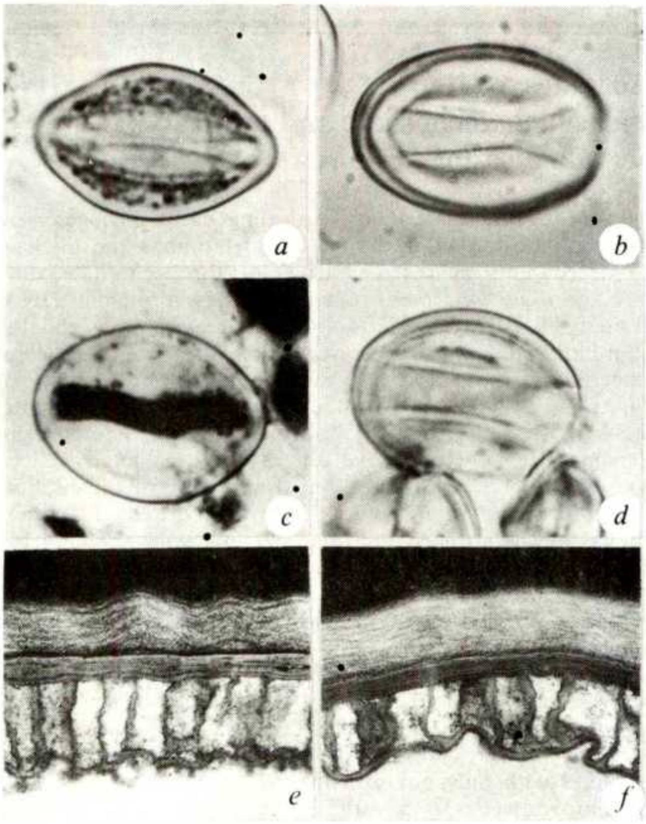


Fig. 2 Pollen of the cycad *M. reidlei*. *a*, Nonspecific esterase activity (× 1,000). *b*, Esterase control (× 1,000). *c*, Acid phosphatase activity (× 1,000). *d*, Acid phosphatase control (× 1,000); *e*, Electron microscope localisation of nonspecific esterase activity between the exine and intine at the sulcus (× 20,000). *f*, Control for (*e*) (× 20,000).

possesses no capacity for suppressing germination or frustrating the growth of the pollen tube in wide pollinations.

The female gametophyte in the zooidogamous gymnosperms is contained by a multilayered megaspore wall, comparable with the flowering plant pollen wall[13]. During development material derived from autolysis of the sporophyte cells immediately external to the gametophyte accumulates in the chambered outer layer (exine) of both walls. In the flowering plants the source cells comprise the tapetum[10,14,15] and in the gymnosperm ovule they are the inner layers of the nucellus[13]. There is a degree of chemical conformity between the walls and sporophytic loads in the two groups. Strong nonspecific esterase activity, indubitably of sporophytic origin, is found in the residue resulting from the breakdown of the nucellus cells in *C. thouarsii* ovules (Fig. 3*a*). There is no detectable acid phosphatase activity. Esterases, but not acid phosphatase, occur in the pollen exines of many flowering plants and their activity is judged a characteristic marker for the transfer of proteins from the tapetum to the pollen grain surface[16].

My experiments have demonstrated a carbohydrate moiety in the cycad megaspore wall able to bind con A. Electron microscopy shows that in *C. thouarsii* con A is bound specifically to the surface of an electron-lucent wall component incorporating sporopollenin droplets derived from the nucellus cells (Fig. 3*c*). Moderate to strong FITC fluorescence is emitted by the degenerating nucellus cells and by the megaspore exine in freeze-sectioned ovules treated with con A–FITC (Fig. 3*e*), the fluorescent material on the wall corresponding to the con A-binding layer observed in con A–HRP coupling. The specificity of con A towards oligosaccharides with terminal glucose and mannose residues is well authenticated[17], and acceptor sites for it are present in the pollen wall[18] and stigma surface pellicle—the receptor site for pollen-borne recognition molecules[19–21]—in flowering plants[22,23]. If the pellicle is coated with con A, penetration of the stigma is prevented in compatible pollinations[23], suggesting that the con A sites are necessary to one level of acceptance response in the reproduction of flowering plants. This cannot apply in the cycad megaspore, because above the archegonia the wall is dispersed before the male gametes are released (Fig. 1). But if this process is contingent on necrosis of the female gametophyte tissue to form the archegonial chamber (Fig. 1), the fertilisation pool could hold in solution molecules from both components. A concentrated extract of megagametophyte plus wall of *C. siamensis* haemagglutinates trypsinised human erythrocytes (Fig. 4*a*), signifying the presence of a phytohaemagglutinin or lectin[24]. Electrophoretic analysis of the extract reveals nine protein bands (Fig. 4*c*) three of which give a reaction for carbohydrates (Fig. 4*d*). In the conditions

Fig. 3 Ovule of cycad *C. thouarsii*. *a*, Nonspecific esterase activity in the degenerating nucellus cells. Cells were treated with 0.15 M saline instead of extract. *c*, Protein bands in an SDS–polyacrylamide gel of the extract. *d*, Complementary gel stained for carbohydrates.

of the run these are likely to mark carbohydrates of glycoproteins.

This finding offers an intriguing possibility for the control of intraspecific mating in the primitive, zooidogamous gymnosperms. It has been suggested that lectins in plants have a defence function and may also be involved in the determination of self-recognition between cells[25]. Lectins interact with animal cells[24] and with plant cell protoplasts[26] and can detect intraspecific variations in surface oligosaccharides[24]. As a consequence of these properties a function in recognition can be envisaged for the lectin in the gymnosperm ovule: as a constituent of the fertilisation pool it could be involved in discrimination between male gametes.

Financial support from the Research Fund of the University of London is acknowledged. I thank the Director, Royal Botanic Gardens, Kew, for permission to collect material, Professor R. B. Knox for helpful discussion and Dr A. E. Clarke, Dr K. Roberts and Mr G. Ross for technical advice.

Isozymes of a tunicate and a cephalochordate as a test of polyploidisation in chordate evolution

IN view of the uncertainty regarding early phylogeny of the chordates[1,2], Atkin and Ohno[3] determined the nuclear DNA contents of representatives of three chordate subphyla. *Ciona intestinalis* (Tunicata) has a diploid DNA content of 0.42 pg, while *Amphioxus lanceolatus* (Cephalochordata) contains 1.2 pg—very close to the 1.4 pg considered as the basic vertebrate value[4,5]. Assuming a tunicate-like ancestry of the cephalochordate-vertebrate stock[6–9], Ohno[10] proposed that the threefold difference in genome size between *Ciona* and *Amphioxus* might reflect the occurrence of at least one round of polyploidisation preceding vertebrate evolution. To test further this hypothesis we determined the number of genes coding for various enzymes in *C. intestinalis* and *Branchiostoma* (*Amphioxus*) *lanceolatum*. Only few genetically interpretable isozyme data from *B. lanceolatum* have been reported[11,12]. An isozyme study on a related species, *B. moretonensis* has been published recently[13]. Systematic isozyme investigations in tunicates have not been reported before. We report here that *C. intestinalis* and *B. lanceolatum* have identical gene numbers for homologous enzymes with only one exception.

Comparative isozyme studies have proved a powerful tool in substantiating ancestral diploid–tetraploid relationships, for example in teleostean fish[14] and various examples of gene duplication in mammals including man have been taken as support of the idea of ancestral polyploidy in this taxonomic category[15,16]. Thus, if relative to *Ciona*, *Branchiostoma* represents an ancestrally polyploid organism, it is conceivable that it still possesses an increased number of functional gene loci. Table 1 summarises the results of our electrophoretic investigations. Data from 10 of the 12 isozyme systems analysed were interpretable in each, *Ciona* and *Branchiostoma*. Of these, nine lend themselves to a direct comparison: five enzymes seem to be encoded for by a single gene locus in *Ciona* as well as *Branchiostoma*; one system (AAT) is clearly encoded for by two gene loci in both organisms, whereas the number of loci underlying the multiple zones of superoxide dismutase activity remains unclear, since only the slowly migrating zone resolved into sharp bands. The NAD-MDH pattern observed in *Ciona* is best interpreted by the assumption of two loci while in *Branchiostoma* a third, additional NAD-MDH locus is present. Multiple zones of esterase activity were seen when 4-methylumbelliferyl-acetate was substrate. The dimeric enzyme seen in human tissue in these conditions[17] appeared in *Branchiostoma* only.

Our data do not support the polyploidisation hypothesis of Ohno, since in one isozyme system only (NAD-MDH) *Branchiostoma* is endowed with a higher number of genes than *Ciona*. It should be emphasised, however, that our data do not contradict a polyploidisation hypothesis. In the course of regaining diploidy, a tetraploidised organism tends to functionally eliminate the duplicate genes by accumulation of 'forbidden' mutations, unless some special selection pressure favours their maintenance[5,14,18,19]. *Branchiostoma*, if anciently polyploid, may already have silenced the majority of duplicated genes. It should be mentioned that with respect to the ribosomal DNA content, apparently subject to especially drastic change during evolution[20], there is a 1 : 6 ratio between *Branchiostoma* and *Ciona*[21]. The failure to detect more duplicated genes in *Branchiostoma* using the whole body extracts from adult animals may also be due to a possible differential activity of gene duplicates during development and/or in different

All animals were caught in the North Sea at Helgoland. *C. intestinalis* individuals were freed from their tunics before further preparation. All animals were homogenised in 0.01 M phosphate buffer, *p*H 7.4, containing 10^{-4} M $MgCl_2$, in a glass–glass homogeniser, and the 20,000*g* supernatants were subjected to horizontal starch gel electrophoresis. All enzymes were analysed in gels consisting of 14% starch in 0.08 M Tris/0.03 M citrate buffer, *p*H 8.0 (bridge: 0.223 M Tris/0.068 M citrate buffer, *p*H 8.0) except esterase, adenosinedeaminase glyoxalase and superoxide dismutase (the latter in the case of *Branchiostoma* only); these enzymes were investigated in 13% starch in 0.006 M potassium phosphate buffer, *p*H 7.4 (bridge: 0.375 M. potassium phosphate buffer, *p*H 7.4). Staining was performed by conventional methods[17, 24–26]. Attempts to stain lactate dehydrogenase, glucose-6-phosphate dehydrogenase, sorbitol dehydrogenase and alcohol dehydrogenase were either unsuccessful or yielded results too poor for genetic interpretation. MDH, maleate dehydrogenase; IDH, isocitrate dehydrogenase; 6–PGDH, 6–phosphogluconate dehydrogenase; AAT, aspartate amino transferase (GOT); PGM, phosphoglucomutase; PGI, phosphoglucose isomerase.

*Most cathodal variant first.

organs[5,12]. Furthermore, as Ohno[5] has pointed out, duplicated genes may have been altered with respect to kinetic properties, *p*H and temperature optima, and substrate specificity. Thus their detection by standard electrophoretic and staining procedures may be prevented.

An alternative to the polyploidisation hypothesis is that the common ancestor of tunicates—cephalochordates and vertebrates already possessed a DNA content similar to the basic present-day vertebrate value, and that during the evolution and specialisation of the tunicates an appreciable part of the nuclear content was lost. Loss of nuclear DNA content concomitant with specialisation has been noted by Hinegardner[22].

As pointed out by Ohno[10] a further alternative to the polyploidisation hypothesis relies on the assumption that the genome size increase in *Branchiostoma* relative to *Ciona* (or its ancestor) was due to accumulation of repetitious DNA. It has been shown[23] that the *Ciona* genome contains approximately 30% repetitive DNA, but the genome composition of *Branchiostoma* is not known. Its analysis might clarify chordate interrelationships.

We thank the Biologische Anstalt Helgoland for supply of materials and laboratory space. This work was supported by the Deutsche Forschungsgemeinschaft.

Similarity of the general designs of protochordates and invertebrates

THE protochordate amphioxus is clearly differentiated from the invertebrates by most taxonomic criteria[1,2], and is recognised as the organism most closely resembling the early fish-like vertebrate progenitors[3,4]. Recently, however, Manwell[5] has provided evidence that, with respect to enzyme variability, amphioxus resembles invertebrates rather than vertebrates. We report here that, in terms of gross sequence characteristics of DNA, amphioxus and two other protochordates, *Ascidia mentula* and *Ciona intestinalis*, more closely resemble the DNAs of the invertebrates, echinodermata and brachiopoda, rather than the DNA of higher vertebrates (craniata).

Characterisation of the DNA was by nearest-neighbour two-base sequence (doublet frequency) analysis and subsequent determination of the patterns of deviation from random expectation of the doublet frequencies (general designs)[6–8]. The technique of doublet frequency analysis, originally developed by Kornberg and his colleagues[9–11], measures the frequencies of occurrence of the sixteen possible doublet sequences in DNA. Normalisation of the observed doublet frequencies to give the general design yields a characteristic pattern which has six degrees of freedom for a double-stranded DNA. Expressing doublet frequencies as patterns of deviation from random expectation removes the components of variation in frequency which are a consequence of base composition alone, leaving an underlying pattern of sequence-dependent characteristics which are independent of G+C content. This is a very stable characteristic of DNA (refs 7 and 12), and similarity in general designs in DNAs is considered to reflect past response to similar or identical evolutionary selection pressures (and is thus a measure of evolutionary relatedness). When general designs were calculated from the results of Swartz *et al.*[10] for three echinoderms (2 echinoidea and 1 asteroidea) and six vertebrates (1 fish, 1 bird and 4 mammals), the echinoderm and vertebrate DNAs fell into two readily distinguishable groups while the DNAs within each group were closely similar[12].

Table 1 gives the doublet frequencies and base compositions of three protochordate DNAs from amphioxus (*Branchiostoma lanceolatum*), *Ciona intestinalis* and *Ascidia mentula*, two brachiopod DNAs from *Crania anomala* and *Terebratulina* sp. and two echinoderm DNAs from *Antedon bifida* (Crinoidea) and *Thyone fusus* (Holothuroidea). The lower craniates are represented by the DNAs of two fish; the primitive cartilagenous dogfish (chondrichthyes) and the higher bony fish, coelacanth (osteichthyes; crossopterygii). For comparison, Table 1 includes the doublet frequencies determined by Swartz *et al.*[10] for the echinoderm, *Echinus esculenta* (Echinoidea) and the higher fish, salmon (Osteichthyes; Actinopterygii), the most primitive vertebrate previously analysed. Also shown are the G+C contents gained from doublet frequency data and, where available, from buoyant density determinations. The observation that G+C contents calculated from doublet frequency data are generally slightly lower than those given by buoyant densities has already been noted[8,13]. It is relevant that none of the DNAs was found to contain any significant proportions of density satellite DNAs. Even on close examination of the doublet frequency data of Table 1, it is difficult to come to any firm conclusions with regard to comparisons of the invertebrate and craniate DNAs. However, when the general designs (that is, functions of sequence characteristics independent of total base composition) are compared (Fig. 1), those of the protochordates are found to be very similar, not only to each other, but also to the general designs of the echinoderms and brachiopods. Like these invertebrates, the protochordates differ from the lower craniates with particular reference to the relative frequencies of the doublets AG-CT and CG.

Evaluation of the differences seen in the histogram presentation of the general designs was achieved by cluster analysis using the weighted average linkage method[14] with Euclidean squared distance. This was done for the general designs shown in Fig. 1 together with those of the DNAs of the higher vertebrates: guinea pig (Mammalia), chicken (Aves) and bullfrog (Amphibia) and the echinoderms *Paracentrotus lividus* (Echinoidea) and *Asterais rubens* (Asteroidea). The resulting dendrogram (Fig. 2) clearly shows that the craniate and protochordate DNAs fall into separate groups. The protochordates are indistinguishable from the invertebrates by this method. The small differences within the protochordate–invertebrate group are not much greater than the experimental error inherent in doublet analysis[13], and differences in undetected satellite populations could have contributed here. The larger differences seen within the vertebrates are undoubtedly real with the design remaining stable from mammalia to amphibia, but with differences becoming pronounced at, and within, the fish. Some of these differences may be due to satellite DNAs, but in the dogfish the general design for slow renaturing nuclear DNA is identical to that of total nuclear DNA (unpublished results).

'Total DNA' preparations were purified from tissue homogenates (1 g per 5 ml 0.15 M NaCl, 0.1 M EDTA; *p*H 8.0) by treatment with SDS and Pronase[15], followed by two cycles of banding at equilibrium in neutral CsCl buoyant density gradients[16]. Density satellite DNAs were not detected in these preparative gradients and each DNA appeared as a single band in analytical neutral density gradients. Doublet frequencies of the purified DNAs were determined as described by Josse *et al.*[9] with minor modifications[17,18]. The percentage base compositions and G+C contents were determined from doublet frequency data. Also given are the G+C contents derived from the buoyant density measurements shown. Exceptions are *Antedon** and coelacanth* where the molecular weights of the isolated DNAs were too low for accurate evaluation of the peaks. Doublet frequencies are expressed in doublets per 1,000 and doublets shown in pairs are the dependent doublets[7,8], that is, those doublets which are complementary in the anti-parallel strands and are theoretically present with equal frequencies in double-stranded DNA. The observed values therefore give no measure of the frequencies on any one strand of the DNA. Doublets shown singly are the independent doublets, each being its own anti-parallel complement with the observed values being true for either strand of the DNA.

It can therefore be concluded that, in terms of gross sequence characteristics, protochordate DNA more closely resembles the DNAs of the invertebrates, echinodermata and brachiopoda, than the DNAs of the craniates. Other invertebrate DNAs which have so far been examined (for example, arthropod DNAs; G.J.R. and J.H.S.-S., in preparation) are even more dissimilar to the craniate pattern than the protochordate, echinoderm and brachiopod DNAs.

On the basis of taxonomic criteria[1,2], amphioxus has become accepted as the 'prototype' chordate closely related to the ancestors of the earliest craniates[3,4]. However, using the criterion of enzyme polymorphism, Manwell has now suggested that the protochordate amphioxus is much more like invertebrates than vertebrates. Our findings, based on a very stable general characteristic of the total genome, not only provide strong support for Manwell's observation, but also show that the protochordates as a group relate much more closely to the higher invertebrates than to the craniates.

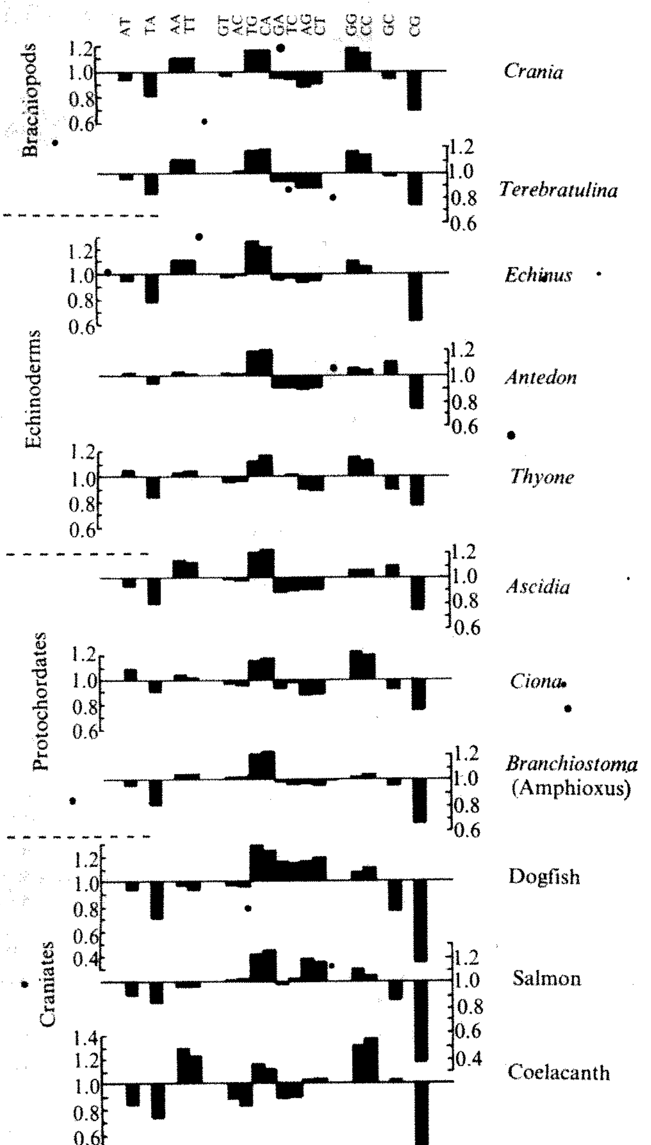

Fig. 1 Deviations from random expectation. Patterns of deviation from random expectation were determined from the doublet frequencies and base compositions shown in Table 1 by calculating the ratios of the observed doublet frequencies to the expected random frequencies[8]. The expected random frequency of a particular doublet is the product of the frequencies of the bases comprising that doublet. Both doublet frequencies and the base frequencies were expressed as fractions of unity in order to determine the ratios. A doublet with a random frequency would therefore give a ratio of one and the results are expressed in histogram form as deviations from unity. The doublet CG in salmon, for example, has a frequency of 17 doublets per 1,000 (0.017). The two bases, C and G, occur with frequencies of 22.1% (0.221) and 21.0% (0.220) respectively. The expected random frequency of a two-base sequence containing C and G is therefore $0.221 \times 0.220 = 0.046$, and the ratio of the observed frequency of CG to the expected random frequency is therefore $0.017/0.046 = 0.37$, that is, salmon DNA has only 0.37 times the expected amount of CG.

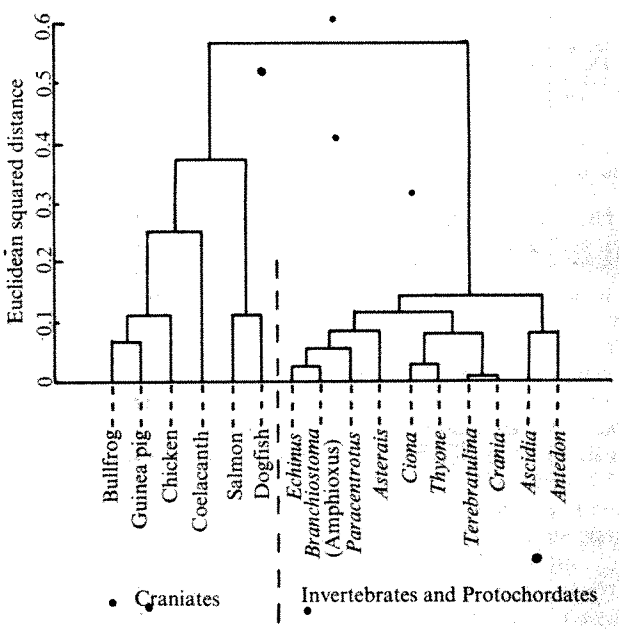

Fig. 2 Cluster analysis of the general designs of vertebrate, protochordate, echinoderm and brachiopod DNAs. The weighted average linkage method was used with Euclidean squared distance (that is, the sum of the squares of differences of ratios of observed to random frequencies between two DNAs) as the measure of distance[14]. The general design values for chicken, salmon, *Echinus*, *Paracentrotus* and *Asterias* DNAs were calculated from the results of Swartz *et al.*[10]. The values for bullfrog DNA are from McGeoch[10] and those for guinea pig DNA are from Russell *et al.*[13].

Diversification of general designs in other invertebrate phyla are being further investigated for comparison with existing phylogeny. There clearly remains a wide gap between the protochordates (acrania) and craniates, and analyses of other primitive chordates, such as cyclostomata (lamprey), are obviously needed.

The doublet frequencies for *Echinus esculenta* and salmon are from Swartz *et al.*[10]. We thank Dr R. H. Harris, Liaison Officer of the Coelacanth Committee of the Royal Society, for providing the coelacanth tissue.

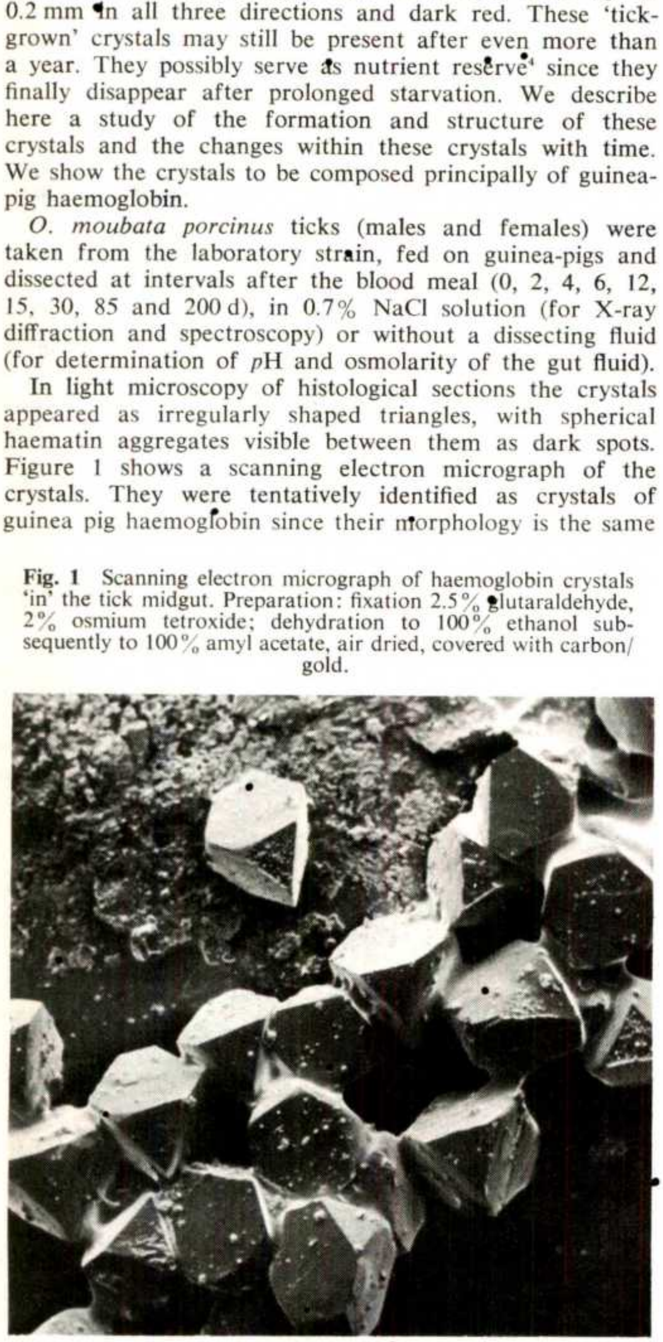
Haemoglobin crystals in the midgut of the tick *Ornithodorus moubata* Murray

Ticks of the *Ornithodorus moubata* Murray (Ixodoidea, Argasidae) complex, distributed through East Africa, are known as vectors of African relapsing fever[1]. A laboratory strain of *O. moubata porcinus* (originally from Tanzania and bred according to the method of Geigy and Herbig[1]) uses the guinea-pig (*Cavia porcellus* L.) as experimental host. Guinea pig blood crystallises more easily than that of other hosts[2] in the gut of blood-sucking arthropods[3]. In *O. moubata* crystals appear 5–10 d after the blood meal, first small (0.015–0.05 mm) and clear red, later up to 0.2 mm in all three directions and dark red. These 'tick-grown' crystals may still be present after even more than a year. They possibly serve as nutrient reserve[4] since they finally disappear after prolonged starvation. We describe here a study of the formation and structure of these crystals and the changes within these crystals with time. We show the crystals to be composed principally of guinea-pig haemoglobin.

O. moubata porcinus ticks (males and females) were taken from the laboratory strain, fed on guinea-pigs and dissected at intervals after the blood meal (0, 2, 4, 6, 12, 15, 30, 85 and 200 d), in 0.7% NaCl solution (for X-ray diffraction and spectroscopy) or without a dissecting fluid (for determination of *p*H and osmolarity of the gut fluid).

In light microscopy of histological sections the crystals appeared as irregularly shaped triangles, with spherical haematin aggregates visible between them as dark spots. Figure 1 shows a scanning electron micrograph of the crystals. They were tentatively identified as crystals of guinea pig haemoglobin since their morphology is the same as described for those crystals[5]. After soaking in a standard 3 M $(NH_4)_2SO_4$ solution buffered with 0.1 M potassium phosphate at *p*H 6.7 (*p*H measured after 10-fold dilution) the crystals were further characterised by taking 16° precession photographs of single crystals.

Fig. 1 Scanning electron micrograph of haemoglobin crystals 'in' the tick midgut. Preparation: fixation 2.5% glutaraldehyde, 2% osmium tetroxide; dehydration to 100% ethanol subsequently to 100% amyl acetate, air dried, covered with carbon/gold.



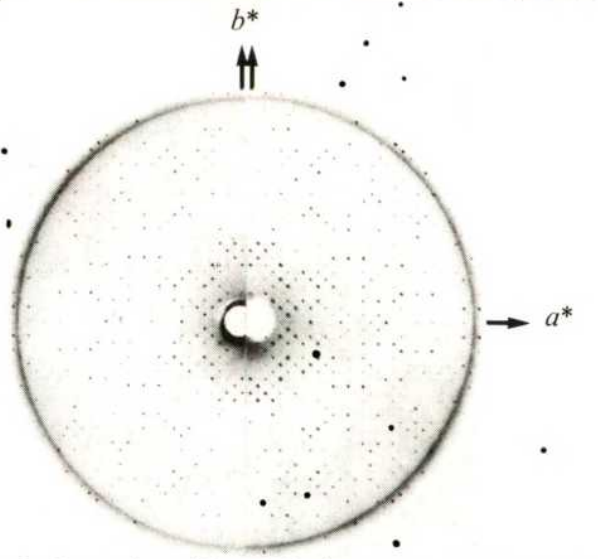


Fig. 2 Comparison of X-ray diffraction patterns of 'tick-grown' (left half) and '*in vitro*-grown' (right half) crystals. 16° Precession photographs (2.8 Å resolution) of the *hk*0-zone, CuKα radiation, graphite monochromator. Arrows indicate reciprocal axes.

Haemoglobin from guinea pigs of the same strain was purified on DEAE–Sephadex[6]. Single crystals of the major haemoglobin component (~80% of total haemoglobin) were grown from 1 and 4% solutions, using the Zeppezauer technique[7], from either 3 M $(NH_4)_2SO_4$ solutions, buffered with 0.1 M potassium phosphate at *p*H 6–7, or from 3 M potassium phosphate solutions in the same *p*H range. These '*in vitro*-grown' crystals were soaked in the same standard solution as the 'tick-grown' crystals and 16° precession photographs were taken for comparison.

The '*in vitro*-' and 'tick-grown' crystals are both orthorhombic and, since extinctions are observed for $h+k$ odd for general *hkl*- and for *l* odd for 00*l*-reflections, belong to space group $C222_1$. The cell dimensions are $a=84.5\pm0.05$ Å, $b=89.9\pm0.1$ Å (ref. 5), $c=83.1\pm0.05$ Å and they are the same for the two types of crystals. On the basis of the observed range of V_M values for a variety of protein crystals[8], there can only be four haemoglobin molecules (molecular weight 64,500 each) per unit cell. The V_M value[8] is then calculated to be 2.45 Å^3 per dalton. The alternative of eight tetramers per unit cell would lead to the unrealistically low V_M value of 1.22 Å^3 per dalton (<0% crystal solvent). Since space group $C222_1$ has eight general positions[9] the haemoglobin tetramers must lie on the crystallographic axes parallel to either the *a* or the *b* axis as has been found for reduced horse haemoglobin[10]. The intensity patterns to 2.8 Å resolution are identical on visual inspection for '*in vitro*-' and 'tick-grown' crystals (Fig. 2) and we therefore conclude that the 'tick-grown' crystals are in fact composed of guinea pig haemoglobin.

In order to exclude even small changes, such as scission of the chain at one or a few discrete points or limited degradation from the termini, which might explain why guinea-pig haemoglobin crystallises so readily in the midgut of *O. moubata*, we analysed the 'tick-grown' crystalline material by sodium dodecyl sulphate–polyacrylamide gel electrophoresis[11] (12.5% gels, cross linked 1: 15). The sharpness of the protein bands was dramatically increased by using sodium phosphate instead of Tris-HCl buffer. 'Tick-grown' crystals were thoroughly washed with standard 3 M $(NH_4)_2SO_4$ solution, to remove any non-crystalline material,

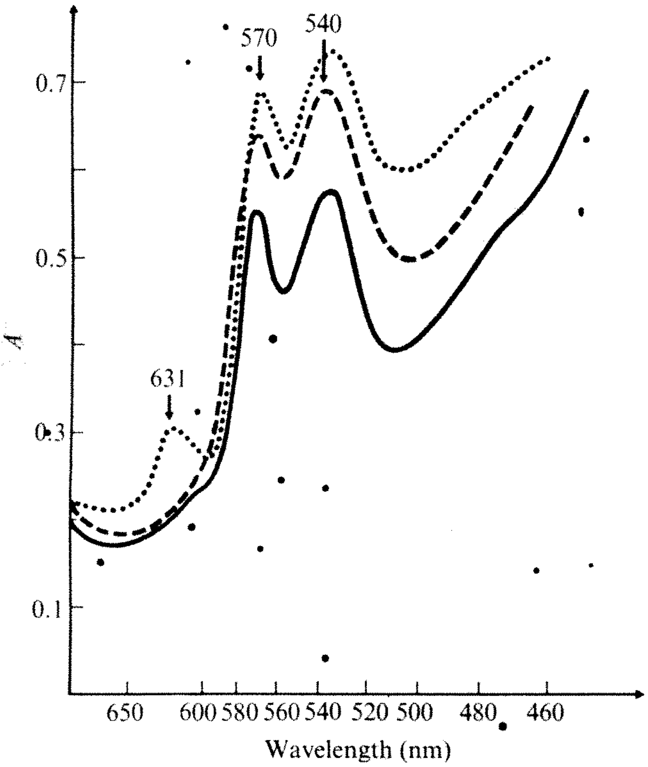

Fig. 3 Spectra from single 'tick-grown' crystals. Crystal from gut of male tick 6 d after blood meal on guinea pig (——). Crystal from gut of male tick 30 d after meal (· · · ·). Same crystal (30 d after meal) after addition of KCN to 0.01 M (– – –). The methaemoglobin peak at 630 nm disappeared after addition of KCN. Spectra were taken on the universal microspectrophotometer of the Wissenschaftlicher Dienst/Kriminalpolizei Zuerich. The wavelength scale is given by the dispersion of the quartz monochromator (M4QIII). Solvent was 3 M ammonium sulphate, 0.1 M potassium phosphate buffered at *p*H 6.7, saturated with CO. Specific absorption maxima occur for CO-haemoglobin at 540 and 570 nm, for aquomethaemoglobin at 631 nm, and for cyanmethaemoglobin at 540 nm. Conclusion—guinea pig haemoglobin crystallises in tick gut in oxy-form but transforms *in vivo* into methaemoglobin crystals with time.

and subsequently dissolved in sodium phosphate buffer. The main haemoglobin component of guinea pig blood served as a reference. In these conditons are α and β chains of guinea pig haemoglobin are clearly separated in the crystalline material and the reference haemoglobin. The R_F values are 0.452 and 0.502 for the two bands of the crystalline material and 0.448 and 0.491 for the reference haemoglobin. Calibration with lysozyme, human globin A and myoglobin and the difference in relative mobility between α and β chains of guinea pig haemoglobin yielded a difference in molecular weight of about 650. In human haemoglobin[12] the difference between α and β chains is 741 daltons. On ageing the guinea pig haemoglobin preparation gave broader electrophoretic bands as observed for carp haemoglobin[13]. The combined probe of 'tick-grown' crystalline material and fresh haemoglobin showed only two bands demonstrating the lack of significant fragmentation or extensive degradation from the termini. Removal of only one or two residues cannot be entirely excluded.

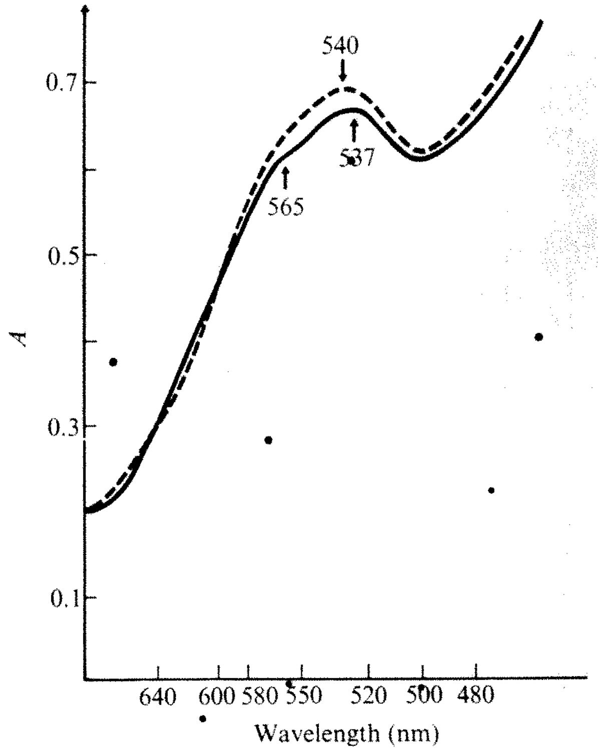
A still more sensitive test for the conformation of haemoglobin and the oxidation state of its iron in 'tick-grown' crystals is visible absorption spectroscopy on single crystals and comparison with absorption spectra of haemoglobin in solution[14]. Conversions of crystalline haemoglobin were followed by recording spectra from single crystals of different age (Fig. 3) obtained at different time intervals after the blood meal. Immediately after dissections the contents of the midguts were brought under a CO atmosphere to freeze the momentary equilibrium between Fe^{2+} and Fe^{3+}. From Fig. 3 we conclude that haemoglobin crystallised in the tick midgut in the oxy-form but with time it transformed into methaemoglobin. This, however, is not the end state of the crystalline haemoglobin since the absorption spectra of single crystals from a tick dissected 15 months after its last blood meal show a typical haemichrome absorption spectrum with a single absorption maximum at 537 nm and a shoulder at 565 nm (Fig. 4, solid line). On soaking in a cyanide-containing solution (standard 3 M $(NH_4)_2SO_4$, 0.01 M KCN) the absorption maximum at 537 nm shifts to 540 nm and the shoulder at 565 nm almost disappears (Fig. 4, dashed line). Thus the haemichrome is not yet entirely in its irreversible state since, on KCN addition, it can be partially converted to cyanmethaemoglobin. Apparently with time methaemoglobin in the 'tick-grown' crystals transforms *in vivo* into haemichrome. The transformation to haemichrome is not associated with cracking of the crystals since, in X-ray diffraction experiments, the haemichrome-containing crystals still diffract well and behave as single crystals.

From the above it is clear that partial degradation or conformational changes are not the cause of the crystallisation of guinea pig haemoglobin in the midgut of *O. moubata*. Other factors which could effect crystallisation are changes in *p*H, osmolarity, or concentration of the blood meal.

The osmolarity of midgut fluid and of guinea-pig blood determined with a Knauer Halbmikro-osmometer was 300 milli-equivalent per kg. Changes in the osmolarity are therefore not responsible for the crystallisation.

Directly after a meal the midgut fluid *p*H is 7.5. It drops later to 6.5. This decrease initiates earlier in males (from the 6th day after the meal) than in females (from the 12th day). It is not clear whether this *p*H drop triggers the crystallisation. Other rodent haemoglobins are relatively insoluble in acid environment[15]. The decrease in *p*H could

Fig. 4 Spectra from single 'tick-grown' crystal. Crystal showing spectrum of haemichrome (——). Same crystal, spectrum partially converted to cyanmethaemoglobin after addition of KCN to 0.01 M (– – –). Conditions as in Fig. 3. Conclusion—methaemoglobin crystals *in vivo* undergo transformation into haemichrome crystals with time. This is not associated with cracking of the crystals.



also be caused by loss of haemoglobin from solution on crystallisation. *In vitro* experiments show that a decrease in *p*H results in an increased solubility of guinea pig haemoglobin. So it seems more likely that the decrease in *p*H is a result of the crystallisation (and of cellular disintegration processes) rather than its cause.

Concentration of the meal takes place by elimination of water through the coxal organ[16]. The concentration factor of guinea pig haemoglobin in the midgut fluid compared with haemoglobin in guinea pig blood was determined by Drabkin's method[14] on 10 μl of fluid or blood. For ticks, dissected 2 h 45 min after their blood meal, a concentration factor of about 1.9 was found which compares well with the value of 1.72 found by Kaufman[17] 2 h after completion of the blood meal. Crystallisation in the midgut starts only after several days, thus the initial, about 2-fold, concentration of the meal is not directly responsible for it. It is, however, possible that concentration of the meal, after the initial steep phase, goes on at a reduced rate and thus eventually triggers crystallisation.

Guinea pig haemoglobin crystallises in the midgut of the tick *O. moubata* as oxyhaemoglobin and, with time, transforms to methaemoglobin and then to haemichrome without disruption of the crystals. Partial haemoglobin degradation or changes in *p*H or osmolarity of the midgut fluid are not responsible for crystallisation. Continued concentration of the blood meal may have a role.

In tick biology, the crystals seem to have an important but not essential role in the preservation of the nutrient reserves since Argasids fed with human blood (which does not crystallise[2]) may also starve for very prolonged periods. It is not known how the nutrient stored in the crystal is made available for intracellular digestion by the starving tick. Distortion of the equilibrium between solid state (crystals) and liquid state (midgut fluid) by the digestive activity of the midgut cells, however, could lead to a gradual solvation of the crystals.

We thank Dr R Halonbrenner for recording the spectra, and Professors J. N. Jansonius and A. Aeschlimann for support.

Effect of a tumour promoter on myogenesis

EVIDENCE that viruses and chemical carcinogens alter the ongoing synthetic programme of cells has been presented[1,2]. Chondroblasts and melanoblasts transformed with a temperature-sensitive Rous sarcoma virus cease synthesising the chondroblast-unique sulphated proteoglycan and melanin, respectively[3]. Shifted to non-permissive temperature, these cells re-initiate the synthesis of the chondroblast-unique sulphated proteoglycan and melanin. Similar results have been obtained using chick myogenic cells[4,5]. Normal presumptive myoblasts undergo a limited number of replications, yielding postmitotic, mononucleated myoblasts. Postmitotic myoblasts initiate the synthesis of muscle-specific myosin heavy and light chains and fuse into myotubes[6,7]. In contrast, ts-viral transformed myogenic cells continue to replicate, do not initiate the synthesis of muscle-specific myosins and do not fuse. 24–48 h after shifting to non-permissive temperature, many transformed myogenic cells withdraw irreversibly from the cell cycle, initiate the synthesis of muscle-specific (unpublished data) myosins and fuse. Apparently when the transformation factor is expressed the cells do not withdraw from the cell cycle, and as a consequence of being forced to cycle, do not terminally differentiate. To probe the mechanisms

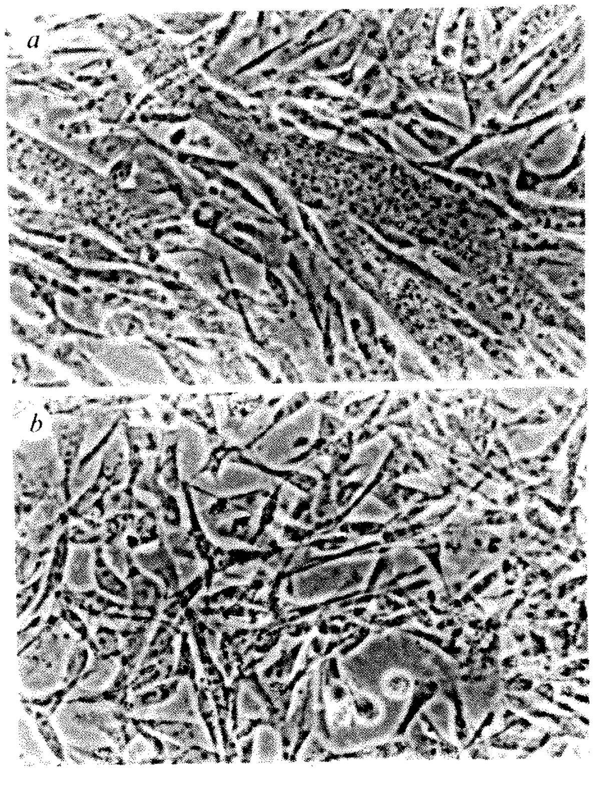

Fig. 1 Phase micrographs of living 4-d primary muscle cultures grown in *a*, normal medium and *b*, normal medium plus PMA. The myotubes may achieve lengths of over 1 mm, may contain hundreds of postmitotic nuclei, and contract spontaneously. The replicating mononucleated cells in both cultures are in various compartments of the myogenic and fibrogenic lineages, and cytologically the cells in these lineages cannot be distinguished. The vast majority of cells in PMA-treated cultures are small bipolar cells. Under higher magnification occasional bi- and trinucleated cells are observed in the PMA-treated cultures; the frequency of such cells is less than 1 per 10^3 mononucleated cells. The multilayered arrangement and overlapping of cell processes demonstrates the absence of density-inhibited replication and migration in the PMA-treated cultures.

that might be common to the generation of terminally differentiated cells from normal precursor cells, and to the generation of malignant cells from normal precursor cells, we studied the effects of phorbol-12-myristate-13-acetate (PMA) on myogenesis. Of the purified phorbol esters, PMA is the most potent as a tumour-promoting agent and as a mitogen[8-12]. We report here that PMA mimics some of the effects of the Rous sarcoma tumour agent on myogenesis.

Primary myogenic cultures were prepared from muscles of 11-d-old chick embryos[13]. PMA (5×10^{-8} M) was added at various times. Muscle-specific myosin heavy chains were assayed, using antibodies specific for muscle heavy chains. Some properties of these myosin antibodies are detailed in Fig. 2 and refs 6 and 7. The actomyosin was extracted from cells by the method of Adelstein *et al.*[14]. Muscle-specific myosin light chains were determined by running partially purified actomyosin extracts in SDS–polyacrylamide gels[7,15]. Postmitotic, mononucleated myoblasts were collected by treating primary cultures with Cytochalsin-B[6,16] or EGTA plus cytosine arabinoside (Ara-C)[7,17].

A micrograph of a control 4-d culture is shown in Fig. 1*a*. Over 50% of all nuclei were in myotubes. The myosin heavy chains from these cultures formed a single precipitin band with antisera against muscle myosin (Fig. 2). Actomyosin extracts in SDS–polyacrylamide gels exihibited muscle-specific, fast myosin light chains, LC_1 and LC_2, with molecular weights of 25,000 and 18,000 (data not shown)[7,15].

Figure 1*b* is a micrograph of a culture reared continuously in PMA for 4 d and clearly shows the absence of myotubes. Myosins from these cells did not form precipitin bands with antibody against muscle-specific myosin (Fig. 2). Furthermore, the light chains from these cells co-migrated with the light chains from presumptive myoblasts or fibroblasts and have MWs of 20,000 and 16,000.

When myogenic cells grown in PMA for 6 d were shifted to normal medium, many withdrew from the cell cycle and terminally differentiated within 24–48 h. In another series cells were subcultured in PMA for 1 or 2 passages. During each passage the number of cells increased over sevenfold (Table 1). The cells did not fuse during these subcultures. At the end of the first or second subculture the cells were shifted to normal medium. Within 24–48 h many cells withdrew from the cell cycle, fused and terminally differentiated. The ratio of myotube nuclei/total nuclei in these 'reversed' cultures equalled that of primary cultures. These findings, and additional autoradiographic data are shown in Table 1. The mitogenic effect of PMA (Table 2) preceded fusion, which in these cultures begins on day 3 and peaks on day 4. This type of mitogenic effect with PMA is also observed with ts-transformed myogenic cells and with cells that have incorporated BudR into their DNA[13].

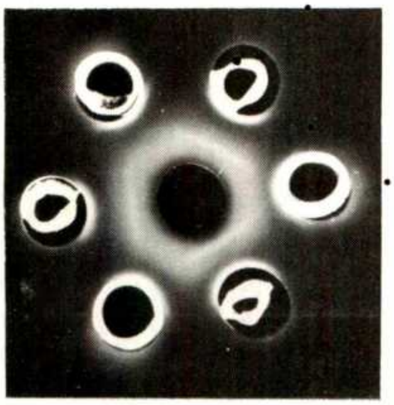

Fig. 2 Control and PMA-treated cultures were extracted for actomyosin and diffused against antibody to adult chicken skeletal mysoin. In the experiment shown, this particular myosin antibody in Ouchterlony tests did not form precipitin bands against C protein[26]. Similar antibodies did not precipitate myosin from chicken cells (replicating presumptive myoblasts, fibroblasts, mesenchyme, smooth muscle, embryonic nerve cells or Rous-transformed myogenic cells grown at permissive temperature) or human blood platelets or mouse Lcells. This antibody did form precipitin bands with acto-myosin extracted from (1) postmitotic precipitin bands with acto-myosin extracted from (1) postmitotic, mononucleated myoblasts, (2) normal myotubes and (3) myotubes that formed when Rous sarcoma ts-transformed myogenic cells were reared at non-permissive temperature (refs. 6, 7, 16, 18 and unpublished results). Actomyosin solutions, antibody solutions and gels were equilibrated with 0.4 M KCl 0.03 M phosphate buffer, *p*H 7.3: 40 µl of solution were placed in each well and allowed to diffuse at 4 °C for 48 h. The gels were washed on phosphate buffer for 24 h, stained with thiazine in H_2O and destained with 1% acetic acid. Wells are numbered clockwise and the upper right-hand well is no. 1. The centre well contains antibody to adult skeletal chick myosin. Wells 1, 3 and 5 contain 4 mg ml^{-1} actomyosin from control cultures. Wells 2, 4 and 6 contain 5 mg ml^{-1} actomyosin from PMA-treated primary cultures. In other experiments, similar results were obtained when the protein concentration of actomyosin from cells reared in PMA was four times that of control cultures. Lastly, fluorescein-labelled antimysoin experiments performed as described in refs 7, 25 yielded results consistent with the agar diffusion tests. For this photograph the stained gel served as a negative.

The following experiments demonstrate that the mitogenic target of PMA was the replicating presumptive myoblasts and fibroblasts, and that PMA was not a mitogen for nuclei in the definitive, mononucleated myoblasts or the nuclei within myotubes. Mononucleated myoblasts synthesising muscle-specific myosins were collected by treating primary cultures with cytochalasin-B or EGTA

Table 1 Autoradiographic analysis of standard, PMA-treated and PMA-reversed myogenic cultures

	% of all labelled nuclei per dish		% of all unlabelled nuclei per dish	
	Nuclei in mononucleated cells	Postmitotic nuclei in myotubes	Nuclei in mononucleated cells	Postmitotic nuclei in myotubes
Standard 4-d	26	0.2*	28	46
primary cultures	20	< 0.1*	25	55
4-d PMA-treated	51	0	49	0
primary culture	46	0	52	0
PMA-treated primary culture subcultured into normal medium	28	1*	20	51
PMA-treated	52	0	48	0
primary culture subcultured into PMA-medium	59	0	41	0

Late 3-d cultures were exposed to ^{3}H-TdR for 10 h, processed for autoradiography, and cells counted as described[13]. Initial inoculum 0.5×10^6 nuclei per 35-mm Petri dish. In standard 4-d cultures there were 3×10^6 to 4×10^6 nuclei per dish, of which roughly 50% were postmitotic and in myotubes. In PMA-treated primaries there were 4×10^6 to 5×10^6 nuclei per dish, virtually all mononucleated. Secondary cultures of PMA-treated cells if again grown in PMA achieved densities of up to 6×10^6 nuclei per dish after 4 d. If, however, PMA-treated primaries were grown as secondaries in normal medium, they again achieved densities of 3×10^6 to 4×10^6 nuclei per dish, of which 50% were postmitotic and in myotubes. Additional experiments are required to determine what percentage of unlabelled mononucleated cells in both types of culture were in fact (1) definitive postmitotic myoblasts, and (2) myogenic and fibrogenic cells that simply did not enter S during the period in ^{3}H-TdR. It should be stressed that normal and PMA-treated cultures did not cease replicating when confluent, but multilayered.

*The small percentage of labelled nuclei in myotubes were due to the fusion of labelled daughter cells whose mothers passed through at least the later part of S and then divided during the 10 h the cells were in ^{3}H-TdR.

Table 2 DNA determination of controls and PMA-treated cultures

Type of culture	DNA content (μg per dish) at various times 48 h	72 h	96 h	120 h
Control primary	52	93	144	144
PMA-treated primary	70	147	235	292

Each value (mean of two separate experiments performed at different times) represents the amount of DNA (in μg) per 100 mm Petri dishes. Initial inoculum 0.5×10^6 cells per ml, 8 ml per dish. DNA was determined by the method of Burton[24]. The values for the 120-h cultures are difficult to interpret. In both types of cultures cells are lost into the medium. In the controls, entire multinucleated myotubes often degenerate, whereas in the PMA-treated cultures many mononucleated cells are displaced from the substrate and die.

plus Ara-C[6,7,16]. These definitive myoblasts were subcultured into medium with PMA and ^{3}H-TdR or with ^{3}H-TdR alone, and both series autoradiographed. Less than 2% of the cells incorporated the label after 36 h in both series. In subcultures prepared from untreated primaries, over 70% of the cells were labelled after 36 h. Not a single nucleus within a myotube was labelled when PMA plus ^{3}H-TdR was added after myotubes had formed.

Fusion is the end step of several distinct events. First, the generation by way of cell divisions of postmitotic, fusible-competent myoblasts[18]. Second, the mutual recognition, lateral alignment and adhesion of these postmitotic myoblasts[19–21]. And third, the physical event of fusion itself. Fusion, as determined with living cells under the phase microscope, requires no more than 30–60 min[22,23]. The following demonstrates that, in addition to acting as a mitogen, PMA blocks the physical event of fusion. Fusible-competent, postmitotic myoblasts were collected from cultures treated with cytochalsin-B or EGTA plus Ara-C. When these myoblasts were subcultured into normal medium, over 60% fused within 15–20 h. When these definitive myoblasts were subcultured into medium with PMA, fusion was blocked, although as mononucleated cells they continued to synthesise the muscle-specific myosin heavy and light chains.

With respect to promoting cell replication, PMA-treated myogenic cells mimic the behaviour of myogenic cells transformed with ts-Rous sarcoma virus, and of myogenic cells that incorporated BudR into their DNA. Possibly PMA, the ts-virus and BudR all exert their common effect on myogenesis by forcing cells in the penultimate compartment of the myogenic lineage to replicate. In addition, however, PMA, but not the virus or BudR, blocks the event of fusion. It may be that PMA acts directly on the cell surface of replicating presumptive myoblasts and postmitotic myoblasts. The former are inhibited from pulling out of the cell cycle, the latter from fusing. In any case, the final effect of such dissimilar agents as Rous virus transforming factor, BudR, and PMA seems to be to force presumptive myoblasts to undergo proliferative cell cycles which in turn precludes the flipping of the 'master-switch' which permits activation of the synthetic program of the post-mitotic mononucleated myoblast[5,7,20,25].

Human LD antigens are present on xenogeneic cells

THE mixed leukocyte culture (MLC) reaction is largely a measure of specific responsiveness of thymus-derived lymphocytes to foreign allogeneic and xenogeneic major histocompatibility complex (MHC) controlled LD antigens[1]. In view of the remarkable primary structure homologies of MHC-controlled SD antigens between humans and mice[2], we have investigated whether MHC LD antigens have also been conserved in evolution by studying the extent of LD sharing between different species. Using the primed lymphocyte typing (PLT) test, we have found extensive sharing of LD antigens between humans and monkeys, and less, but still significant, sharing between humans and dogs and humans and cattle. In no case was there evidence that mouse LD antigens were shared with those of humans.

Human lymphocytes cultured in primary allogeneic MLC proliferate extensively and revert to small lymphocytes by day 10. If then restimulated with the original sensitising cell these primed lymphocytes (PLT cells) give a much more rapid proliferative response, which can be assayed by ^{3}H-TdR incorporation as early as 24 h. This secondary, or typing, response is specific for HLA LD determinants and is also elicited by random restimulating cells (test cells) that share LD determinants with the original sensitising cell[3]. PLT cells can also be generated in xenogeneic combinations and appear specific for the LD antigens of the sensitising species[4].

If individual human cells are sensitised to a pool of 20 allogeneic stimulating cells, the resulting PLT cells (pool-PLT cells) seem sensitised to essentially all human LD determinants, as virtually any human test cell used for restimulation elicits a strong secondary response[5]. Test cells that elicit a poor secondary response from a pool-PLT cell must either share LD determinants with the responding cell or carry LD determinants that are not represented in the sensitising cell pool. The primary MLCs between test and responding cells distinguish between these two possibilities. The magnitude of the secondary response correlates very well with that of the primary MLC ($r=0.89$) (Fig. 1). This indicates that human test cells that fail to restimulate a pool-PLT cell fail to do so because of LD determinants shared with the responding cell. The sensitising cell pool thus seems to include essentially all human LD determinants.

Restimulation of a human pool-PLT cell with a xeno-

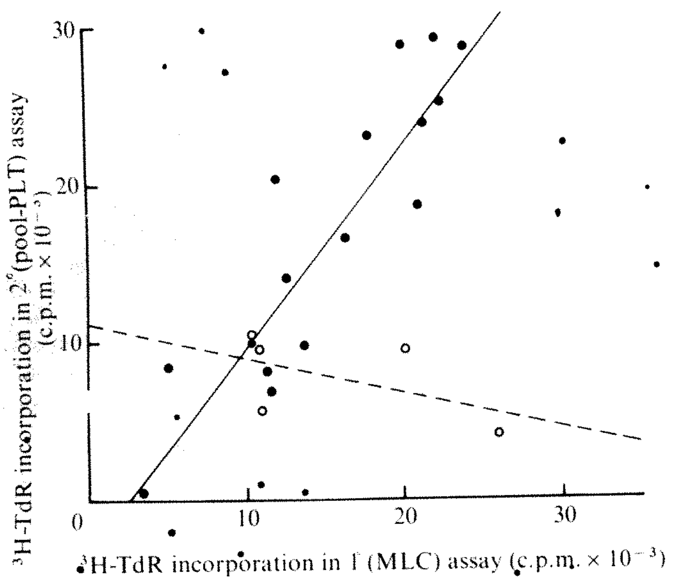

Fig. 1 Correlation of MLC and pool-PLT responses. Pool-PLT cells were generated and assayed as follows: 1×10^7 human responding cells were cultured with 1×10^7 irradiated, pooled human stimulating cells (consisting of 20 random donors) in upright flasks (Falcon No. 3013) in 30 ml RPMI 1640 medium supplemented with 25 mM HEPES buffer, penicillin, streptomycin and 10% heat-inactivated pooled human plasma. After 10 d the cells were collected, resuspended in fresh supplemented medium and distributed to flat-bottomed microtitre plates (Linbro No. IS-FB-96TC). 10^5 pool-PLT responding cells were restimulated with 2×10^5 irradiated human (●) or monkey (○) stimulating cells per well. Cultures were labelled with ^{3}H-TdR for 8 h on day 2 after restimulation. Primary MLCs were done using 10^5 fresh human responding cells and 2×10^5 irradiated human (●) or monkey (○) stimulating cells per well and were labelled for 8 h on day 5 of culture. ———, least squares regression line for human stimulating cells ($r = 0.89$, $P < 0.01$); ········, least squares regression line for monkey stimulating cells ($r = -0.55$, not significant).

geneic test cell should give a positive response if LD determinants on the xenogeneic test cell are shared with human LD determinants. Data for four species whose cells were tested for their ability to restimulate a pool-PLT cell (Table 1) show that in four experiments with five different pool-PLT cells, cells from all 10 rhesus monkeys tested caused significant restimulation. This restimulation was 44–135% of the average restimulation caused by a panel of random human test cells. There is a decreasing percentage of positive responses as well as percentage of restimulation by those cells that are positive. The primary MLC data show that those xenogeneic test cells that do not restimulate the pool-PLT cell still elicit a good primary MLC response from the same responding cell, indicating that the LD determinants recognised on those xenogeneic cells in a primary MLC are not represented in the human sensitising cell pool.

The data obtained with the pool-PLT test show that LD antigens are shared between species. The degree of sharing is quite extensive in rhesus monkeys, where all animals tested shared antigens with human cells, and less in dogs and cattle. In the 17 mouse strains we tested (11 independent and 6 recombinant H–2 haplotypes) there was no evidence for LD antigens shared with human cells.

Even in rhesus monkeys, where all animals so far tested have given positive secondary responses with pool-PLT cells, shared specificities do not seem to be the sole basis of recognition. In addition to the human cells shown in Fig. 1, five rhesus cells were also tested. All of these cells gave positive secondary responses, but the correlation between primary and secondary responses was poor ($r = -0.55$, not significantly different from zero), suggesting that there are additional LD determinants on the xenogeneic cells, not shared with human LD determinants, that are still recognised in a primary xenogeneic MLC.

Estimates of the frequency of initially responding cells in MLC to any one haplotype range from 1 to 6% (refs 6–8). As well as extensive polymorphism for LD antigens, in at least some cases the LD antigens controlled by two different haplotypes in the same species seem to be non-cross reactive[4,9]. We thus have to account for the ability of an individual animal to respond to all of the different LD antigens in its species, given the apparent clonal nature of this response[10,11].

That lymphocytes can also respond to xenogeneic cells in MLC[12,13], and that this response is specific and apparently directed towards the MHC LD antigens of the sensitising species[4], further compounds the problem in a quantitative sense. To overcome this difficulty it has been suggested that allogeneic recognition is unique[14] and, to the extent

Table 1 Pool PLT-cells restimulated by allogeneic or xenogeneic test cells*†

*All human responding cells are designated A, although different individuals were used as responding cells in each experiment.

†A_x, B_x: irradiated human stimulating cells.

X_x, Y_x: irradiated xenogeneic stimulating cells of species indicated.

‡Cultures were performed as in Fig. 1 legend, using 2×10^5 irradiated monkey or dog stimulating cells (peripheral blood lymphocytes), 8×10^5 irradiated cattle stimulating cells (peripheral blood lymphocytes), or 10×10^5 irradiated mouse stimulating cells (spleen cells depleted of erythrocytes by hypotonic shock) per well.

§All animals scored as positive gave restimulation values significantly different from autologous controls ($P < 0.05$).

‖Expressed as percentage of average restimulation by a random panel of human test restimulating cells.

¶c.p.m. ^{3}H-TdR incorporation.

that it occurs, xenogeneic recognition simply represents recognition of those xenogeneic antigens identical to, or cross-reactive with, the LD antigens of the responding species[15]. This would considerably limit the number of foreign MHC LD antigens that any animal would need to recognise. Our data indicate, however, that this is not the case. The very significant xenogeneic MLC seen between human and mouse cells, which seems to reflect specific recognitoin by human cells of mouse H-2 LD antigens, suggests that xenogeneic antigens can be recognised in MLC even when they are not cross-reactive with human LD antigens.

Thus we are left with the high frequency of initially responding cells in MLC, which must include specific recognition of allogeneic as well as non-cross-reactive xenogeneic LD antigens. Models that could explain this high frequency of initially responding cells have been discussed before[16-18]. One possibility is that the LD antigens coded for by different haplotypes within a species are to a large extent cross-reactive. The high frequency of responding cells in the rat system with the lack of any sharing of LD antigens in the few haplotypes tested could be the unusual case[9]. The very low number of MHC haplotypes existing in rat[19] is in marked contrast to mice[20] and humans[21], where cross-reactivity may be extensive. In fact, the high degree of LD sharing between humans and rhesus monkeys, and the still significant homologies with more distantly related species such as dog and cow, supports the concept that the large number of phenotypes that exist in all species may be based on the expression of different combinations of a limited number of determinants.

We thank Charles Blystad, Genia Gordon, Kent McLaughlin, Bill Rasmus and William H. Stone for help in obtaining blood samples. This work was supported in part by the US NSF, NIH and NF.

Circulating immune complexes in normal human pregnancy

CIRCULATING antigen–antibody (AgAb) complexes are important pathogenic factors in various diseases. In addition to their inflammatory effect, immune complexes can interfere with cellular immunity. For instance, in cancer, the so-called blocking factors are apparently circulating AgAb complexes[1,2]. Factors interfering with cellular immunity specifically directed against placental and foetal antigens have also been described in pregnancy serum[3-5], and some data suggest a role of immune complexes as blocking factors in pregnancy[6]. We report here that circulating AgAb complexes are a constant feature of every normal pregnancy. This, of course, raises interesting questions as to the possible involvement of such complexes in the tolerance of the foetus by the mother.

Agglutination inhibition tests were carried out as before[7] using latex suspension provided by the Behring Institute (Marburg, FRG). However, human rheumatoid factor (RF) or Clq which failed to react with the immune complexes of pregnancy, were replaced by rabbit RF. RF was induced in rabbits by injecting 1 mg of autologous aggregated IgG mixed with complete Freund's adjuvant intradermally every 2 weeks. IgG was isolated by DEAE–cellulose chromatography and aggregated by heating at 63 °C for 10 min. For the isolation of RF, the animal sera were passed through a column of human IgG coupled to 6-aminohexyl-Sepharose 4B activated by glutaraldehyde[8]. The fraction eluted between 1 M and 2 M NH_4SCN was used after dialysis against saline. This fraction consisted almost exclusively of IgM.

Rabbit RF was inhibited by all sera from non-pregnant women ($N = 14$) at dilution titres ranging from $\frac{1}{4}$ to $\frac{1}{16}$, whereas the inhibition titres of 84 sera collected from 55 women at various stages of normal pregnancy before the 38th week, ranged from $\frac{1}{32}$ to 1/256 (Fig. 1). Those samples collected after the 38th week had a titre of $\frac{1}{16}$. The courses of two typical pregnancies showed an increase up to 1/128 of the RF inhibition titre with the advancement of pregnancy. At 3–4 weeks before delivery the inhibition titres dropped to levels observed in non-pregnant women.

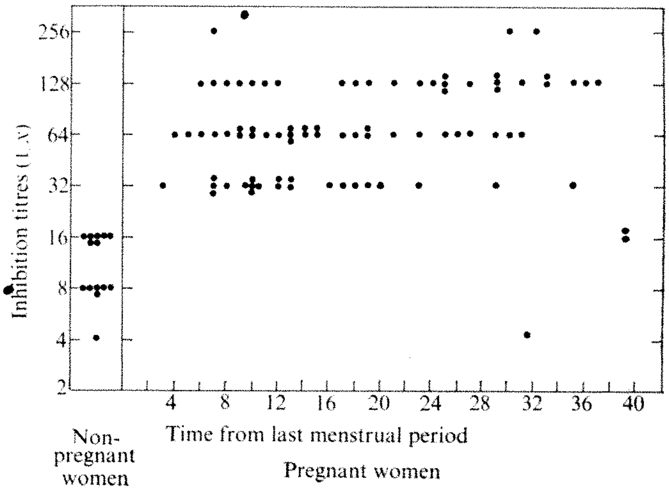
In an attempt to characterise the inhibiting factors, fresh sera from six pregnant women (gestation of 12–37 weeks) and with RF-inhibition titres ranging from $\frac{1}{64}$ to 1/256 were fractionated by gel filtration (Fig. 2).

In all sera from pregnant women, a high inhibitory activity towards RF was detected in the fractions corresponding to molecular sizes $\geqslant 10^6$. Sera from non-pregnant women were devoid of these large size inhibitory factors but, like sera from pregnant women, contained inhibitory factors eluted in the 7S region. In general, this inhibitory activity was maximal in the ascending slope of the peak of IgG (Fig. 2).

All sera from pregnant and non-pregnant women contained, in addition to 7S IgG, a small amount of this immunoglobulin eluted in a region corresponding to a molecular size ranging from 500,000 to several millions. On the average, 'heavy' IgG corresponding to 0.27% (s.d. 0.20) of our standard was recovered from 1 ml pregnancy serum, and 0.21% (s.d. 0.16) from 1 ml of control serum. These two quantities did not differ significantly. In one pregnant woman, both IgA and IgG were detected in the elution zone of IgM.

The C3 factor of complement was also found to be dis-

Fig. 1 Inhibitory activity toward rabbit RF of sera from pregnant and non-pregnant women.



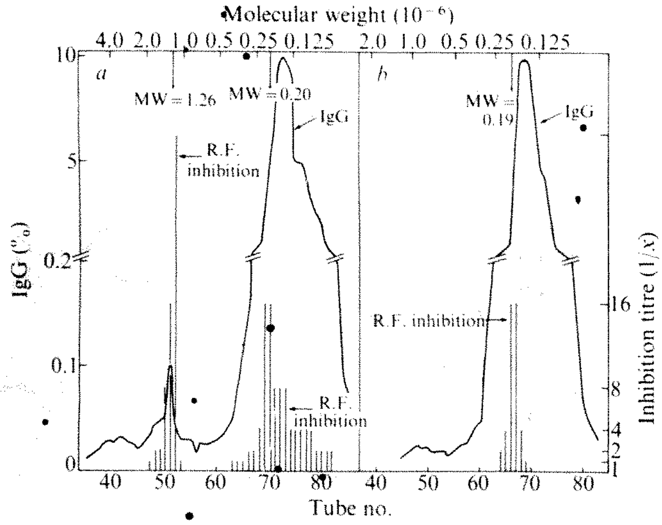


Fig. 2 Gel filtration of two serum samples (3 ml) on a calibrated Ultrogel AcA 22 column. *a*, Serum from a 24-week pregnant woman. *b*, Serum from a non-pregnant woman. The fractions of 5 ml were analysed by nephelometric immunossay of IgG (Technicon AIP system) and tested for their inhibitory activity towards rabbit RF. The concentrations of IgG were expressed in percentage of the IgG content of a pool of normal sera. Presence of IgA, IgM and C3 complement were followed similarly. Sera from age-matched non-pregnant women served as controls.

tributed in two fractions. The major one was detected, as was expected, in the ascending slope of the IgG peak, and the minor one in the elution zone of heavy IgG. In contrast to IgG, however, a highly significant difference ($P < 0.001$) was observed between the amounts of 'heavy' C3 occurring in pregnant and non-pregnant women. The pregnancy sera contained heavy C3 corresponding to 2.5% (s.d. 0.41) of our standard and the control sera 0.46% (s.d. 0.37).

Sometimes, the peak of heavy IgG or heavy C3 did not exactly match the peak of heavy inhibitory factors. Such a discrepancy was also observed in the fractionation of sera from patients with immune complex diseases. A possible cause could be the extreme sensitivity of RF for immune complexes of a certain size[7].

To determine whether the inhibitory factors of large molecular size corresponded to antigen–antibody complexes, the corresponding fractions were concentrated 10-fold by ultrafiltration, dialysed against 0.1 M HCl-glycine buffer, *p*H 3.0 to dissociate the complexes, and passed through a column of Sephadex G200 in the same buffer to separate the antigen from the antibody. Five peaks of material absorbing at 280 nm were obtained. After neutralisation by addition of 100 µl of 1 M Tris solution to the 5-ml fractions, they were analysed for IgG content by immunonephelometry and for their inhibitory activity toward RF. All fractions were found to be devoid of inhibitory factors. IgG was detected in the third fraction which was eluted in the position expected for a 7S protein.

A sample of 200 µl of each fraction was mixed with the same volume of each of the other fractions. After incubation at 37 °C for 30 min. and overnight at 4 °C, the 10 mixtures were titrated for their inhibitory activity. Only the mixture of the IgG-containing fraction with the second fraction gave an inhibition which was still detectable after a 1/512 dilution. This second fraction was eluted in a position suggesting a molecular weight of about 400,000. The resolution at acid *p*H of the inhibitory factors into five peaks was confirmed with a serum sample of another pregnant woman, and the identification of the material constituting each of these fractions is now in progress.

It is known that rabbit RF is capable of reacting with human IgG, especially when it is aggregated or involved in AgAb complexes[9]. Our gel filtration experiments clearly show that the increase of RF inhibition occurring during pregnancy is due to the appearance of factors of molecular sizes of between 500,000 and several millions. The presence of IgG and C3 in these heavy fractions and the dissociation-reassociation experiments leave little doubt about the AgAb complex nature of the heavy inhibitory factors. It remains to be explained, however, why rabbit RF was inhibited by heavy serum fractions from pregnant women and not from non-pregnant women, despite the fact that these fractions contained the same amount of IgG. This discrepancy might be due to a difference in the IgG subclass involved in the complexes. The hypothesis that rabbit RF would preferentially react with certain human subclasses of IgG is suggested by the elution pattern of the inhibitory factors detected in the 7S region. In sera from most pregnant and non-pregnant women, the maximal inhibition in the 7S region was found where material with a molecular size of about 170,000–200,000 was eluted. This inhibitory factor, therefore might correspond to IgG3, which has a molecular weight of 172,000 (ref. 10).

It has been reported that healthy individuals may possess IgG endowed with RF activity which can form an immune complex with other IgG molecules by a self-association mechanism[11]. The heavy IgG that we have detected in control sera presumably correspond to this type of complex. But, the type occurring during pregnancy seems clearly different since it contains larger amounts of C3 and an antigen which was not IgG but a substance with an estimated molecular size of about 400,000. We presume that this antigen originates from placental or foetal tissues.

The detection of circulating AgAb complexes in the serum of pregnant women opens several new perspectives. In gynaecology, the determination of immune complexes seems to be a possible test for monitoring the evolution of pregnancy. In pathology these immune complexes might be recognised as the pathogenic factors of preeclampsia, especially in view of the observation that deposits of IgG and C3 have been detected in the renal glomeruli of normal pregnant guinea pigs and mice[12]. In immunology, investigations of the blocking effect of immune complexes of pregnancy, and identification of the antigen and antibody involved may clarify the intriguing mechanism responsible for the immune tolerance of the mother toward the foetus.

We thank Professor J. Ferin for providing sera from pregnant women and Dr A. Leek and Dr G. Jackson for criticism. This work was supported by the Fonds de la Recherche Scientifique Médicale, Brussels, and by the Cancer Research Fund of the Caisse Générale d'Epargne et de Retraite, Brussels.

Y-antigen killing by T cells of women is restricted by HLA

CYTOTOXIC T cells are important in graft rejection and in the control of virus infections, but the mode of interaction of these cells with their targets, particularly in man remains unclear. It has been shown in mice that products of genes in the major histocompatibility complex (H-2) are involved in these interactions even when the cytotoxic T cells are specific for viral or non-H-2 antigens. This involvement is seen as the requirements that the target cell must express the specific non-H-2 antigen and in addition the same H-2, D or K region antigens as were present on the cells which initiated the immune response[1-4]. Cytotoxic T cells specific for viral or non-H-2 antigens are thus restricted in the targets that they can kill by the H-2 antigens on the targets. For example, cytotoxic T cells from H-2^b female mice suitably primed to the Y antigen of H-2^b males, will only kill cells from male mice carrying an H-2D region derived from H-2^b (refs 5, 6). This report is to our knowledge the first clear demonstration that a similar restriction occurs in man. We describe a situation in man where cytotoxic reactions specific for non-HLA antigens can only occur when target cells carry both the HLA-A2 antigen of the original sensitising cell and the non-HLA target determinant(s). The strong association with maleness suggests that one of the specific antigens involved was coded for by the Y chromosome.

Table 1 Killing pattern of cells from patient Reef. against her own target cells and those from other family members

Targets			HLA compatibility with patient	% Killing of CML	
Donor	♂	ac*	yes	63†	18‡
Patient	♀	ac	yes	−1	NT
Sib 5	♂	ac	yes	63	NT
Sib 3	♂	ad	no	53	13
Sib 4	♀	ad	no	31	NT
Mother	♀	cd	no	4	0

Table 1 shows percentage of chromium release of tests in which the patient's cells were tested against members of her family. NT, not tested.

*HLA haplotypes: a, A2, BW40, W6, CW3; b, A2, BW40, W6, CW3; c, A2, B12, W4, —; d, AW31, BW35, W6, CW4.

†Results after *in vitro* sensitisation to donor.

‡Results without previous *in vitro* sensitisation. MLRs between donor, patient and sib 5 were sufficiently low to exclude the possibility of a recombination between HLA-B and HLA-D.

Our study began with an observation that a female patient (Reef) who had been suffering from aplastic anaemia rejected a bone marrow graft from her HLA-identical brother. Before this rejection, a transient chimaerism of peripheral blood cells indicated that the graft had initially taken. Rejection was accompanied by a spontaneous recovery of the patient's bone marrow haemopoietic function, thus allowing further investigations. Peripheral blood lymphocytes from the patient were used as effector cells to measure the level of cytotoxicity against target cells from the patient's family and an unrelated panel. The patient's lymphocytes were first restimulated *in vitro* by incubating them for 6 d with irradiated stimulator cells from her HLA identical brother. Cytotoxicity was measured using an isotope release assay[7] with target cells which had been incubated with phytohaemagglutinin for 3 d and then labelled with sodium ^{51}chromate. Effector cells (70×10^4) and target cells (1×10^4) in RPM-1640 plus 20% heat-inactivated human AB serum were incubated for 4 h in round-bottomed microtitre plates. Plates were centrifuged for 5 min at 200g and the supernatant removed and counted in a γ-counter. Each cell combination was tested in triplicate. After subtraction of background the percentage of isotope release was calculated according to the following formula:

$$\frac{\text{experimental mean} - \text{mean of spontaneous release}}{\text{freeze–thaw mean (100\% release)} - \text{mean of spontaneous release}} \times 100 = \%\text{ kill}$$

In our initial studies performed 31 weeks after grafting, cytotoxicity was demonstrated against the donor's lymphocytes even when the patient's cells had not been restimulated *in vitro* (Table 1). This suggested that killing was to a non-HLA target as the donor was HLA identical to his sister. Three further experiments were performed using effector cells from the recipient sensitised to the donor and using cells from an unrelated panel as targets. HLA phenotypes are shown in Table 2.

*The HLA antigens compatible with patient Reef are underlined.

In several cases positive reactions were observed. The level of killing seemed to decline with time, and the gradual waning seemed to be associated with the patient's recovery. Family segregation studies were performed on the relatives of positive panel members. In three such studies the killing pattern failed to segregate with the HLA haplotype, again confirming that killing was directed to a non-HLA target or targets (Table 3).

We have searched for HLA restriction of killing, and a subsequent retrospective analysis revealed a strong association with HLA-A2. All targets that were killed carried the HLA-A2 antigen, although not all HLA-A2 cells were killed. The possibility that a split in HLA-A2 specificities was being recognised was excluded by the family studies (families 2 and 3, Table 3). Here the HLA-A2-bearing haplotype was associated with killing when expressed in one cell, but when expressed on another cell this haplotype was not associated with killing (family 2—c haplotype, family 3—a haplotype). Also, in family 3, no killing was associated with the antigen HLA-A28 which by serology was highly cross-reactive with HLA-A2.

Further analysis revealed that 15 out of 17 targets that were killed were male. Target cells from all fifteen of the HLA-A2 males were killed (Table 4) but cells from males not carrying HLA-A2 were not killed. Cells derived from two females were killed—both females were also HLA-A2 positive, but the level of killing was at a lower level than that observed with other positive reactions in the same test. This suggested that at least two specificities were involved, one associated with the Y chromosome exclusively and the other carried by a proportion of A2 females. One of the females that gave target cells showing positive killing was a sister of the patient (Table 1). The presence of the second system in the males will have been masked by the killing specific for the Y antigen. A clear example of the independent inheritance of an HLA-A2 gene product and the presumed Y product was shown in family 3 (Table 3). Here the HLA-A2 specificity inherited by the male child C1 was from the mother's a-haplotype. Cells from the two other male children were not killed.

Table 3 Pattern of killing of a non-HLA target by effector cells (raised between the patient Reef and her donor) tested on 3 families

Family 1 (week 64)		HLA haplotypes	Sex	% Kill
Target				
Mother	ab	1, 8, W6/2, W22, W6	♀	0
Father	cd	1, 8 W6/2, W40, W6	♂	23
C1	ac		♀	0
C2	ad		♂	19
C3	bc		♂	23
Family 2 (week 64)				
Mother	ab	3, 7, W6/1, 8, W6	♀	−1
Father	cd	2, 12, W4/2, W40, W6, CW4	♂	42
C1	ac		♂	34
C2	bc		♀	5
C3	ad		♂	41
C4	ac		♀	1
C5	bc		♀	3
Family 3 (week 72)				
Mother	ab	2, W40, W6, CW3/28, 12, W4	♀	1
Father	cd	1, 8, W6/2, W35, W6, CW4	♂	13
C1	ac		♂	15
C2	bc		♂	−1
C3	bc		♂	−2

In family 2 the female C2 inherited the A2 from the father and was not killed, but her brother who inherited the same A2 was killed. In family 3 the male C1 inherited the A2 from the mother and was killed, but C2 and C3 did not inherit A2 and were not killed. The weeks represent the time after bone marrow grafting that the family studies were performed. Compatibility with patient is underlined.

Table 4 Y chromosome linkage of non-HLA target and restriction of killing to HLA-A2 positive targets

		Sex of HLA-A2 targets	
		♂	♀
CML	+	15	2*
	−	0	17

*Level of killing was much lower than other positive targets in same experiment.

These results demonstrate that the cell-mediated cytotoxic reactions of the patient's lymphocytes are specific for non-HLA antigens but restricted by an HLA product in as much as only targets carrying HLA-A2 are lysed. This is very similar to the restriction seen with murine cytotoxic T cells reacting with non-H-2 antigens[1–6].

We have not yet unambiguously identified the effector mechanism in this human cell-mediated cytotoxicity system but feel it is not an antibody-dependent system as the cytotoxic reactions occurred in 20% heat-inactivated human AB serum. In these conditions it has been impossible to measure antibody dependent cell-mediated cytotoxicity (L. Doyer, personal communication). This is important as serum from the patient Reef, when tested against the panel members (Table 2) using the two-colour fluorescence technique[8], gave a positive reaction with some target cells that were positive in the cytotoxicity test.

Our observations of male-associated killing are analogous to those of Gordon *et al.* in the mouse[5,6]. In their case, cytotoxicity was only observed after *in vivo* sensitisation with a male skin allograft followed by *in vitro* priming. The clinical relevance of the Y-associated killing phenomenon is that it is probably an *in vitro* reflection of the known inefluence of sex on the incidence of graft against host disease in bone marrow transplantation between HLA identical siblings[9]. In kidney grafting, several workers have observed that female recipients of male grafts survived longer than female recipients of female grafts (ref. 10, and Kissmeyer-Nielsen, Opelz and Terasaki, personal communication). This was interpreted by Oliver to indicate that the Y-linked histocompatibility antigen may actively induce a prolongation of renal allograft survival in man. Although these results contrast with our own, they should be interpreted with caution as HLA-A2 positive combinations were not separately analysed, and some modes of immunisation to the Y-linked histocompatibility antigen may result in protective immunity.

We thank Dr Alan Munro for discussions, Miss E. Blokland for technical assistance and Miss C. S. L. Mackenzie and Mrs C. Petit-Gerris for secretarial assistance.

Selective cellular natural killing against human leukaemic T cells and thymus

NATURALLY-occurring antibodies against thymocytes, certain leukaemias and other tumour cells have been observed in various species including man[1,2]. In addition, natural cellular immunity—also known as cellular natural killing (CNK)—has been described recently in man[3–5] and in mice[6–9]. The possible role of CNK in tumour surveillance and the nature of the effector cells are presently subject to extensive research. Relatively little is known, however, about the nature and sensitivity of the target cells in relation to CNK. We report here that human leukaemic T cells and human thymocytes are highly sensitive to CNK by normal human peripheral blood and that B cell lines are relatively insensitive. The response seems to be unrelated to HLA and expressed variably by different individuals.

Table 1 Characteristics of tissue cultured human lymphoid cell lines

Cell line	HLA phenotype	Cell type	Cell origin	References

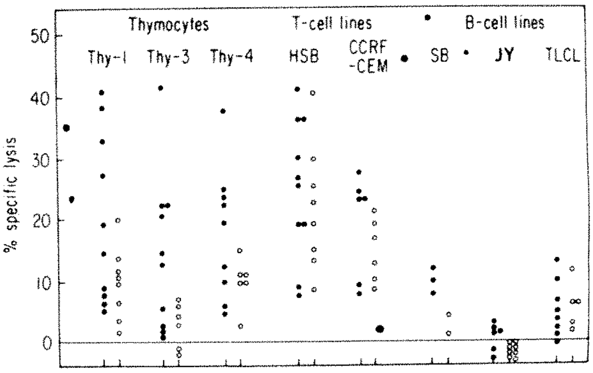

Fig. 1 Distribution of CNK of 18 individuals tested against thymocytes, T- and B-cell lines. A total of 18 samples of human mononuclear cells were tested in several experiments against ^{51}Cr-labelled PHA-stimulated thymocytes of three individuals (Thy-1, Thy-3 and Thy-4), against two T-cell lines (HSB and CCRF-CEM) and against three B-cell lines (SB, JY and TLCL). The ratio of effector cells to targets was 50:1 in all experiments. Activity is expressed as % specific lysis in a 4-h assay, performed as for Table 2. ●, Male donors ; ○, female donors.

Tumour cells with T- and B-cell characteristics as described in Table 1 were cultured in minimal essential medium (MEM) supplemented with 10% foetal calf serum (FCS). HSB and SB were obtained from the same individual; HSB is a leukaemic T-cell line, SB is a B cell established from the patient's peripheral blood leukocytes (PBL) in culture. CCRF-CEM is another leukaemic T cell and JY, TLCL, PY and HL are established B-cell lines. Thymocytes were obtained from patients undergoing open-heart surgery. The cell lines and phytohaemagglutinin (PHA) stimulated thymocytes were labelled with ^{51}Cr and used as target cells in a 4-h modified microcytotoxicity assay[7]. Mononuclear cells from normal individuals were separated from heparinised whole blood on Ficoll–Hypaque as described by Boyum[12] and served as effector cells. To test whether human T- and B-cell lines differ in their susceptibility to lysis, they were labelled with ^{51}Cr and incubated with normal PBL. Table 2 summarises the results of one such experiment showing that three donors of differing HLA phenotype exhibited high cytotoxic activity against the leukaemic HSB and CCRF-CEM T-cell lines in all ratios tested and had comparatively low activity against SB and JY B-cell lines. This 'cross-reactivity' is discussed in more detail below. Although HSB and SB were obtained from the same individual and are therefore identical for their HLA and presumably for other cell-surface HLA loci (see Table 1), their reactivities in CNK differ markedly. The other B-cell lines studied—TLCL, PY and HL—behaved similarly to SB and JY (data concerning PY and HL are not presented), while CCRF-CEM, the other leukaemic T-cell line tested, was as sensitive to CNK as HSB. CCRF-CEM and HSB are from different and unrelated subjects. Since leukaemic T cells are thought to be thymus derived it was of interest to investigate the sensitivity of human thymocytes as targets in our cytotoxic assay. Fresh thymocytes used as targets on the same day they were obtained from surgery or cryopreserved thawed thymocytes were unsuitable targets owing to poor ^{51}Cr incorporation and rapid spontaneous release. Prestimulation with PHA (PHA HA 16/17, Wellcome) at 1 μg ml^{-1} for 3 d or less resulted, however, in a highly viable population of cells incorporating up to 20-fold more ^{51}Cr than non-PHA-stimulated cultures on day 0. These cells were then used as targets in the cytotoxic assays. Blood samples from 18 normal individuals were tested against thymocytes obtained from 4 HLA different individuals and prestimulated with PHA for 3 d (Thy-1, Thy-2, Thy-3, Thy-4). All donors tested exhibited significant cytotoxic activity against all thymocyte targets. Table 3 shows the results of four representative donors only. The selectivity of the CNK was demonstrated by the lack of activity against JY, a B cell line. It should be noted that all the B cell lines used in this study served as excellent targets when tested with *in vitro* allogenically sensitised human PBL (A.O., unpublished data). To our knowledge this is a unique and first example demonstrating CNK against 'normal' cells in general and thymocytes

Table 2 Selective CNK activity against T- and B-cell lines

		% Specific lysis*

*Target cells were labelled with 100 μCi of ^{51}Cr for 2 h at 37 °C, washed three times and resuspended in MEM 10% FCS to 1×10^5 per ml. The cytotoxic assay was performed in Cooke round-bottom microtitre plates by mixing 100 μl of effector cells with 100 μl of target cells and incubated for 4 h at 37 °C in a humidified CO_2 incubator. The reaction was terminated by centrifugation at 250*g* for 10 min and removing 100 μl of supernates from all wells to be counted in a well-type γ-counter. Specific cytolysis was calculated as $[(E-SR)/\text{Max})] \times 100$ where E is c.p.m. of experimental wells; SR is spontaneous release from targets incubated in medium alone and Max is maximal release from targets after hypotonic lysis. The standard deviation of triplicate cultures was ±2% of the mean. ND, not determined.

Thymocytes from four individuals and PBL of two donors (A.M. and A.O.) were stimulated in culture with PHA at 1 μg ml^{-1} for 3 d, then labelled with ^{51}Cr and used as target cells in the cytotoxic assay. Assay as for Table 2. The ratio of effector to target cell was 50: 1 throughout.

in particular. Normal human PBL from two individuals (A.M. and A.O.) stimulated by PHA *in vitro* were not lysed by lymphocytes of normal individuals, confirming an earlier observation[3]. By screening normal individuals for their activity in CNK it became obvious that different values of specific lysis are obtained with different donors. Figure 1 illustrates this variability when normal donors were tested against three thymocyte populations, two T-cell lines and three B-cell lines. Using thymocytes as targets, cytotoxic activity was 0–42%, compared with 10–40% with the T-cell lines and < 0–15% with the B-cell lines. It seems, therefore, that lymphocytes from different individuals have different killing activities. The range of lytic capacity extends from low to high and does not seem to fall into distinct categories. The difference in the killing activity between males and females seems to be distinct only when thymus target cells are used with males being more reactive. We have noticed that individuals with high reactivity against thymus and T-cell lines occasionally show 'cross-reactivity' against B-cell lines as shown above (see Table 2). Low killers have a more restricted 'specificity' — killing thymus and T cell lines only.

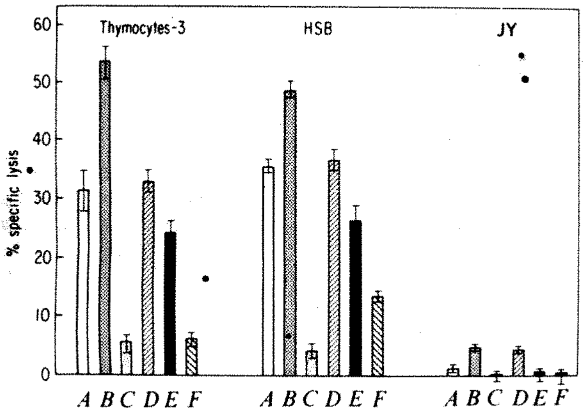

Fig. 2 Partial characterisation of the effector cell in CNK. Normal human mononuclear cells were subjected to various depletion and separation techniques (see below) resulting in populations of cells with different degrees of CNK when tested against ^{51}Cr-labelled PHA-stimulated thymocytes, HSB and JY cell lines. The ratio of effector cells to targets was 25:1. Activity is expressed as % specific lysis in a 4-h assay (as for Table 2). Spontaneous release of the target cells used in this experiment was as follows: Thy-3, 9.3%; HSB, 21.3%; JY 23.8%. *A*, Normal unfractioned cells; *B*, PBL depleted of phagocytic cells following ingestion of carbonyl iron (1 g per 5×10^6 cells incubated at 37 °C for 20 min); T-cell enriched fraction was obtained by incubating equal volumes of neuraminidase (Behring Diagnostics) treated sheep red cells (SRC) and lymphocytes for 10 min at 37 °C followed by a centrifugation at 200*g* for 5 min and incubation in ice for 1 h. The pellet was then gently resuspended in medium and rosetted cells were separated from non-rosetted cells by the use of a Ficoll–Hypaque gradient. *C*, SRC of the rosetted fraction were lysed with an anti-SRC haemolysin at a 1:10 dilution and fresh undiluted human serum; *D*, non-rosetted cells with neuraminidase treated SRC after Ficoll–Hypaque gradient separation; *E*, F_c positive cells were separated from F_c negative cells based on their ability to bind to SRC anti-SRC complexes bound to poly-L-lysine pretreated plastic dishes following the technique of Hsia *et al.*[13]; *F*, F_c negative cells were obtained by collecting cells not adhering to the antigen–antibody complexes described above.

The nature of the effector cell in CNK is a controversial issue. We have partially characterised them in our system, in limited and preliminary experiments. Different depletion and fractionation procedures resulted in populations of cells with different degrees of CNK activity. Similar profiles were obtained by testing these populations against either thymocytes or HSB target cells. The experiment illustrated in Fig. 2 shows the following. (1) Removal of phagocytic cells by carbonyl iron and magnet enriched the cytotoxic activity against both thymus and HSB targets. (2) Using sheep red blood cells as indicators, the rosetted cells, presumably T cells, were almost inactive. (3) The non-rosetted cells retained their activity. (4) Cells possessing a receptor for the F_c portion of immunoglobulin (F_c+) retained most of the activity against both thymus and HSB cells. And (5), F_c− cells had diminished activity but were by no means depleted of effector function. It therefore seems that the effector cell is not a mature T cell, nor a macrophage but is F_c+.

We have, therefore, demonstrated cellular immunity of normal individuals against T-cell lines and PHA stimulated thymocytes and a relative lack of activity against B-cell lines even when the T- and B-cell lines came from the same individual. The CNK activity that we observe also does not seem to correlate with HLA. This is in contrast to reports[14,15] of H-2 specificity in a mouse system. Our results suggesting that males have higher CNK activity than females against thymus cells, are in agreement with the findings of Santoli *et al.*[16] with human (non-lymphoid) cell lines as targets. It is tempting to speculate that our *in vitro* finding of selective CNK against leukaemic T cells but not against B-cell lines may be reflected *in vivo* by the relatively low incidence of acute lymphocytic leukaemias usually associated with cells of the T-axis characteristics[17]. Moreover, since T cells are known to be poor antigenic stimulators in MLC[18], it would be logical to propose a different naturally occurring immune mechanism controlling proliferation of immature thymocytes and leukaemic T cells. We suggest that CNK might function in such a surveillance pathway and may also discriminate between mature peripheral T cells on the one hand and immature or leukaemic T cells on the other.

We thank Drs J. Cox, G. Oldham, R. Miller, D. Sabiston, P. Cresswell, and S. Hsia for providing material for these studies, and Ms J. Kerber for secretarial assistance. This work was supported by grants from the US PHS.

Carcinogen-induced mutations at two separate genetic loci are not enhanced by leukaemia virus infection

THE interrelationship between cellular mutagenesis and carcinogenesis has been studied primarily by measuring these two events in separate target systems using chemicals with known biological activity[1]. Most carcinogens, in appropriate experimental conditions, induce mutations in prokaryotic[2] and eukaryotic[3] test systems. There are, however, some well known exceptions. Some nucleic acid base analogues and the acridines, which are excellent mutagens, are not known to be carcinogenic *in vivo*. Similarly, asbestoid minerals and some metallic salts which are potent carcinogens do not produce gene mutation. We describe here a study of the relationship between transformation and mutation with different experimental approaches, and show that carcinogen-induced mutations at two separate genetic loci are not enhanced by leukaemia virus infection.

The use of Fischer rat embryo (FRE) cells for *in vitro* assay of chemical carcinogens has been well documented[4]. In appropriate conditions, most of the ultimate carcinogens and procarcinogens transform FRE cells synergistically only after being preinfected with murine leukaemia virus (MuLV)[7]. Since infection by MuLV so profoundly affects the expression of chemically induced transformation in this sytem, it was of interest to determine the effect of MuLV on the carcinogen-induced cellular mutagenesis in FRE cells.

A clonal subpopulation of the FRE cell line F1706 used in these studies (hereafter designated as M81 cells) has been described previously[6]. Logarithmically-growing M81 cells were infected with 10^4 XC plaque-forming units of the Rauscher strain of MuLV (RLV). RLV-infected or uninfected M81 cells were treated with various doses of the potent carcinogen–mutagen, 4-nitroquinoline-1-oxide (NQO), for 1 h, washed and incubated at 37 °C in the growth medium for 72 h (expression time). The post-expression cells from each treatment group (M81+acetone; M81+RLV+acetone; M81+NQO; M81+RLV+NQO) were then used for the determination of DNA polymerase activity[7], NQO-induced transformation[8,9], and mutagenesis at two separate genetic loci.

To determine transformation in M81 cells, a previously described 'horizontal–vertical' assay[4] which involves both morphologic criterion and the loss of anchorage dependence (soft agar assay) was used. Colonies in semi-solid agar and morphologically transformed foci in liquid medium first appeared in the culture flasks after 5 and 7 subcultures respectively in the dually treated group (RLV and NQO 0.1 μg ml^{-1}). After several more subcultures, the focal characteristic of morphological transformation was lost and the entire culture appearedto be transformed. No morphological transformation or loss of anchorage dependence could be detected in the other treatment groups (M81+acetone; M81+RLV+acetone; M81+NQO 0.1 μg ml^{-1}) before the experiment was terminated at the tenth subculture. The transformation of RLV-infected FRE cells by NQO confirms the results previously reported by other investigators[10,11]. It should be noted, however, that due to the number of subcultures involved before there was evidence of transformation, enumeration of the foci or the soft agar colony counts should not be used quantitatively.

The number of mutants in M81 cells was determined by plating the post-expression cells at low densities and then, after 72 h, adding appropriate selecting media. For mutation in the recessive locus governing the expression of the enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT: EC 2·4·2·8), 8-azaguanine (AZ) was used for selection and all experiments were performed with a single lot of commercial foetal bovine serum. The frequency of the appearance of AZ-resistant colonies per plate followed a typical Poisson distribution ($\lambda = 0.1$) and were verified by χ^2 test ($P > 0.99$). Table 1 shows the number of AZ-resistant phenotypes per 10^5 survivors in a typical experiment 72 h after chemical treatment (NQO 0.1 μ ml^{-1}, 1 h). A statistically significant increase ($P < 0.01$) over the spontaneous mutation rate was clearly demonstrated with NQO treatment in both RLV-infected and uninfected groups. Using a standard one-tailed test of significance for the observed differences between two Poisson variables[12], however, there was no significant difference ($P < 0.05$) between the number of spontaneous AZ-resistant colonies in the RLV-infected or uninfected M81 cells. Similarly, RLV infection did

Table 1 Transformation and 8-azaguanine resistant phenotypes in RLV$^+$ and RLV$^-$ post-expression FRE cells

	RLV$^-$		RLV$^+$	
Carcinogen	No addition	0.1 μg NQO	No addition	0.1 μg NQO

No. of replicate plates for AZ-resistance assay	16	20	20	20
% Relative PE (at 72 h)	100	52	188	125
Total no. of AZ-resistant colonies	3	27	8	65
% Plates containing following groups of resistant colonies:				
0	81	40	65	5
1	19	20	30	0
2 or 3	0	30	5	60
4 or more	0	10	0	35
Mean no. of resistant colonies per 10^5 survivors	1.77	19.20	1.39	19

Virion-associated DNA polymerase activity in the cell culture fluids were measured using an established procedure[7] with synthetic template primer dT_{12} rA and expressed as pmol of acid-precipitable H^3-TMP per h per ml of supernatant collected at 72 h. The input radioactivity used for polymerase assay contained 1930 c.p.m. per picomole of TTP. Transformation assays[8,9] were performed for 10 subcultures after NQO treatment when the experiment was terminated; results were expressed as either positive or negative at indicated numbers of subculture. For AZ-resistance assay, 1×10^5 M81 cells were plated in 90-mm Falcon Petri dishes 72 h after NQO treatment in EMEM growth medium (Earle's minimal essential medium with 10% newborn calf serum and antibiotics). After 3 d, growth media supplemented with AZ 30 μg ml^{-1} (selective media) was added. The cultures were subsequently fed every third day with selective media and the dishes were stained with Giemsa on the fifteenth day for enumeration of AZ-resistant colonies. Plating efficiency of each treatment group was determined simultaneously by plating 5×10^2 post-expression cells in growth media without AZ. These parameters for selection of AZ-resistant cells were optimal for M81 cells in pilot experimentations performed for standardisation of the assay procedure.

Table 2 Reconstruction experiment with HGPRT⁻ subclones

Input cell mixing ratio (AZ-mutants/M81 RLV⁺)	Carcinogen treatment	% Absolute PE (72 h)	Mean no. of recovered AZ-resistant colonies per 10^5 survivors

10 AZ–2/10^5	None	56.6	24.91
	NQO 0.1 μg ml⁻¹	52.8	45.83

5×10^2 AZ-resistant mutants, AZ-1 or AZ-2 were mixed with 5×10^6 RLV infected M81 cells. 2×10^6 mixed cells were plated in T-flasks and incubated at 37 °C. After 6 h, cells were washed and treated in NQO 0.1 μg ml⁻¹ or acetone for 1 h. Each flask was then washed and incubated at 37 °C for 72 h. Selection of the AZ-resistant cells in the mixed population was performed as for Table 1 in order to determine the efficiency of the selection technique.

not significantly alter the outcome of NQO-induced mutation. Thus, although treatment with NQO produced an increase of AZ-resistant cells in both infected or uninfected groups, infection of the target cells with RLV did not alter the spontaneous or induced rate of mutation for the appearance of the drug-resistant phenotype. Several of the AZ-resistant colonies were isolated for further characterisation. Two of these clones, AZ-1 and AZ-2, were propagated for at least 50 generations in nonselective growth medium and still retained their high resistance to AZ (PE 18 and 19.6 respectively and sensitivity (PE < 0.01%) to THMG supplemented growth medium[13]. A reconstruction experiment using these two resistant subpopulations was performed to check the validity of the calculations used for the determination of the HGPRT⁻phenotypes. The results of the reconstruction experiment (Table 2) indicate that the estimates of the proportions of AZ-resistant cells, based on the selection procedure, are within the same order of magnitude of the actual proportions used for mixing resistant cells with the the parent M81 population.

Since the phenotypic expression of AZ-resistance can vary several-fold due to minor variations in the experimental protocols, it was considered necessary to determine mutation at another locus. Resistance to the synthetic steroid, ouabain, involves mutation of the gene controlling the expression of cell membrane-bound enzyme $Na^+/K^+\text{–}Mg^{2+}$-dependent adenosine triphosphatase (ATPase: EC 3.6.1.3). The mutation is codominant and a single step selection can be performed over a wide range of input cell concentrations[14]. To evaluate the effect of RLV infection on the NQO-induced mutation at the ATPase locus, subconfluent cultures were treated with different doses of NQO and the number of ouabain-resistant phenotypes was determined after 72 h expression period.

Figure 1 shows the dose–response pattern for the appearance of ouabain resistant colonies. It can be seen that over a wide range of NQO input doses, a linear response for the appearance of the ouabain resistant cells is evident in both RLV-infected or uninfected M81 cells. For uninfected cells, the regression line can be best described by the equation $F^- = 19.51 \times \mu g\ ml^{-1}\ NQO + 0.27$, while for RLV⁺ cells the linear relationship is $F^+ = 18.2 \times \mu g\ ml^{-1}\ NQO + 0.81$, where F^- and F^+ represent mutation frequencies per 10^5 survivors. However, the slopes of the two regression lines (19.51 and 18.2, respectively) are not significantly different by Student's *t* test ($P \gg 0.05$). Thus, RLV infection again failed to enhance the mutagenic response of M81 cells at any of the NQO doses tested. As before, several ouabain-resistant colonies were isolated, cultured in nonselective medium and these subpopulations were tested in a regular or K⁺-deficient

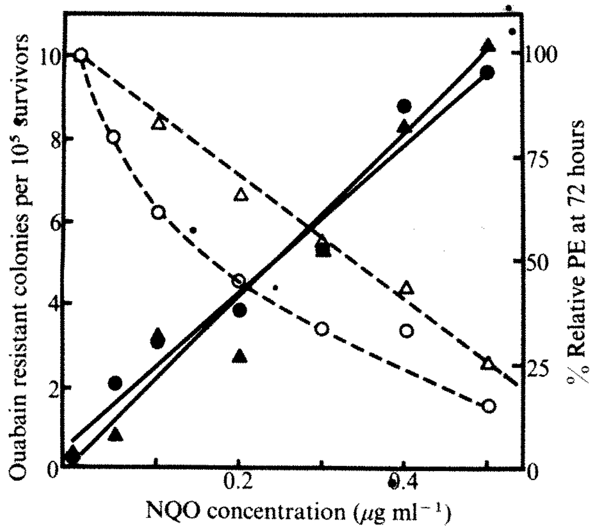

Fig. 1 Percentage survival and ouabain-resistant colonies per survivor in FRE cells as a function of input NQO dose. △, M81 relative PE (%); ○, M81+RLV relative PE (%). ▲, Ouabain-resistant colonies in 10^5 surviving M81 cells; ●, ouabain-resistant colonies in 10^5 surviving M81+RLV cells. For ouabain resistance tests, 5×10^5 cells were plated in 90-mm Falcon Petri dishes 72 h after NQO treatment in EMEM growth medium. Ouabain (2.5 mM) was added to the medium after 3 d and dishes were incubated at 37 °C without any subsequent feeding and stained with Giemsa on the fifteenth or eighteenth day for counting the drug-resistant colonies. Each point represents a mean obtained from 10 dishes, except that 20 replicates were used for groups without NQO treatment. It should be noted that normalised relative survival of each test group was based on plating efficiencies obtained at 72 h without NQO treatment (five replicates) and all PEs were performed simultaneously with the ouabain selection procedure. Solid symbols (ouabain resistant colonies) represent means of the experimentally obtained data and solid lines connecting them represent calculated regression lines. See text for regression equations for each line.

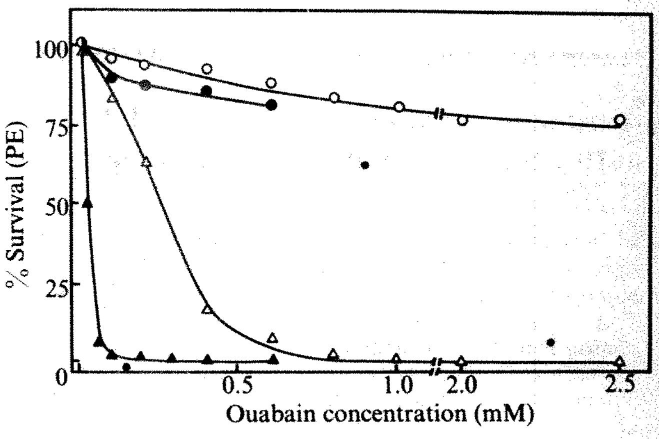

Fig. 2 Relative plating efficiencies of M81+RLV cells and an ouabain-resistant subclone (M418) as a function of ouabain concentration. △, M81+RLV cells cultivated in EMEM (55%); ▲, M81+RLV cells in K⁺-deficient EMEM (27%); ○, M418 cells in EMEM (58%); ●, M418 cells in K⁺-deficient EMEM (49%). The PE of each experimental cell line in ouabain was determined as described in the legend to Fig. 1, except that 10% dialysed calf serum (ds) was used in conjunction with ouabain treatment. Cells were plated at three different concentrations (5×10^2; 5×10^3; and 1×10^4 per plate) in triplicate and accordingly zero PE simply reflects that no surviving colonies were observed at the highest plated cell concentration. The average % PE for each of the four experimental groups without ouabain, which has been used as a basis for the normalisation of the data (100%) are given in parentheses.

selective medium for ouabain resistance. The toxicity of ouabain for M81 clones, as manifested by the reduction in the number of surviving colonies, is dependent on K$^+$ content of the medium. A typical toxicity pattern for one of the resistant subpopulations (M418) is shown in Fig. 2.

Our results indicate that although RLV infection profoundly affects the expression of transformation in FRE cells, mutation rates at two unlinked genetic loci—one co-dominant and the other recessive—are not affected by the virus. Perhaps a specific, privileged role of the ecotropic MuLV on the promotion of cellular transformation at the genetic level can be envisioned which is not applicable to other non-specific and random genetic events like mutation induced by carcinogens. In this context, it is interesting to note that chemical promoters of transformation, such as phorbol esters[15], which presumably act epigenetically, has recently been shown to also enhance the cellular mutagenesis rates[16].

Antibodies to major histocompatibility antigens produced by hybrid cell lines

FUSION between myeloma cells and spleen cells from immunised donors has been shown to be a successful method of deriving homogeneous anti-SRBC (anti-sheep red blood cell) and anti-TNP antibodies[1,2]. One of the most powerful features of this approach is that, by cloning, one may easily derive cell lines synthesising monoclonal antibodies despite using non-purified immunogens. The multiple components of a heterogeneous population of hybrid cells are resolved by cloning techniques. This feature makes the system a very powerful tool in the study of complex antigenic structures. The established cell lines offer the further advantage of unlimited permanent supply of material, and the possibility of worldwide standardisation.

We report here the derivation of lines of hybrid cells secreting antibody to rat major histocompatibility antigens. The hybrids were made by fusion of a mouse myeloma cell line[1], P3-X63-Ag8, with spleen cells of AO strain rats immunised against DA strain antigens. In previous experiments we used Sendai virus as a fusing agent. In the experiments described here we used polyethylene glycol (PEG). Fusion of animal cells with PEG is becoming a method of choice. Various protocols have been described in detail, usually for cells growing as monolayers[3–5]. We adopted some of these suggestions, which take special care with the rate of addition of reagents, time and temperature of incubations, molecular weight of PEG and so on (see legend to Fig. 1 for details). After the hybridisation the preparation was divided in Linbro plates, each 2-ml well containing about 2×10^6 spleen cells. Vigorous growth was observed in all the wells indicating the presence of multiple hybrid clones in each well. The supernatants of each well were tested for their ability to mediate the complement-dependent lysis of ^{51}Cr-labelled red cells and lymphocytes from DA strain donors. Of 113 cultures from two independent fusions 107 contained significant lytic activity. The most active cultures were further grown to larger volumes. During growth, some cultures gradually lost activity, whereas others retained or even increased their lytic activity. This presumably reflects the clonal complexity of the cultures—after a certain period, dominant clones (fastest growing) are likely to take over regardless of their antibody activity.

The individual cultures displayed lytic activities which, in some cases, could be shown to be distinctive. For instance, hybrid R2/10 lysed 100% of DA red cells, while R3/13 never lysed more than about 55%, although the titres of the two supernatants were very similar on this target (Fig. 1). Furthermore, the R3/13 supernatants tested for lympholytic activity showed a markedly higher titre than R2/10.

After about 2 months of growth, hybrid R3/12 was cloned in soft agar and 14 individual clones were selected for further studies. Supernatants from six of these were positive in three tests for specific immunological activity, while the eight others were negative in all three tests (Fig. 1). Clones R3/13-6 and R3/13-8 had lower antibody titres than the other positive clones. The Ig produced by the isolated clones was analysed by isoelectric focusing and SDS–polyacrylamide gel electrophoresis of ^{14}C-lysine-labelled secreted products (Fig. 2). In all cases the characteristic pattern of products of the parental X63 cells due to MOPC 21 IgG1 (κ) was present. All positive clones had very similar patterns of additional bands which clearly established the presence of extra components, presumably responsible for the antibody activity. These extra components were seen in IEF as a few extra bands (Fig. 2) and a background of radioactivity. A similar background of radioactivity has been observed with another plasma cell hybrid (Sp2/HLGK, ref. 2). The presence of the background in this latter case was associated with the presence of a specific IgG2b, an euglobulin which precipitates at low ionic strength (D. Secher, unpublished). Electrophoresis in reducing SDS–polyacrylamide gels shows the presence of an additional light chain in all cases. The putative specific heavy chain co-migrates with the myeloma $\gamma 1$ chain but can be separated on much longer runs. A clear indication of clonal heterogeneity was observed in clone R3/13-6 with a weak band in the position of a μ chain and an unusually high molecular weight putative L-chain (Fig. 2). This clonal heterogeneity may explain the low titre of its supernatant (Fig. 1). The reason for the low titre of clone 8 has not been investigated further.

Specifically positive clone supernatants from R3/13 were tested in various ways to demonstrate that the antigenic target for the antibody was associated with the rat major histocompatibility complex, Ag-B. Supernatants were tested against target cells of four inbred rat strains each carrying a different Ag-B haplotype including AO, the strain of the parental spleen cells used for fusion (Table 1). By ^{51}Cr release from target lymphocytes and by binding to erythrocytes, clone supernatants were reactive only against cells from the original immunising strain, DA. Chromium release data for clone supernatants were compared with two dilutions of a standard AO anti-DA immune serum. This antiserum, which maintains cytotoxic activity at a plateau up to a dilution of about 1/6,000 for DA lymphocytes, cross-reacts detectably on HO targets at about 1/800 and on AGUS targets at about 1/100. Since R3/13 clone product has a plateau cytotoxic titre of 1/384 for DA cells (Fig. 3), detectable cross-reactions would be expected at 1/48 on HO and at 1/6 on AGUS if the specificity of the clone product were similar to that of the AO anti-DA antiserum. The absence of any detectable cross reactions at 1/6 (maximum concentration tested) shows that the R3/13 clone product is much more specific than the immune serum.

Since positive clone supernatants were not reactive against HO

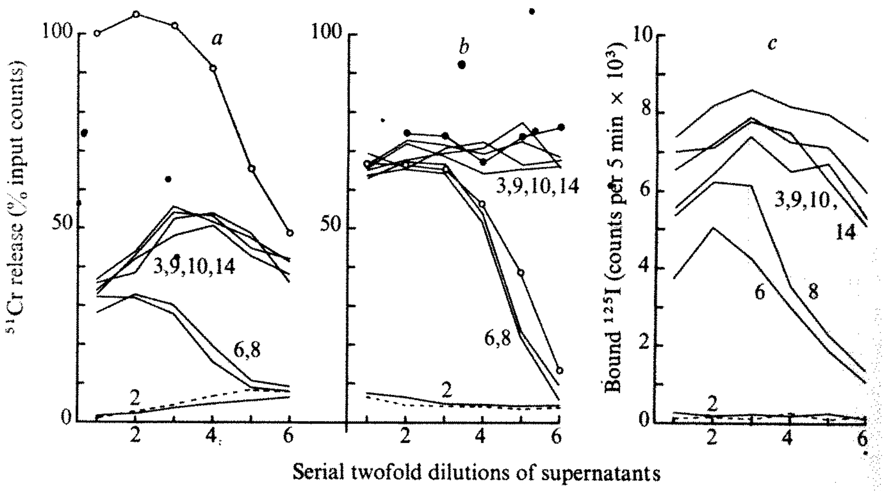

Fig. 1 Immunological activity of spent medium from plasma cell hybrids. Hybrid culture R3/13 was cloned in soft agar and 14 individual clones (R3/13-1 to R3/13-14) removed from the agar and grown separately. Supernatants from numbered R3/13 clones (—) were tested in three assays for immunological activity. Supernatant from the uncloned hybrid R2/10 (○) was included for comparison in two assays. Supernatants from clones R3/13-3, 6, 8, 9, 10, 14 were positive in all three assays, and from clones R3/13-1, 2, 4, 5, 7, 11, 12, 13 were negative in all three assays. Of the negative clones, results are shown only for R3/13-2. DMM served as negative control (– – –). *a*, Complement-dependent lysis of DA erythrocytes assayed by ^{51}Cr release. 10^8 fresh washed erythrocytes were labelled for 90 min at 37° with ^{51}Cr-sodium chromate (CJS • 4, Radiochemical Centre, Amersham) at approximately 5 mCi ml^{-1} in 0.025 ml. Assays were performed in V-bottomed microtitre trays in a final volume of 0.075 ml consisting of equal volumes of diluted clone supernatant or medium, washed labelled erythrocytes at a concentration of 5×10^7 ml^{-1} in Dulbecco's phosphate buffered saline (PBS), and guinea pig serum (absorbed with rat erythrocytes) diluted 1:1 in Dulbecco's PBS. Trays were incubated for 60 min at 37 °C. After adding 0.1 ml PBS to each well, trays were spun 10 min at 400*g* and 0.1 ml collected from each well for gamma counting. Input counts (32,994 counts per 5 min) were measured from 0.025 ml of labelled erthrocytes at 5×10^7 ml^{-1}. Final concentration of supernatant at the first dilution was 1/3. *b*, Complement-dependent lysis of DA lymphocytes assayed by release of ^{51}Cr. Viable lymph node lymphocytes were separated from erythrocytes and dead cells by centrifugation over Ficoll–Isopaque[6]. Chromium labelling and assay were as described for erythrocytes except that both procedures were performed at room temperature, labelled lymphocytes were diluted to 2.5×10^6 per ml, and the assay was extended to 90 min. Input counts (23,261 counts per 5 min) were measured from 0.025 ml of labelled lymphocytes at 2.5×10^6 per ml. (●), Titration of (AO × HO)F_1 anti-DA serum against DA lymphocytes. This serum lyses 100% of DA lymphocytes by Trypan blue exclusion at the dilutions studied in the conditions of this assay. Final concentration of supernatant at the first dilution was 1/3. *c*, Binding of R3/13 clone products to DA erythrocytes. 1.5×10^6 fresh washed erythrocytes were incubated for 15 min on ice with serial dilutions of supernatants in V-bottomed microtitre trays in a total volume of 0.05 ml. Cells were then washed twice in 0.2 ml PBS and resuspended with 0.01 ml (180,547 counts per 5 min) ^{125}I-rabbit F(ab')$_2$ anti-rat Fab (from Dr A. F. Williams). After a further 15 min on ice, cells were washed five times in 0.2 ml PBS and collected for gamma counting. Final concentration of supernatant at the first dilution was 1/2. Cell hybrids were prepared as follows: AO strain female rats were hyperimmunised by combined i.p. and subcutaneous immunisations with pooled spleen and lymph node cells from DA strain donors at monthly intervals (approximately 1/3 donor equivalent per recipient). Two and a half days before collecting spleen cells for hybridisation, hyperimmune AO rats received a final i.v. injection of DA lymphoid cells. Spleen cells for fusion were initially prepared in Dulbecco's PBS containing 2% FCS. The cells were then washed with Dulbecco's modified medium in the absence of serum (medium D), and 10^8 spleen cells mixed with 10^7 P3-X63-Ag8 cells[1] suspended in medium D' The mixture was centrifuged in a 50-ml plastic conical tube at 600*g* for 7 min. The supernatant was removed and the cell pellet disrupted by gently tapping the bottom of the tube. Further operations were performed at about 37 °C. A 1-ml pipette containing 0.8 ml of 50% PEG 1500 in medium D (*p*H 7.6–7.8) was used to suspend the cells gently while the solution was added over a period of 1 min. The suspension was kept at 37 °C for 1 min and 1 ml medium D added over a period of another min. A further 20 ml of medium D was added over a period of 5 min. The cells were centrifuged and gently resuspended in Dulbecco's modified medium containing 20% foetal calf serum (DMM). The suspension was distributed in 48 + 2 ml wells in Linbro BCL-5041 trays. In some experiments 3 + 10^5 untreated spleen cells were also added to each well to serve as a feeder. After 24 h half of the medium was replaced with HAT[8] medium. This operation was repeated in the two subsequent days and then every 2 d. Vigorous growth in a well after 14 d was taken as a successful hybrid clone(s). These were transferred into HAT medium lacking aminopterin for 4–7 days and thereafter into DMM.

(Ag-B5) cells, it was possible to show that the antigenic target for R3/13 antibody was specified in or near the chromosome region determining the major histocompatibility complex. The tests were performed on progeny from a breeding programme in which the Ag-B4 haplotype of DA is being backcrossed on to the HO background. Selected Ag-B5/Ag-B5 homozygotes and Ag-B5/Ag-B4 heterozygotes were used as target cell donors to assay the reactivity of positive R3/13 clone supernatants. The results of binding to erythrocytes and complement-dependent lysis of lymphocytes from these genetically typed donors show clearly that

Table 1 Strain distribution of antigenic target for R3/13 clone products

	Donor strain				
	AGUS	AO	DA	HO	
Input ^{51}Cr Cp5min	18,671	19,698	24,122	18,003	
C' control	2.6	2.0	2.5	2.3	Lymphocyte targets*: ^{51}Cr release as % of input counts

14 at 1/8	144	324	3,995	119	

* Complement-dependent lysis of lymph node lymphocytes from AGUS (Ag-B1), AO (Ag-B2) (syngeneic control), DA (Ag-B4) and HO (Ag-B5) donors prepared and labelled with ^{51}Cr-NaCrO$_4$ as in Fig. 1*a*, *b*. Data extracted from full titrations of supernatants and serum performed as in Fig. 1. C' control contained DMM (1/6) instead of spent medium. AO anti-DA serum cross-reacts with AGUS and HO.

† Binding of clone supernatants to erythrocytes from AGUS, AO, DA and HO donors assayed by the second stage binding of ^{125}I-rabbit F(ab')$_2$ anti-rat Fab as in Fig. 1*c*.

the antigenic target of the R3/13 clone product is specified by a gene closely linked to Ag-B (Fig. 3).

The antigenic target of clone R3/13 is present on erythrocytes and on all lymphocytes of the DA strain. Furthermore, it has been shown (unpublished results) to be inherited with the main Ag-B4 serological specificities in the only described rat MHC recombinant[7]. These observations and the restricted strain distribution suggest that the R3/13 clone product recognises a K/D-like private specificity of the Ag-B4 haplotype. We presume that analysis of further clone products will enable other specificities of the Ag-B4 haplotype to be identified.

A remarkable feature of the lymphocytotoxic results in the linkage experiment (Fig. 3) was that the R3/13 clone product released only about 45% as much ^{51}Cr from the Ag-B5/Ag-B4 heterozygous cells and from the (HO × DA)F_1 as from cells of the DA strain, with a marked plateau at this level, suggesting that the target specificity in the Ag-B4 haplotype is weakly expressed, if at all, in about half the lymphocytes from a heterozygote. This phenomenon is not seen with an immune serum (unpublished results). Whether there is total exclusion of one allele for this individual specificity, or whether its expression is being modulated by other elements remains to be seen.

The results described here extend the use of fusion techniques for the derivation of permanent lines producing homogeneous antibodies to the increasingly important area of transplantation antigens. It is hoped that such antibodies will be invaluable in the precise definition of the rat MHC, in study of the expression of its components, and in analysis of functional properties of alloantibodies such as, for example, their role in enhancement. The antigenic target of clone R3/13 is the first uniquely defined antigenic specificity in the MHC. We suggest that this approach should eventually provide the basis for a standard MHC nomenclature. The derivation of a rat–mouse hybrid cell line producing antibody against a rat transplantation antigen brings the goal of producing standard permanent supplies of monoclonal antibodies for human tissue typing and other clinical uses one step nearer.

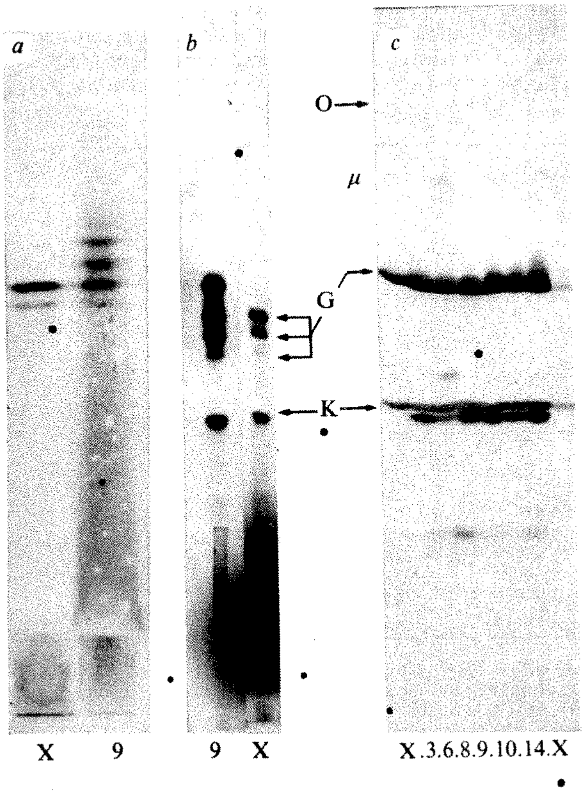

Fig. 2 Analysis of the products secreted by isolated plasma cell hybrid clones from R3/13. Cells were incubated with ^{14}C-lysine and the supernatants analysed as before[2]. *a*, Isoelectric focusing (*p*H 5, bottom; *p*H 9, top). *b*, Isoelectric focusing after reduction to separate the chains. *c*, SDS–polyacrylamide gel (10%) electrophoresis after total reduction. X refers to X63 control supernatants. Numbers refer to clones from culture R3/13 (see Fig. 1). O, origin; G and K, γ and κ chains from the Ig secreted by X63 cells; μ, putative μ chain referred to in the text.

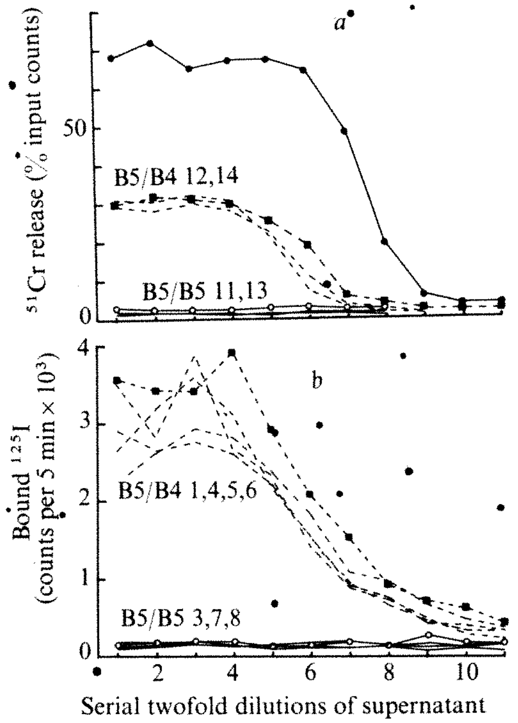

Fig. 3 Linkage of antigenic target of R3/13 clone products to Ag-B. Individuals from progeny of the fifth backcross of the Ag-B4 of DA onto the HO (Ag-B5) background were typed as either Ag-B5/Ag-B4 heterozygotes or Ag-B5/Ag-B5 homozygotes by conventional procedures[7]. Cells from typed individuals were then tested in two assays for the activity of the R3/13 clone product. *a*, Complement-dependent lysis of lymph node lymphocytes by R3/13 supernatant, assayed by release of ^{51}Cr. Lymphocytes were prepared, labelled and assayed as for Fig. 1*b*. Cells from DA (●), (HO × DA)F_1 (■) and the Ag-B5/Ag-B4 heterozygotes 12 and 14 (– – –) were lysed, while cells from HO (○) and the Ag-B5/Ag-B5 homozygotes 11 and 13 (—) were unaffected. Input ^{51}Cr counts for the seven populations tested ranged from 23,066 to 30,521 counts per 5 min. Final concentration of supernatant at the first dilution was 1/12. *b*, Binding of R3/13-9 clone product to erythrocytes. The binding of clone product was assayed indirectly as for Fig. 1*c*, by the subsequent binding of ^{125}I-rabbit F(ab′)$_2$ anti-rat Fab. Supernatant was bound to erythrocytes from the (HO × DA)F_1 (■) and the Ag-B5/Ag-B4 heterozygotes 1, 4, 5 and 6 (– – –) but not to erythrocytes from the HO (○) and the Ag-B5/Ag-B5 homozygotes 3, 7 and 8 (—). Input ^{125}I counts were 113,077 counts per 5 min. Final concentration of supernatant at the first dilution was 1/4.

Neurite induction in mature cortical neurones in feline G_{M1}-ganglioside storage disease

PYRAMIDAL neurones of the human cerebral cortex develop spine-bearing structures (meganeurites) between the cell body and the initial portion of the axon in lysosomal storage diseases characterised by intraneuronal accumulation of gangliosides[1]. Meganeurites attain enormous proportions and acquire bizarre shapes, suggesting that their development involves restricted reactivation of embryonic growth mechanisms of the neurone. Because outgrowth of neurites is a sign of differentiation in embryonic neurones we have sought evidence for neurite outgrowth from meganeurites in feline G_{M1}-ganglioside storage disease[2–4]. We report here that in this system meganeurites of mature cortical neurones regularly exhibit extensive secondary outgrowth of neurites.

Brain tissue was obtained from an 11-month-old mutant cat with confirmed β-galactosidase deficiency and abnormally high levels of the monosialoganglioside G_{M1}-ganglioside in the brain[2]. The cat was killed with pentobarbital sodium near the terminal stage of the disease. This enabled us to obtain well preserved neurones and their processes for Golgi studies[1]. The brain was then perfused with a mixture of glutaraldehyde and paraformaldehyde for morphological studies.

Aberrant growth processes were observed in several varieties of cortical neurone. Most small and medium-sized pyramidal neurones of the cerebral neocortex had large pleomorphic meganeurites between the base of the perikaryon and the initial axonal region, as in human G_{M2}-gangliosidosis[1]. But the meganeurites in the feline G_{M1}-gangliosidosis had morphological features rarely observed in the human condition, in particular many fine neurites arising from them. These outgrowths had morphological features related to the cell type and characteristics of the relevant meganeurite (Fig. 1).

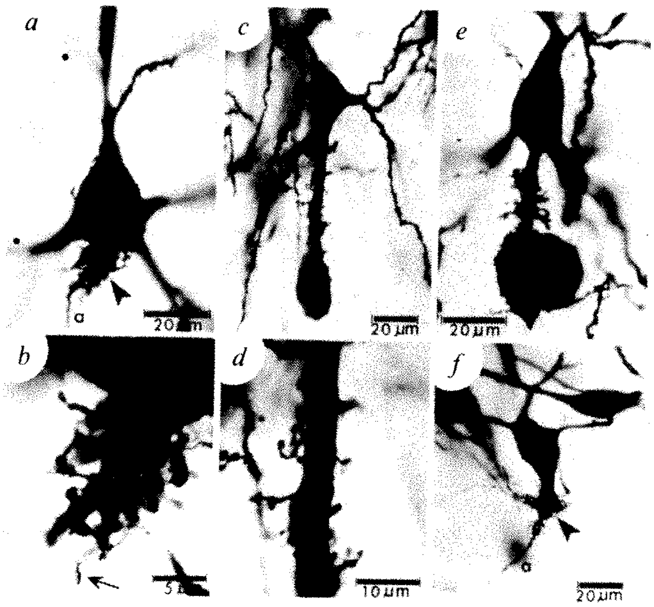

Fig. 1 Rapid Golgi preparations of cortical neurones in feline G_{M1}-gangliosidosis. *a*, Medium-sized pyramidal cell of the entorhinal cortex, meganeurite identified, at arrowhead. *b*, Enlargements of meganeurite in (*a*) to show tangle of neurites one of which has an expanded terminal head (at arrow). *c*, A neurone with a long meganeurite that gives rise to multiple neuritic growth processes, seen at higher magnification in (*d*). *e*, Another small pyramidal neurone of the cerebral cortex has a meganeurite that ends in a huge globular process. Outgrowth of neurites is prominent in the connecting stalk of the meganeurite. *f*, Granule cell of the fascia dentata of the hippocampus. Meganeurite, at arrowhead, exhibits extensive neuritic outgrowth (a, axon).

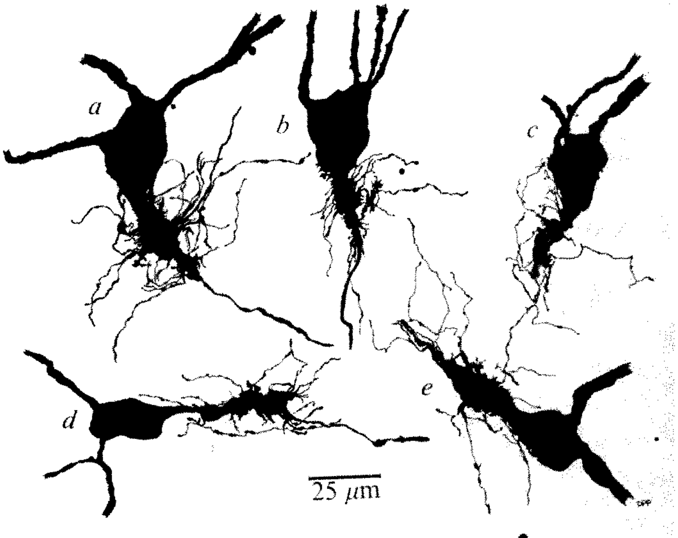

Fig. 2 Camera lucida drawings of granule cells of the fascia dentata. Only the proximal dendrites of these elements are illustrated. Cell bodies show variable shape distortion. Meganeurites arise from the base of the cell body and displace the axon distally. Extensive neurite proliferation and other growth processes are evident. Axons are identifiable in cells (*a*), (*b*) and (*d*). Fine processes also occur on portions of the cell bodies of neurones (*b*), (*c*) and (*e*).

A pyramidal neurone of the entorhinal cortex is shown in Fig. 1*a* with a meganeurite emerging from the base of the cell body. Many neuritic processes are shown as tangled outgrowths from the meganeurite, often with expanded terminal heads (Fig. 1*b*). A wide variety of neurites and other growth processes (spinules, spicules, filopodia-like elements) occur on larger meganeurites of small pyramidal neurones (Fig. 1*c*, *d* and *e*).

Extensive development of neurites on meganeurites was particularly clear in granule cells of the fascia dentata. In this relatively homogeneous population of small neurones, meganeurites formed large fusiform extensions from the base of the cell body, which is normally devoid of processes other than an axon. Long thin neurites appeared as tangled outgrowths from the meganeurite (Fig. 1*f*). The 'medusa-like' characteristics of these outgrowths is illustrated in camera lucida drawings of fascia dentata granule neurones (Fig. 2). In each of these elements the meganeurite is the site of extensive secondary neurite production. Neurites exhibit beading and tufted expansions, which are common features of neuronal growth processes in Golgi preparations[5].

G_{M1}-gangliosidosis is associated with the development of meganeurites on many types of cortical neurones in the cat, as is G_{M2}-gangliosidosis in man. Although secondary neurite formation has rarely been observed on meganeurites in classical Tay–Sachs disease[1] (infantile G_{M2}-gangliosidosis, B variant) accumulation of G_{M1}-ganglioside in feline cortical neurones seems to be a powerful stimulus for the outgrowth of secondary neurites from meganeurites in the feline mutant. Golgi studies of neurones in human G_{M1}-gangliosidosis will be necessary to determine whether the neurite proliferation is uniquely related to G_{M1}-ganglioside accumulation or the specific response of feline neurones to the ganglioside.

The demonstration that meganeurites in feline G_{M1}-gangliosidosis have growth characteristics typical of differentiating embryonic neurones raises the question of the role of gangliosides in neuronal development and synaptogenesis. Their distribution and content in the brain change during development and they are found in high concentrations in synaptosomes[6]. Although butyrate-induced process formation in differentiating HeLa cells is associated with an increase in G_{M3}-ganglioside[6], previous studies have not suggested specific involvement of gangliosides in neurite induction in normal embryonic neurones. Our results link G_{M1}-ganglioside accumulation to neurite formation in well-differentiated cortical neurones in an inherited metabolic disorder. It will be interesting to determine whether gangliosides induce or facilitate process formation in normal immature mammalian cortical neurones *in vitro*.

We thank M. Buschke and S. Brown for technical assistance and the NIH for support.

The neural representation of visual space

THE approximate form of the projection of visual space on the striate cortex in man has long been established from neurological evidence[1–3] and estimates of cortical magnification M (the extent of striate cortex in millimetres corresponding to a degree of arc in visual space) have been derived from studies on cortical phosphenes and visual acuity[4], and migraine scotoma dimensions[5]. The possibility that M could be estimated from the density of retinal ganglion cells which provide the output from the eye to the brain has received support from studies on monkeys[6–8]. It has been shown that M is proportional to $\sqrt{D_c}$ (where D_c is the projected ganglion cell density in cells per solid degree of visual space) for peripheral angles (θ) greater than 10°. More centrally, where D_c is maximal, this relationship breaks down because the cells are displaced from their receptive fields by an amount which is difficult to determine[8]. If data on ganglion cell receptive field density, D_r (in receptive fields per solid degree) were available, they might be expected to relate to M at every point in the visual field. I report here that I have obtained such estimates of D_r and examined their usefulness as predictors of M. The results are summarised in three basic equations.

In previous studies on human retinal ganglion cell density it was assumed that solid angles were directly related to retinal areas[9–11]. Subsequently, it was reported that even at retinal level the projection of the visual field is progressively compressed towards the periphery[12]. Errors in estimates of D_c, due to the outward projection of an area of retinal section, and its location in the field could easily approach 100%. To avoid these, the original data from three studies on twelve human eyes (refs 9–11) were corrected by use of a specially designed schematic eye[12] which also diminished the errors arising from tissue shrinkage and sampling variations in ocular dimensions. The reprocessed values of cell density expressed in the form $1/\sqrt{D_c}$, plotted against θ, are shown in Fig. 1. This mode of display, originally popularised by Weymouth[13] is crucial to the argument by which the values of $1/\sqrt{D_c}$ are transformed to values of $1/\sqrt{D_r}$. As M is believed to be proportional to D_r the receptive field curve affords the possibility of estimating M at any peripheral angle θ. This relationship can, however, be further evaluated by correlating the $1/\sqrt{D_r}$ values with $1/M$ derived from studies of cortical phosphenes, visual acuity and migraine scotomata.

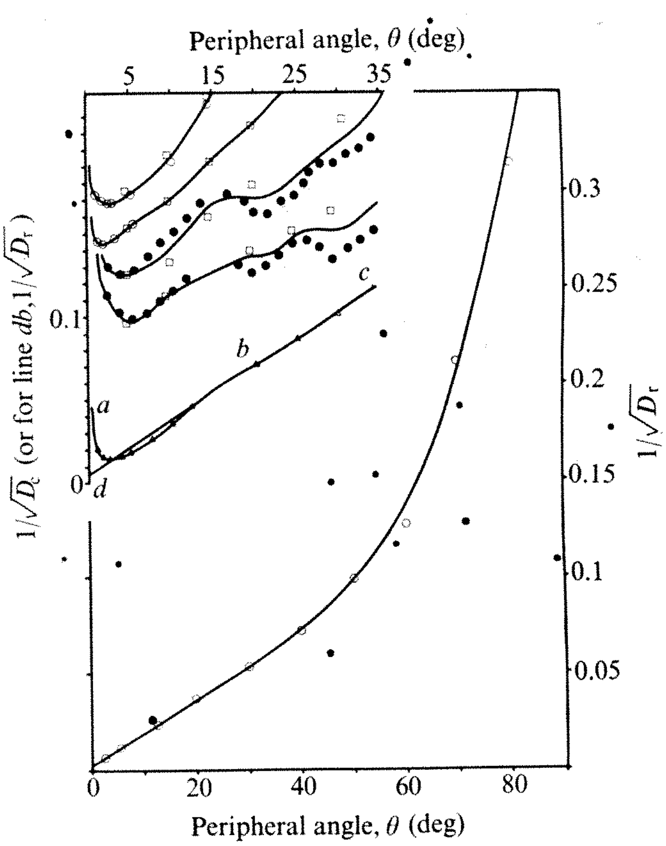

Fig. 1 The curve *abc* relates the value $1/\sqrt{D_c}$ (where D_c is the number of ganglion cells per solid degree) for the peripheral angle θ. It is the mean of the curves for the temporal nasal inferior and superior meridians of the visual field, sections of which are shown displaced upwards to avoid superimposition. The curves are based on the modified data (see text) of Vilter[9] ○, Van Buren[10] □, and Opel[11] ●. The curve *dbc* is similar but applies to receptive fields instead of ganglion cells. D_r is the receptive field density (per solid degree) and the curve relates $1/\sqrt{D_r}$ to θ. It was obtained by interpolating from *b*, beyond the area affected by excavation to *d*, at 0.0055 following Polyak's observations on the separation of the central-most foveal cones which he considered were equal in number to their ganglion cells[12]. It was realised that the two curves should determine equal populations of cells and numerical integration of D_c and D_r with solid angle showed only 6% difference in cell counts. The populations could be equated by slightly reducing the intercept value but conversely it would need to be slightly increased to take account of the findings of Missotten of the ratio of 0.9:1 for ganglion cells to cones in the rod free area[15]. The initial value was, therefore, retained as the best compromise for the purpose of the regression curve. The lower right coordinates refer to the plotted points of the final $1/\sqrt{D_r}$ values. The fitted curve is the curve of equation (1) when $k = 0.0055$. Integration of D_r with solid angle yielded an estimated total count of 1.5×10^6 receptive fields per eye.

The minimum angles of resolution obtained from the mean values of Wertheim's data on visual acuity[16], for horizontal and vertical meridians at eight selected eccentricities were compared with the receptive field data at the same points (Fig. 2). The points were chosen to give an appropriate weighting for the numbers of receptive fields within 40° peripheral angle which included more than 85% of the total count. The correlation coefficient with $1/\sqrt{D_r}$ values was very high ($r = 0.9934$) confirming some earlier suggestions[13,17]. The same approach was used on the data of Frisén and Glansholm for the horizontal meridian, which were obtained by a method which reduces optical degradation[18]. Surprisingly, the correlation was not quite so high, a fact which might be attributed to their use of a constant size of task field (4°) as Wertheim had enlarged the task details and field size equally.

The migraine scotoma has a characteristic angular velocity[19] and segment size[5,20] which varies with peripheral angle and is related to cortical magnification. Data were extracted from a graphical display[5] of scotoma dimensions and the least squares regression line predicting scotoma bar length from peripheral angle was used to derive best estimates for comparison with the $1/\sqrt{D_r}$ values. The correlation coefficient was again very high ($r = 0.9995$).

The most direct evidence of human cortical magnification was derived from the graphically displayed findings of Brindley and Lewin on visual field phosphenes resulting from cortical stimulation[21]. The angular separation of phosphenes was divided by the linear separation of electrodes to yield a value inversely proportional to cortical magnification. The method of obtaining these values, though completed independently, resembled that of Cowey and Rolls[4]. A regression line again provided the best estimate of the reciprocal of cortical magnification for selected values of θ which were correlated ($r = 0.9992$) with the $1/\sqrt{D_r}$ values (see Fig. 2).

These comparisons clearly show that $1/M$ is almost exactly proportional to $1/\sqrt{D_r}$. Evidently therefore M^2, the cortical projection of a solid degree is proportional to D_r the number of receptive fields per solid degree, and the constant which relates them must be the total striate area (for which 6,000 mm² would be an acceptable estimate[4]), divided by 1.5×10^6, the total ganglion cells of one eye (Fig. 1 legend). For the data of this study therefore, $M^2 = 0.004\ D_r$ and since the central foveal value of $1/\sqrt{D_r}$ was found to be 0.0055, D_r must be 33,058 cells per solid degree so that $M^2 = 132$ mm² per solid degree, and $M = 11.5$ mm per degree. This maximal value of M is close to that suggested by Richards[5], but differs substantially from the 15.6 mm per degree found by Cowey and Rolls[4]. It has been found, however, that the discrepancy diminishes peripherally and the results are not statistically incompatible. Cowey and Rolls used the M values of Brindley and Lewin, and related these to the acuity data of Wertheim to obtain their result. This depended in the similarity of the visual characteristics of two individual subjects. The finding of the present report is clearly based on extensive new data, and probably therefore more reliable.

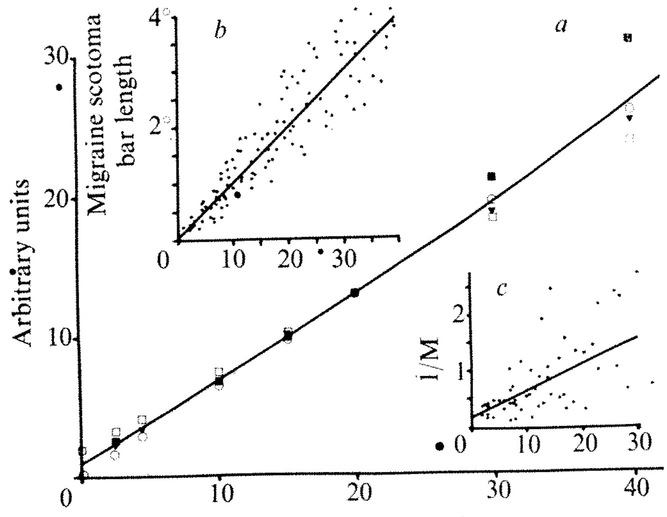

Fig. 2 *a*, Receptive field data (▼) and curve plotted for comparison with minimum angle of resolution data (■), best estimates of migraine scotoma size (○) and cortical magnification (□). All data are scaled to coincide at 20° where the ganglion cells are unaffected by excavation and where the best estimates of migraine scotoma lengths and cortical phosphene M values are most reliable. Visual resolution at this point is also considered to be relatively unaffected by optical degradation. The origin of the best estimates is shown in (*b*) and (*c*) which are based on the data of Richards[5] and Brindley and Lewin[21]. The main ordinate is scaled in arbitrary units based on the intercept of the receptive field curve which therefore satisfies equation (1) when $k = 1$. The displacement of the receptive field data points relative to the curve as compared with Fig. 1 is due to the rescaling at the 20° point. The graph shows the proportionality between the different criteria of cortical representation which are reflected in the high correlation coefficients quoted in the text.

Due to the near-perfect correlations between the $1/\sqrt{D_r}$ values and other criteria, the following equation not only describes the variation of $1/\sqrt{D_r}$ with θ, but has some remarkably general properties in relation to the structure and functions of the visual system

$$V=k[1+S\theta(1+3\theta^2\times10^{-5}+8(S\theta)^{5.5}\times10^{-10})] \qquad (1)$$

V provides an estimate of $1/\sqrt{D_r}$ or any of its correlates, such as $1/M$ or the threshold of resolution, at a peripheral angle θ if in each case the foveal value is substituted for k. S determines the initial slope of the regression curve but the peripheral slope and the limit of the visual field are controlled by the last two terms. If data averaged for all meridians are considered, $S = 0.59$ and the linear relationship, $V = k(1+0.59\theta)$ gives a useful approximation when θ is less than 30°.

The number of receptive fields per solid degree at a peripheral angle θ is easily estimated from equation (1). If $k = 0.0055$ the $1/\sqrt{D_r}$ value at the fovea, V gives $1/\sqrt{D_r}$ at θ from which D_r is deduced. Similarly, if $k = 1/M$ for the fovea, or 1/11.5 then $V = 1/M$ at $\theta°$, and M, and thus M^2 are easily obtained. (In the case of the monocular temporal crescent, however, the estimates of M and M^2 should be divided by $\sqrt{2}$ and 2, respectively.) Again, if k is the foveal threshold of resolution in minutes of arc, V provides the value at θ and thus its reciprocal, the Snellen decimal acuity. The maximum spacial information density in bits per solid degree is then $3600/V^2$, following the logic of simple information models of vision[22]. Such estimates are, of course, primarily related to the threshold of practiced observers.

The use of equation (1) is extended specifically to the temporal nasal, superior and inferior portions of the principal meridians of the visual field, if $S = (0.46-0.00043\theta)$, $(0.50+0.0019\theta)$, $(0.62+0.0033\theta)$ or $(0.66-0.0006\theta)$. The corresponding curves, as with the general form of equation (1), have a short portion which is adequately simulated by a straight line. In this case $S = 0.46$, 0.50, 0.62 or 0.66 and $V = k\ (1+S\theta)$. This simple relationship is applicable when $\theta <$ 35°, 20°, 10°, and 20°, taking the meridians in the above stated order.

The linear function, $V = k(1+S\theta)$, for small angles permits the possibility of the following analytical solution to the problem of cumulative estimates:

$$C = \int_0^\theta \frac{2\pi\theta d\theta}{[k(1+S\theta)]^2} = \frac{2\pi}{(kS)^2}\left[\log_e(1+S\theta)+\frac{1}{(1+S\theta)}-1\right] \qquad (2)$$

This gives a cumulative estimate which is within 1% of the value indicated by this study if $\theta <$ 10°, thereafter it becomes less accurate and overestimates by 5% at 45°. The symbols are as in equation (1), thus if K is 0.0055 equation (2) gives an estimate of the total number of receptive fields in a concentric solid angle of visual space, where θ is the angular semi-diameter. Similarly, if $k = 1/M$ for the fovea, that is 1/11.5, equation (2) gives the area of cortex (mm²) again corresponding to the same concentric solid angle. Due to the nature of the cortical projection, however, areas of less than 100 mm ² are best described as a percentage of cortical input.

When the receptive field counts assessed by numerical integration of D_r and solid angle were examined it was noted that the cumulative count can be described by the simplest and perhaps the most useful equation

$$Q = 100[1-\exp(-0.0574\theta)] \qquad (3)$$

where Q gives a close approximation to the percentage of total receptive fields, striate area or information channel

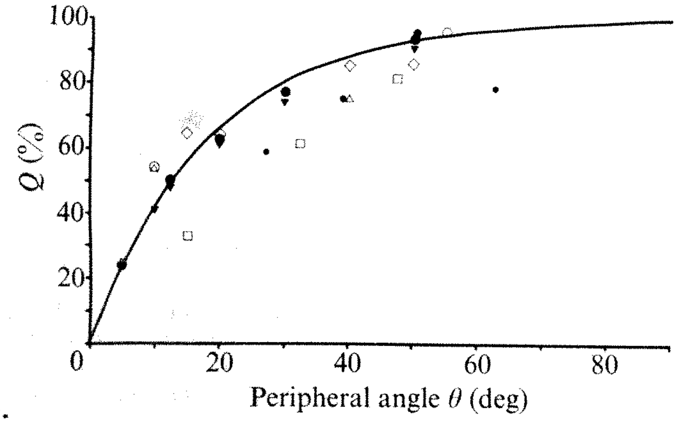

Fig. 3 Cumulative counts of ganglion cell receptive fields provided a method of estimating the percentage of the surface area of the striate cortex corresponding to a concentric region of visual space. Q is cumulative % of receptive fields, cortical area or channel capacity; ●, % receptive fields found in this study; ▼, % using equation (1) instead of actual data, curve is that of equation (3). Additional points derived from the estimates of areas from neurological maps of Holmes[1] □, Spalding[2] △, Teuber *et al.*[3] ◇, and Duke Elder[23] ○ are shown for comparison. Although such charts are designed to convey a quantitive impression, ambiguity is inevitable with the two-dimensional projection of the brain surface. Approximate values were obtained by studying the charts in conjunction with anatomical material and models, and assessing the area of redrawn sections by use of rectangular grids.

capacity for a concentric solid angle of visual space with angular semi-diameter of θ°. The cumulative count and the curve of equation (3) are shown in Fig. 3 and these may be compared with the result of an attempt to relate the present findings to accepted neurological schemes.

Contemporary theories present a complex picture of the neural connections of the visual system, but this does not diminish the usefulness of these equations which merely reflect the quantative relationships between assembled data and do not depend on a hypothesis involving sensory units.

I thank Mrs Angela Barnes for assistance with the integration for equation (2), and Miss L. F. Jenkins and Mr J. K. Querido for translations.

Enkephalin may mediate euphoria and drive-reduction reward

THE identification in brain of opiate receptors[1] and morphine-like pentapeptides (methionine-enkephalin and leucine-enkephalin)[2] has led to suggestions that enkephalin receptors may be sites at which opiate drugs induce analgesia and euphoria, and that the enkephalins themselves may be transmitters or modulators in brain systems for the regulation of pain and pleasure[3–6]. Observations in animals reveal that appropriate central administration of enkephalin produces morphine-like analgesia[7–9] and physical dependence[10]. We report here that enkephalin also may share the euphorigenic or rewarding properties of morphine in that rats will work for enkephalin injections delivered directly into the ventricles of their own brains[11]. Of particular interest, in the light of the generally superior potency of the methionine peptide[2,8,9], is the observation that leucine-enkephalin is self-administered with greater avidity than methionine-enkephalin.

Guide cannulae, of 19-gauge stainless steel tubing, were implanted above the lateral ventricle in 300–400-g male Charles River rats under pentobarbital anaesthesia. Following a recovery period of at least 1 week, rats were tested for intraventricular self-administration behaviour in a Skinner Box[12]. A 25-gauge stainless steel injection needle was inserted in the lateral ventricle via the guide cannula. The needle was connected by polyethylene tubing through a feedthrough swivel device to an infusion pump. The tubing contained one of the substances (dissolved in Ringer's solution and adjusted to pH 5.8) listed in Table 1. Each lever-press response delivered 1 µl of fluid to the brain in 0.9 s; however, responses made during the 0.9-s infusion intervals had no consequences and went unrecorded. Each rat was tested once and had access to only one solution. No lever-press training was given; rats were merely placed in the Skinner box, with food and water available, for a 66-h session.

The peptides were synthesised at Wyeth Laboratories or purchased from Bachem Inc. After purification by gel filtration (Sephadex G10), homogeneity of the peptides was verified by amino acid analysis and thin-layer chromatography. The use of highly purified material was essential; central administration of unfiltered leucine-enkephalin often caused lethal convulsions. After storage in polyethylene tubing for 66 h, solutions of methionine-enkephalin exhibited a negligible loss of activity in a standard opiate receptor binding assay[9].

Rates of self-administration were significantly higher for the enkephalins and morphine (but not the structurally related tetrapeptide, Tyr–Gly–Gly–Phe) than for Ringer's solution (Table 1). The order of preference for the peptides when tested at either 1 or 10 µg per injection was leucine-enkephalin > methionine-enkephalin > Tyr–Gly–Gly–Phe (Fig. 1). Both concentrations of leucine-enkephalin were self-injected at a higher rate than the single dose level of morphine (0.5 µg per injection), although in neither case was the difference statistically significant. The 1-µg doses of both pentapeptides caused more rapid learning of self-administration behaviour than the 10-µg doses, but the 10-µg doses generated a more sustained performance level (Table 1). Massive dosages of leucine-enkephalin (up to 10 mg in 66 h) were taken by the best responders, despite the possibility of tissue damage or other adverse effects that might have been produced by the passage of large volumes of fluid through the brain ventricles. Indeed, injections of the Ringer's vehicle itself suppressed lever-pressing behaviour. The mean response rate in the Ringer's group fell significantly below that of a non-injected group tested with empty syringes ($P < 0.005$).

To test that nonspecific behavioural stimulation was not

Table 1 Summary data of self-administration experiments

Drug	No. of rats	Dose (μg μl^{-1})	Mean self-administration responses ± s.e.m. First 24 h	Final 24 h	66-h Total	Highest 6-h rate
Ringer's	25		64.0±10.7	54.7±11.3	167.9±24.3	47.6±6.2
Morphine sulphate	9	0.5	103.4±35.2	89.1±14.4	283.0±67.1*	54.9±13.6
Tyr–Gly–Gly–Phe	5	1	71.8±29.5	96.8±47.7	237.6±103.0	51.0±18.3
	14	10	74.0±17.4	85.0±26.8	221.8±54.2	56.6±11.8
Tyr–Gly–Gly–Phe–Met	15	1	103.9±16.5†	120.7±41.9*	287.5±70.1*	68.7±13.4

*Significantly different from Ringer's solution, $P<0.05$.
†$P<0.025$.
‡$P<0.005$.

Rats implanted with permanently-indwelling intraventricular cannulae had continuous access to one of the indicated drug solutions in a single 66-h test. Each lever-press response delivered 1 μl of solution into the lateral ventricle in 0.9 s.

responsible for the high response rates in the enkephalin groups, rats previously trained to lever press for food or brain-stimulation rewards were treated with leucine- or methionine-enkephalin (50–200 μg, intraventricularly) just before the behavioural test. Lever-press rates were suppressed rather than facilitated by both peptides (Table 2), and observations of the animals revealed that their activity level had been depressed rather than increased. The behaviour more plausibly may reflect a morphine-like rewarding or addicting action of the peptides. The observed preference for leucine-enkephalin over methionine-enkephalin also may be consistent with a reward interpretation. Opiate receptor binding by the leucine peptide is reduced more by sodium and enhanced more by manganese than is the case for the methionine peptide[9,13]. Since a similar sensitivity to sodium and manganese differentiates the highly addictive opiate agonists from other classes of opiate drugs[13] these observations provide independent evidence that leucine-enkephalin may be a 'purer' opiate agonist with greater addictive or euphorigenic potential than methionine-enkephalin.

Why would a natural substance such as leucine-enkephalin possess addictive properties? One interesting, if highly speculative, possibility is that a peptide similar or identical to leucine-enkephalin may serve as a natural euphorigen[6] or reward transmitter. If this conjecture were true, reward or addiction should also be produced by release of endogenous peptide following electrical activation of enkephalin-containing neurones in the brain. Behavioural and immunohistochemical observations may be consistent with this prediction. Sites that yield high rates of self-stimulation[14] and those that contain dense networks of enkephalin-like immunoreactivity[15] often overlap in precisely the same brain regions (for example, pontine central grey, zona compacta of the substantia nigra, bed nucleus of the stria terminalis and nucleus accumbens). According to our hypothesis, self-stimulation of these regions would depend at least in part on the electrically-induced release of enkephalin and the consequent activation of opiate 'reward' receptors. If so, the behaviour should be suppressed or extinguished following administration of an opiate receptor antagonist such as naloxone.

Fig. 1 Intraventricular self-administration of opiate peptides and morphine. *a*, 10 μg per injection; *b*, 1 μg per injection. Curves show mean number of self-injections, cumulated at successive 6-h intervals over the entire 66-h test, of different groups of rats. For further details see Table 1. ■, Tyr–Gly–Gly–Phe–Leu; ×, morphine SO$_4$ (0.5 μg); ●, Tyr–Gly–Gly–Phe–Met; ▲, Try–Gly–Gly–Phe; ○, Ringer's.

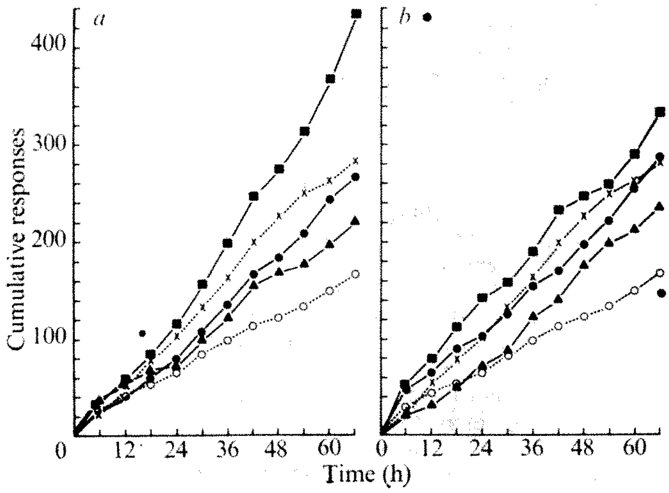

Table 2 Suppressant action of enkephalin on operant behaviour maintained by food or brain-stimulation reinforcement

Drug	Dose (μg)	Lever-press rate (% of no drug) Food	N	Brain stimulation	N
Ringer's		125.5±23.4	4	101.8±12.4	9
Methionine -enkephalin	50	57.6±25.6	4	not tested	
	100	46.1±35.9	4	84.3±5.2	3
	200	not tested		38.8±28.6	2
Leucine -enkephalin	100	57.8±16.1	8*	61.1±2.0	2
	200	39.8±39.5	2	28.6±0.8	2*

*Significantly different from Ringer's, $P<0.05$.

Lever-press responses were reinforced either by electrical stimulation of the medial forebrain bundle on a continuous schedule or by presentations of sweetened milk on an aperiodic schedule (average, once every 2 min). All drugs were dissolved in 10 μl of Ringer's solution and injected in the lateral ventricle either 20 min after the start of the 40-min brain-stimulation reward test or immediately before the 72-min food reward test. *N*, number of rats.

Eight rats with electrodes in or just lateral to the pontine central grey received self-stimulation training until their 1-h response rates had stabilised (range, 1,200–5,000 responses per h). The central grey region was selected for initial testing because electrical stimulation of this site induces profound analgesia as well as high-rate self-stimulation[16]. Naloxone hydrochloride (0.1–10 mg kg^{-1}, subcutaneously) was administered at weekly intervals immediately before the behavioural test. As predicted, dose-related decreases in the self-stimulation rate were obtained in virtually every case (Fig. 2). Because the central grey region contains high concentrations of noradrenaline[17], a substance previously shown to be involved in self-stimulation[18], the same rats were further tested with different doses of the noradrenaline synthesis inhibitor, diethyldithiocarbamate. Again,

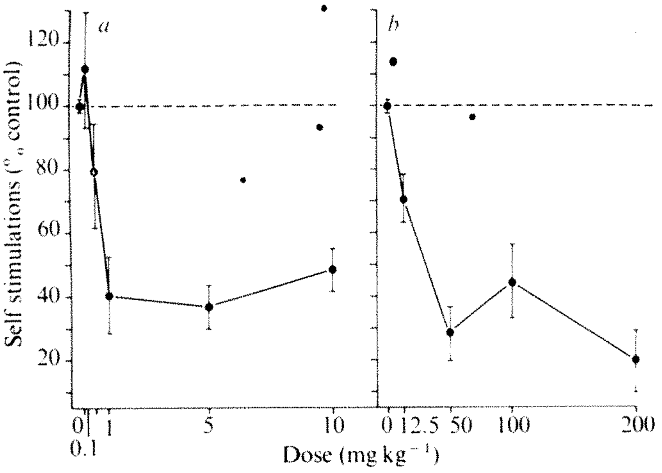

Fig. 2 Dose-related suppression of central grey self-stimulation following subcutaneous administration of the opiate antagonist naloxone (*a*) or the dopamine-β-hydroxylase inhibitor diethyldithiocarbamate (*b*). Each data point is the mean of 3–8 observations. Bars indicate standard errors.

response rates were suppressed in a dose-related fashion (Fig. 2). These results suggest that central grey self-stimulation may depend on the activation of both noradrenaline-containing and enkephalin-containing neurones; indeed, since all of the enkephalin-rich self-stimulation sites referred to above are also rich in catecholamines[17], it is possible that the reward process may generally be regulated by the interaction of noradrenaline, dopamine, and enkephalin systems. Studies on intravenous self-administration of opiate drugs similarly suggest that catecholamine mechanisms are involved in opiate reinforcement[19,20].

Diverse, but complementary, reward functions can also be recognised at the behavioural level. One of these corresponds to a state of incentive, and is the process by which behaviour in pursuit of a goal is motivated and steered; this 'drive-inducing' reward function may be mediated by catecholamines[21]. The second corresponds to a state of satisfaction or well being, and is the process by which an episode of behaviour is ended following the attainment (and consumption) of the goal; this 'drive-reducing' reward function may be mediated by an opiate peptide such as leucine-enkephalin.

We thank C. D. Wise for advice and measurements of opiate receptor binding activity, V. Garsky for purifying the peptides, and A. T. Shropshire and H. Morris for technical assistance.

Selective vulnerability of neurones in organic dementia

THERE are many causes of the clinical state dementia. Excluding those patients with tumours, infection or vascular disease, there remains a large group[1] whose brains are atrophied and contain an excess of senile morphological change (senile plaques, neurofibrillary degeneration and granulovacuolar change) in the cortex. When this condition occurs before the age of 65 years it is known as presenile dementia or Alzheimer's disease; after this age it has been called senile dementia. Since there is no good reason on pathological grounds[2] to maintain this distinction, we use the term Alzheimer's disease irrespective of the patient's age. Together with Parkinson's disease and Huntington's chorea, Alzheimer's disease is one of a group of disorders that Gowers (see ref. 2) called abiotrophies, in which nerve cell loss appears to occur in characteristic patterns (that is, substantia nigra, basal ganglia and cortex, respectively). The cause of this cellular death remains unknown. Morphological assessment of possible nerve cell loss[2] or glial cell increase[3] has been difficult, particularly in Alzheimer's disease. We have sought therefore to complement histological findings by measuring appropriate biochemical constituents of brain as indices of total neural cell numbers. Whole temporal lobes have been homogenised and analysed and the results expressed per lobe. The results[4] suggest that whilst the total number of glial cells is relatively unchanged, there is a loss of approximately half the total nerve cell population. This estimate is based on comparison with age-matched controls, and so the selective neuronal loss is probably a disease-related phenomenon. These findings conform with conclusions drawn from morphological data[5].

Evidence of selective changes in the number or state of specific types of neurone has been obtained by measuring the concentration of putative neurotransmitters and their biosynthetic enzymes. Thus there is selective reduction in the concentrations of dopamine[6] in the substantia nigra and GABA[7] in the striatum in patients with Parkinson's disease and Huntington's chorea respectively, suggesting a defect in dopaminergic or GABA-containing neurones. Choline acetyltransferase (CAT) and glutamic acid decarboxylase (GAD) are believed to be markers of cholinergic and GABA-containing neurones, respectively[8]. In Huntington's chorea GAD activity is selectively depleted only in morphologically affected regions[9,10]. There are indications, however, that in Alzheimer's disease, the activity of CAT is reduced (compare groups 4 and 5, Table 1) and that this parallels increasing senile morphological change[8], which in turn correlates with dementia score[11].

It is unclear whether or not our earlier finding of reduced cortical GAD activity in Alzheimer's disease (group 5, Table 1) accurately reflects the pre-terminal state of GABA-containing neurones[8]. This is because most demented patients die from severe bronchopneumonia[8] and probably also have a defective respiratory reflex[12] with reduced cerebral blood flow terminally[13]. This is important, for GAD activity and the concentration of a soluble acidic brain protein (neuronin S-6) seem to decline both in baboon brain with reduced cerebral blood flow[14] and in human brains from non-demented patients either dying of bronchopneumonia (compare GAD activity in groups 3 and 4, Table 1) or with evidence of more severe terminal cerebral hypoxia[8]. Furthermore, the concentration of neuronin S-6 is markedly depleted in cortex from cases of Alzheimer's disease[8,15]. There are indications[16] that this decrease in GAD activity is because of denaturation at acidic *p*H values. Our findings, and those of McGeer and McGeer[10] on the effects of terminal coma, demonstrate the importance of making allowance for the agonal state.

In an attempt to resolve these difficulties we have examined cortical biopsies removed at craniotomy (group 2, Table 1). Most of these were cases of Alzheimer's disease, and the mean CAT activity is reduced by over 50% while GAD activity is

Table 1 Choline acetyltransferase (CAT) and glutamate decarboxylase (GAD) activities in human post-operation and post-mortem neocortical specimens

Brain specimen and group no.	CAT activity (units per min)	GAD activity (units per min)	Total protein (mg per g wet weight)
Post-operation specimens			
(1) Control tissue*	66.80±26.96 (10)	1333±467 (8)	81.2±17.5 (10)
(2) Alzheimer's disease and related disorders†	27.52±15.38 (6)[a]	1393±329 (5)	75.7±17.6 (6)
Post-mortem tissue‡			
(3) Controls dying suddenly	62.78±14.75 (12)	1090±460 (17)	74.6±14.9 (17)
(4) Controls dying of bronchopneumonia	71.83±16.42 (7)	690±182 (8)[c]	75.1±18.4 (7)
(5) Alzheimer's disease dying of bronchopneumonia	36.62±10.65 (6)[b]	295±89 (9)[d]	75.1±10.4 (8)

CAT, GAD and protein were measured as previously described[8]. Data are mean ± s.d.; numbers in brackets are number of cases; enzyme units are pmol acetylcholine or GABA formed per mg protein. [a]–[d]Identify significant differences between closely matched groups. CAT activity: [a]group 2 compared with 1, $P<0.01$; [b]group 5 compared with 4, $P<0.001$. GAD activity: [c]group 4 compared with 3, $P<0.05$; [d]group 5 compared with 4, $P<0.001$.

*Normal neocortex removed at surgery for tumours; mean age 42±20 (range 10–67). For these specimens neither CAT nor GAD are age-dependent which contrasts with data for post-mortem samples from cases aged 5–50 (ref. 23).

†Neocortex from 2 biopsy confirmed cases of Alzheimer's disease and 2 probable cases; an adolescent with cerebral atrophy and some symptoms of schizophrenia ('dementia praecox') and a case of Parkinson's disease with a sister with pre-senile dementia; mean age 49±18 (range 18–65).

‡Calculated from previously published data for neocortex from cases matched with respect to the interval between death and autopsy. The ages for groups 3, 4 and 5 are 72±13 (range 50–100), 66±16 (range 37–84) and 85±5 (range 79–97). For these specimens neither CAT nor GAD activities are age-dependent[8].

unaffected. For the four Alzheimer cases alone CAT activity (24.10±18.63 units) is reduced ($P<0.02$) by a mean of 64% while GAD activity (1298±205 units) is unchanged. The results for the biopsy samples are unique for this is the first time that CAT activity in diseased human brain has been shown to be reduced with GAD activity remaining unaltered. Comparable results have been reported recently[17] for the density of putative acetylcholine and GABA-receptor binding sites in striatum in Huntington's chorea.

The depletion in CAT activity that we have detected is of particular interest because the anticholinergic glycolate esters, of which the muscarinic cholinergic marker quinuclidinyl benzilate[17] is a prominent example, can cause complete amnesia[18]. Furthermore, despite inconsistencies in the literature[19], at least one pharmacological study[20] on humans indicates that the cholinergic system is involved in age-related memory degeneration. In order to provide a rational basis of treatment other tentative markers of the state and number of specific types of neurones are being measured. Preliminary results are encouraging for in one case (a 63-yr-old patient that probably had Alzheimer's disease) CAT activity in the biopsy was reduced by 67% and the high affinity uptake of choline was found to be reduced by 66% (the control uptake data ±s.d. expressed as c.p.m. per mg protein per c.p.m. per ml medium[14] being 0.0097±0.0029, $N=7$). In contrast, GAD activity and guanylate and adenylate cyclase activities[16] (the latter being potential indices of the post-synapse) and β-alanine independent GABA uptake[14] were all within 1.5 s.d. of the appropriate mean control value.

When the data for the biopsy and autopsy samples are considered together they suggest that at least the presynaptic cholinergic system is selectively affected in Alzheimer's disease. This perhaps offers the possibility of treatment with a centrally acting anticholinesterase for at present only about 14% of cases of organic dementia are treatable[21]. This therapeutic approach may not be entirely successful, however, as there are indications that other aspects of brain metabolism may be decreased, which may interact with the presynaptic cholinergic system[22].

This work was made possible due to the help from many colleagues. We are particularly grateful to Professor J. A. N. Corsellis, Dr Alan Cowey, Mr Anthony J. Strong and Mr Lindsay Symon. The work was supported by the MRC, the Marks Charitable Trust and the Wellcome Trust.

Note added in proof: Data published recently[24–27] substantiate our contention that the pre-synaptic part of the cholinergic system might be selectively affected in Alzheimer's disease.

Catechol oestrogens inhibit oestrogen elicited accumulation of hypothalamic cyclic AMP suggesting role as endogenous anti-oestrogens

THE catechol oestrogens, including 2-hydroxyoestradiol and 2-hydroxyoestrone, are recognised as major metabolic products of oestrogen[1]. Catechol oestrogens are present in both pituitary and hypothalamus in concentrations at least tenfold higher than the parent oestrogens[2]. In addition, the synthesis of catechol oestrogens by rat hypothalamic tissue *in vitro* has also been reported[2,3]. Catechol oestrogens compete with 17-β-oestradiol (E_2) for soluble oestrogen receptors of the pituitary and hypothalamus[4], suggesting a role for these compounds in the control of gonadotrophin secretion within the pituitary–hypothalamic axis. We have investigated the effects of 2-hydroxyoestradiol on the oestrogen-elicited accumulation of cyclic AMP in intact hypothalami *in vitro*, and we report here that 2-hydroxyoestradiol antagonises the increase in cyclic AMP elicited in hypothalami of immature female rats by both diethylstilboestrol (DES) and E_2, suggesting that 2-hydroxyoestradiol may function as an endogenous anti-oestrogen.

Confirming previous reports[5,6,12,13], both DES and E_2 significantly stimulated the accumulation of cyclic AMP in incubated rat hypothalami. Preincubation of hypothalami with equimolar (20 μM) concentrations of 2-hydroxyoestradiol significantly inhibited the DES and E_2 stimulated accumulation of cyclic AMP by 57% and 68%, respectively (Table 1). At 20 μM, 2-hydroxyoestradiol alone did not significantly stimulate the accumulation of cyclic AMP. In contrast to inhibitory effects of 2-hydroxyoestradiol, its O-methylated metabolite (2-methoxyoestradiol) was inactive at concentrations up to 50 μM. Previous studies[5] have shown oestrone and oestriol to have no significant stimulatory effects on the accumulation of cyclic AMP. Equimolar (20 μM) concentrations of either oestrone or oestriol inhibited DES-elicited accumulation of cyclic AMP only marginally. The anti-oestrogen clomiphene citrate (20 μM) was previously shown to antagonise[5] (by 50%) the effects of DES (20 μM); this finding was confirmed in the present study (41% inhibition, see Table 1).

The ability of oestrogenic compounds to stimulate the formation of cyclic AMP in the isolated hypothalamic preparation seems to parallel the oestrogenic potency of these compounds both *in vivo* and *in vitro*[5,6]. In addition, the oestrogen-elicited increases in cyclic AMP are antagonised by the anti-oestrogen clomiphene and are not observed with physiologically inactive oestrogen enantiomers such as 17-α-oestradiol. Furthermore, both clomiphene and 2-hydroxyoestradiol are ineffective in antagonising the effects of DES if added 40 min after the oestrogen, and both α- and β-adrenergic antagonists are effective inhibitors[6,12]. These observations suggested that an initial binding to hypothalamic oestrogen receptors is a prerequisite for DES- or E_2-elicited accumulation of cyclic AMP and the stimulatory effects of oestrogens on cyclic AMP formation result from an oestrogen-receptor dependent release catecholamines rather than a direct activation of an oestrogen-receptor linked adenylate cyclase[6].

Our data clearly demonstrate that the catechol oestrogen 2-hydroxyoestradiol, like clomiphene, antagonises the effects of both DES and E_2 on generation of cyclic AMP in the hypothalamus, whereas weakly oestrogenic compounds such as oestriol and oestrone are ineffective as either agonists[5,6] or antagonists. The observation that 2-methoxyoestradiol does not antagonise the effects of DES *in vitro* indicates that *O*-methylation may serve as a major route of inactivation for these compounds as this pathway proceeds readily both *in vitro*[14] and *in vivo*[15].

The presence of catechol oestrogens in brain and various endocrine tissues in concentrations that exceed those of the parent compounds[2] suggests that these catechols could function as endogenous anti-oestrogens, and thus may regulate the actions of oestrogens *in situ*. Reports that administration of 2-hydroxyoestrone to ovarectomised, oestrogen-primed female rats[16] or immature male rats[17]

Table 1 Inhibition of oestrogen-elicited accumulation of hypothalamic cyclic AMP by 2-hydroxyoestradiol

	Additions	Cyclic AMP (pmol per mg protein)	Inhibition (%)
Series I			
	None	8.9±0.9 (8)	
	DES (20 μM)	25.5±2.4 (7)	
	2-hydroxyoestradiol (20 μM)	9.0±2.6 (3)	
	DES (20 μM) + 2-hydroxyoestradiol (20 μM)	15.9±2.2 (6)	57*
	DES (20 μM) + 2-methoxyoestradiol (50 μM)	25.5±1.5 (3)	0
	17-β-oestradiol (20 μM)	12.0±0.5 (5)	
	17-β-oestradiol (20 μM) + 2-hydroxyoestradiol (20 μM)	9.9±0.9 (4)	68†
Series II	Additions	Cyclic AMP (pmol per mg protein)	Inhibition (%)
	None	6.3±0.6 (7)	
	DES (20 μM)	18.4±0.5 (6)	
	DES (20 μM) + clomiphene citrate (20 μM)	13.4±1.4 (5)	41§
	DES (20 μM) + 2-hydroxyoestradiol (20 μM)‡	16.8±1.5 (6)	14
	DES (20 μM) + oestrone (20 μM)	16.3±1.8 (7)	17
	DES (20 μM) + oestriol (20 μM)	18.6±1.4 (6)	0

Female Sprague–Dawley rats (Taconic Farms), aged 26–28 d were used. Animals were killed by decapitation and hypothalami removed and dissected[5,6]. Hypothalami from groups of 10 rats were incubated at 37 °C in 20 ml Krebs–Ringer bicarbonate buffer with glucose (KRBG)[7] and gassed with 95% O_2–5% CO_2. After 45 min hypothalami were washed once with an equal volume of KRBG and transferred to individual 30-ml beakers containing 10 ml of KRBG plus test agents. Steroids were dissolved in 75% ethanol and added in a volume of 20 μl. Hypothalami were pre-incubated with catechol oestrogen (or clomiphene) for 10 min before addition of oestrogen. Hypothalami receiving oestrogen alone received an equal volume of 75% ethanol 10 min before addition of oestrogen. After addition of oestrogenic compounds incubations were continued for an additional 70 min and terminated by homogenisation of hypothalami in 1 ml of 5% trichloroacetic acid. Recovery of cyclic AMP was monitored by adding 0.1 pmol of ^{3}H-cyclic AMP (22 Ci mmol^{-1}). After centrifugation, 300 μl of supernatant was withdrawn, 20 μl of 1 N HCl was added, and the trichloroacetic acid supernatant was extracted four times with three volumes of diethyl ether. Residual ether was removed by heating at 56 °C for 3 min. Samples were frozen on dry ice and lyophilised. Cyclic AMP was determined by the protein binding technique of Gilman[8] as modified[9]. Protein was determined by the Miller[10] modification of the Lowry[11] technique. Inhibition (as %) of oestrogen effects by putative antagonists was calculated by the formula

$$[1-\left(\frac{(\text{oestrogen}+\text{antagonist})-\text{basal}}{(\text{oestogen})-\text{basal}}\right)] \times 100$$

Steroids, radioisotopes and reagents were from sources described before [5,6]. Values are mean ± s.e.m.

*$P < 0.02$ Student two-tailed *t* test.

†Not significantly different from no additions.

‡2-Hydroxyoestradiol added 40 min after DES.

§$P < 0.01$, Student two-tailed *t* test.

produces marked elevations in plasma luteinising hormone are also consistent with an anti-oestrogen action for the catechol oestrogens.

We thank Dr J. Axelrod for helpful discussions and Mrs Linda Stalvey for technical assistance. Dr J. Fishman provided 2-methoxyoestradiol and 2-hydroxyoestradiol was from Schering, Berlin.

Prenatal exposure of human foetuses to synthetic progestin and oestrogen affects personality

THE offspring of mothers given steroid hormones for the maintenance of at-risk pregnancy provide a human population equivalent to experimental animals for investigating early hormone effects on behaviour and personality[1]. Although patients showing the genetically induced clinical endocrine syndromes[2] associated with diminished or augmented prenatal hormone levels have been used as an alternative source of subjects, they are less useful, as results attributed to the altered hormone environment can also be attributed to genes linked to the primary source of the endocrine disfunction. Investigations using offspring of hormone-supported pregnancies are equivalent to the animal studies because in both cases the source of hormone intervention is exogenous. We report here that prenatal exposure to synthetic progestins and oestrogens affects later personality in humans.

Hormones administered to support at-risk pregnancy include both natural and synthetic progestins and oestrogens. Many of the synthetic progestins are similar chemically and in action to androgen[3,4,5] and in some cases masculinise the genitalia of exposed females. Only three samples of prenatally hormone-exposed individuals have been studied previously[3,6,7]. Unfortunately, all three of these studies suffer from design problems including lack of controls or inappropriate control groups, small sample size, and incomplete treatment information. Although individuals born of pregnancies treated with steroid hormones provide the best population with which to study the effects of the prenatal hormone environment on human behaviour, the paucity of such studies is understandable due to the difficulty of identifying and locating subjects whose mothers received hormonal intervention during pregnancy and appropriate control groups. This investigation was designed to overcome the problems of the previous studies and to expand their findings.

Six hundred records from two Los Angeles clinics and a private medical practice were reviewed. Thirty-four families were identified in which at least one pregnancy had been treated with synthetic progestin alone or in combination with oestrogen and at least one pregnancy had not been treated with these hormones. Of the 600 cases reviewed, only two children exhibited congenital abnormalities; namely a heart defect and missing fingers and toes. All available offspring of every family were evaluated for inclusion in the study. To participate, offspring of the treated and untreated pregnancies had to conform to the following criteria—the same parentage within families; at least 5 yr of age at time of study; and complete doctor and hospital records on pregnancy and delivery. Thirty-six physicians and 50 hospitals across the United States furnished the pregnancy and delivery records for the unexposed siblings and additional information on the treated pregnancies. The criteria for qualification as a treated pregnancy included a dosage minimum of 450 mg progestin (range 478–9,890); duration of at least 4 weeks (range 4–36); and treatment beginning in the first trimester of pregnancy. The final sample comprised 42 hormone-exposed subjects aged 5–17 yr (15 males and 27 females) and 42 unexposed siblings (6–18 yr; 18 males and 24 females). Birth order was balanced between exposed and unexposed subjects.

It was thought that a group of subjects could be found whose mothers were treated with a similar and consistent hormone regime during pregnancy, but review of medical records showed that treatment schedules, dosages and hormone combinations varied considerably not only among doctors but from patient to patient. Physicians frequently administered several different progestins and/or oestrogens to a single woman over the course of pregnancy. The most generally administered hormone preparations were Colprosterone, Norlutin, Delalutin, Deluteval, Provera, Provest and diethylstilbestrol. This necessitated the *post hoc* strategy of segregating subjects into two groups based on treatment regime. Group placement was defined by the ratio of progestin to oestrogen administered to the mothers of exposed subjects. The 26 members of the progestin group (P_o) were exposed to a mean ratio of 548 mg progestin to 1 mg oestrogen, when they were exposed to both hormones. Mothers of 17 subjects from this group received no oestrogen at all. Mean progestin intake per matter was 2,994 mg (range 525–9,890). The 16 subjects in the oestrogen group (O_p) were exposed to more oestrogen than progestin. The mean ratio of progestin to oestrogen was 1 : 4 and the mean total dose of oestrogen per subject was 6,119 mg (range 3,500–13,905). Mean ages for exposed subjects in the P_o and O_p groups were 12.46 and 12.06 yr respectively; mean ages of unexposed siblings for both the P_o and O_p groups were 11.8 yr at time of testing. Subjects were given the age-appropriate Wechsler intelligence scale and Cattell personality questionnaire by testers with no knowledge of the purposes of the study and the treatment category of the child. These instruments were selected for their comparability of scores across age groups.

Analysis of covariance was applied to IQ and personality scores to eliminate possible confounding influences such as heredity–family environment and prenatal and perinatal complications. The covariate of unexposed sibling score acted as a statistical control for heredity and family environment and prenatal and perinatal complications scores (severity and number of pregnancy and delivery problems) acted as controls for the at-risk nature of the treated pregnancies. Statistical application of these covariates to the scores of subjects in the exposed groups adjusted them so that they could be considered as having been generated from subjects obtained through pre-experimental random assignment to groups. This adjustment provided a *post hoc* statistical technique yielding a basis for the assumption of equality of groups before the application of treatment. Covariance analysis was also used on difference scores generated by subtracting the score of the unexposed sibling from that of the exposed subject within families—only prenatal and perinatal complications scores were applied as covariates.

Prenatal hormone exposure significantly affected subjects' responses to the personality measure. Significant differences between the P_o and O_p treatment groups were found on five personality factors: P_o group subjects were significantly more independent, sensitive, individualistic, self-assured and self-sufficient than the exposed offspring of the O_p group, while the O_p group subjects were more group-oriented and group-dependent (Table 1).

Table 1 Progestin (P_o) and oestrogen (O_p) group means for five personality factors

	Ind.	I	J	O	Q_2
P_o	7.30	6.75	7.82	2.54	6.70
O_p	5.13	5.28	4.04	5.07	3.11

Mean scores of P_o and O_p groups on five factors from the Cattell personality questionnaires (Early School Personality Questionnaire, Children's Personality Questionnaire, High School Personality Questionnaire, and 16 Personality Factors) which yielded statistically significant between group differences ($P \leqslant 0.05$). The factors are bipolar dimensions with the high-score pole versus (vs) the low-score pole for each as follows: Ind. (independent vs subdued); I (sensitive vs tough-minded); J (individualistic vs group-oriented); O (insecure vs self-assured); and Q_2 (self-sufficient vs group-dependent). The possible range in which an individual's score can fall is 1–9 with the norm by age and sex set at 5.

Similar results, consistent with the between groups analysis, were obtained when exposed subjects were compared with their unexposed siblings within families (Table 2). The exposed subjects of the P_o group were significantly more independent, individualistic, self-assured and self-sufficient than their siblings. The subjects of the O_p treatment group were significantly less individualistic, and therefore more group-oriented than their siblings and less self-sufficient and therefore more group-dependent. An integration of these findings results in the characterisation of the P_o group subjects as 'inner' or 'self' directed and those exposed to the O_p regime as 'outer' or 'other' directed in relation both to the other treatment group as well as their siblings.

The P_o group profile corresponds well to the findings of Ehrhardt & Money[3]. The mothers of their progestin exposed subjects reported high levels of self-assertive independence and self-reliance and correspondingly low frequencies of dependency and demand for succorance when describing their offspring.

In contrast to the earlier report[3], we found no significant differences on any of the scores generated from the Wechsler IQ tests. The full scale IQ for the exposed subjects of the P_o group was 121.08 with 120.12 for their siblings. The O_p group mean was 122.25 in contrast to 120.19 for their siblings. It seems that exposure to synthetic progestin alone or in combination with oestrogen has no effect on IQ, neither augmenting nor diminishing scores, when exposed subjects are compared to the base line provided by the family. The scores of both exposed and unexposed subjects, however, were 20 points higher than the norm, similar to the results obtained in the study of 10 genitally-masculinised girls[3]. The consistently elevated scores probably reflect the socioeconomic status (SES) of these families who undertook this expensive and time-consuming treatment to support at-risk pregnancy (76%, or 26 families fell into the highest SES categories, I and II, of the Hollingshead scale and no family was from the lowest category, V). As would be expected, the best predictor of the later IQ scores of exposed subjects was the IQ of their siblings (r=0.46).

Table 2 Group mean difference scores on five personality factors

	Ind.	I	J	O	Q_2
P_o	+1.19*	+0.37	+1.39*	−1.30*	+2.93*
O_p	−0.50	−0.65	−1.40*	−0.06	−3.67*

Mean difference scores of P_o and O_p groups on five factors from the Cattell personality questionnaires (see Table 1 for explanation of factors). A difference score is derived by subtracting the score of the unexposed sibling from the score of the exposed sibling. A positive score indicates that the exposed subject received a higher score than the unexposed sibling.

*Significant difference between exposed and unexposed siblings ($P \leqslant 0.05$),

Finally, Cattell has provided a configuration of six personality factors which research identified as having a significant relationship to school achievement and success[8]. The P_o group subjects exhibited high scores on three of these factors (individualistic, self-assured, and self-sufficient), whereas, the O_p groups were significantly low on two (group-dependent and group-oriented). Since there were no significant differences between the treatment groups or between exposed and unexposed siblings on the IQ tests, the groups are in effect matched for IQ. The prediction of higher school achievement in this sample of P_o regime exposed subjects is consistent with the results from the longitudinal study of prenatally progesterone exposed subjects which demonstrated significantly higher school achievement from childhood to late adolescence[6].

Our finding demonstrating a long term effect of early exposure to steroid hormones supports the investigations with animals and extends them solidly into the human realm. The data have shown that exposure to synthetic progestin and oestrogen during the foetal period significantly affects performance on a test designed to assess personality. Of course, to demonstrate conclusively a long term effect on personality in humans contingent upon prenatal exposure to various hormones, longitudinal studies of these and other individuals whose gestations were treated are necessary. The wealth of data related to early hormone influences on behaviour in animals[1] strongly suggests, however, that exposure to hormones of exogenous origin in humans should have some long term effects on such dimensions as personality and/or temperament[9].

Synthesis and processing of ribosomal RNA by the uterus of the ovariectomised adult rat during early oestrogen action

THE rate of RNA metabolism in the uterus of the immature or ovariectomised adult rat is stimulated after the administration of oestrogen[1,2]. Although there is uncertainty concerning the nature of the RNA species synthesised by the uterus during the first hour of oestrogen action[2], it is generally agreed that by 2 h after the injection of the hormone there is a significant increase in the synthesis of ribosomal RNA[3-5]. Furthermore, Luck and Hamilton[5,6] have suggested, on the basis of sucrose gradient analysis of labelled uterine RNA, that the rate or efficiency of processing of precursor ribosomal RNA (pre-rRNA) is also increased by the hormone. We have investigated the effect of oestrogen on the metabolism of rRNA in the uterus of the ovariectomised adult rat and now report the results of gel electrophoretic analyses of uterine RNA, doubly labelled *in vivo* with (^{3}H-methyl)methionine and ^{14}C-uridine. In the atrophied uterus of the ovariectomised adult rat the rate of conversion of pre-rRNA to the definitive rRNA products was slow, and it increased with time after hormone administration reaching a maximal rate after 4 h.

Table 1 Time course for the effect of oestrogen on the ratio of RNA to DNA and the uptake and incorporation of (^{3}H-methyl)methionine and ^{14}C-uridine into RNA in the uterus of the ovariectomised rat

Hormone treatment time (h)	RNA–DNA ratio	Total tissue radioactivity (d.p.m. per mg DNA)		Radioactivity incorporated into whole-organ RNA (%)		Specific activity of isolated RNA (d.p.m. per mg)	
		^{3}H	^{14}C	^{3}H	^{14}C	^{3}H	^{14}C
0	0.34	532,300	10,200	3.9	36	9,200	6,700 (1.4)*
1	0.36	535,000	15,100	4.9	32	15,800	11,700 (1.4)
2	0.39	538,900	11,000	5.2	39	18,400	10,200 (1.8)
3	0.42	672,800	11,400	5.5	40	26,300	8,600 (3.1)
4	0.45	770,700	11,900	6.3	40	44,400	9,400 (4.7)

RNA was isolated from the combined uteri of four ovariectomised adult rats that received 20 μg of 17-β-oestradiol in 0.2 ml of 1,2-propanediol (or the solvent alone), intraperitoneally (i.p.), at the times indicated before killing. All animals received 250 μCi L-(17-β-methyl)methionine (1 Ci mmol^{-1}) and 5 μCi ^{14}C-uridine (55 mCi mmol^{-1}) in 0.4 ml of water i.p. 45 min before killing. The method for isolating samples of undegraded RNA from uteri of ovariectomised adult rats was as described previously, except for the following two modifications. A second extraction of the interfacial material was performed by gently homogenising it with 4 ml of aqueous phase and stirring at 40 °C for 20 min. The phenol solutions contained an equal volume of chloroform–4% isoamylalcohol. The final yield of isolated, purified RNA averaged 67%. RNA and DNA determinations were carried out as before, as were the measurements of radioactivity incorporated[6].

*Ratio of incorporation of methionine to uridine.

Table 1 shows the effect of oestrogen, as a function of time, on the uptake and incorporation of (^{3}H-methyl)-methionine and ^{14}C-uridine into uterine RNA as well as the specific activity of the RNA isolated from uteri of ovariectomised animals that received the radioactive precursors simultaneously 45 min before death. The ratios of RNA to DNA in the various uterine homogenates revealed that oestrogen increased the concentration of RNA in the organ (compare with ref. 5). The total incorporation of (methyl-^{3}H)methionine into whole-organ RNA during the 45 min labelling period was increased 134% by hormone treatment for 4 h. Oestrogen also markedly increased the specific activity of the ^{3}H-labelled RNA isolated. It is important to emphasise that the data presented (Table 1) demonstrate that oestrogen has little or no stimulatory effect on the whole-organ uptake of methionine during the first 2 h of stimulation. After 3 and 4 h of hormone treatment the ^{3}H in the tissue was increased 26% and 45%, respectively. These observations are consistent with previous reports[5,7] and illustrate the usefulness of methionine as a precursor for labelling methylated RNAs synthesised during hormone action.

Oestrogen stimulated the uptake of ^{14}C-uridine by the uterus 48% after 1 h of treatment, 8% after 2 h, 12% after 3 h, and 17% after 4 h (Table 1). The percentage incorporation of ^{14}C-uridine into whole organ RNA was not significantly increased by hormone action. Oestrogen also increased the specific activity of the isolated ^{14}C-labelled RNA 75% after 1 h of treatment, 52% after 2 h, 28% after 3 h, and 40% after 4 h. These results are somewhat at variance with a previous report[6], in which, however, 50 μCi of ^{14}C-uridine was injected into each animal, rather than 5 μCi. The present results compare favourably with those reported by Munns and Katzman[7]. The incorporation ratio of (^{3}H-methyl)methionine to ^{14}C-uridine increased with time after hormone administration, following an initial lag period of about 1 h (Table 1). This finding is in good agreement with previous observations[3-5] that an increasing percentage of the newly synthesised RNA formed by the uterus during the first few hours following oestrogen stimulation is methylated.

The absorbance and radioactivity profiles of the gel electrophoretic analyses of the samples of labelled RNA isolated in the experiment described in Table 1 are shown in Fig. 1. The absorbance profiles of all the RNA samples analysed were essentially the same. The ^{14}C profiles (not shown) revealed that uridine had been incorporated into RNA very heterogeneous in size in both the control and hormone-stimulated uterus. No differences in the shapes of the ^{14}C profiles could be attributed to oestrogen. The ^{3}H profiles, however, reflected differences in the relative amounts of the various classes of labelled precursor, intermediate and mature rRNA species present in the uterus at various times after the injection of the hormone. Incorporation of (^{3}H-methyl)methionine into 45S, 32S, 28S, 21S and 18S rRNAs took place during the 45-min labelling period in both control and hormone-treated animals. In the unstimulated uterus the percentage of ^{3}H found in the precursor 45S and 32S rRNAs totalled 49% of the label incorporated into all rRNA species. But, as the time of the

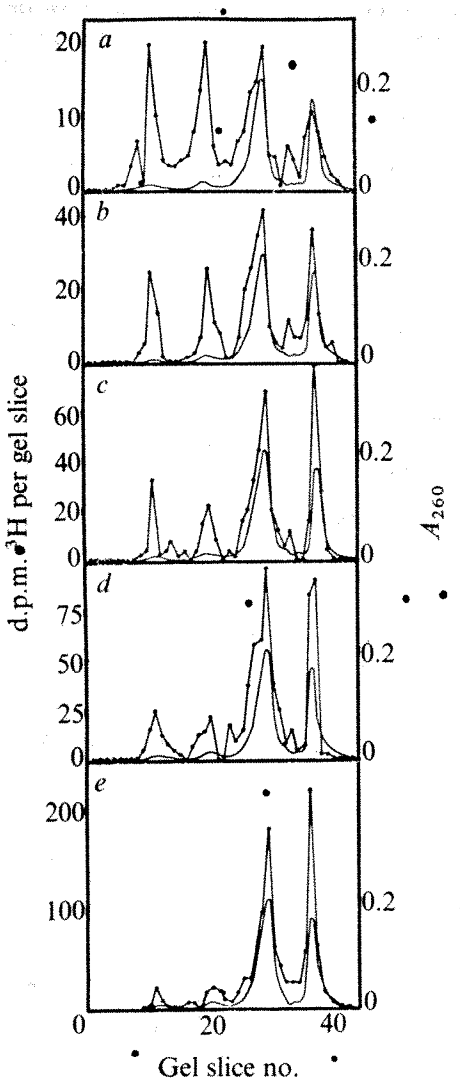

Fig. 1 Absorbance and radioactivity profiles of isolated, uterine RNA, labelled *in vivo* with (³H-methyl)methionine, as a function of time after administration of oestrogen. Experimental details are as in Table 1. Rats received *a*, no hormone, or oestrogen for *b*, 1 h; *c*, 2 h; *d*, 3 h; or *e*, 4 h. (●—●), ³H; ——A_{260}. Samples of doubly-labelled RNA, of exactly 0.5 A_{260}, were fractionated as described by Caston and Jones[8] on 1.8% polyacrylamide–1% agarose gels prepared in quartz tubes (90×5 mm inside diameter). Electrophoresis was for 2½ h at 5 mA per gel. Unlabelled 28S and 18S rRNAs were isolated from rat liver ribosomes and initially used as markers, as was 45S pre-rRNA isolated from nuclei of Novikoff ascites cells. Gels were scanned at 260 nm in a Gilford spectrophotometer and sliced into 2-mm slices. Each slice was placed in a counting vial and 0.1 ml of 30% ammonium hydroxide added to hydrolyse the RNA. After standing overnight at room temperature 1 ml of NCS tissue solubiliser (Amersham/Searle) was added to each vial and all vials were shaken for 1 h. Scintillation fluid, 10 ml, (5 g PPO and 0.1 g POPOP per litre of toluene) was added to each vial and the radioactivity determined to an error of 5% or less in a Beckman liquid scintillation spectrometer. A ³H counting efficiency of 44% was obtained.

hormone treatment increased this percentage decreased until 4 h after oestrogen administration only 12% of the total amount of methyl-labelled rRNA formed was present in the 45S and 32S fractions (Table 2). Longer periods of stimulation by the hormone did not significantly alter this distribution of the label among the 45S, 32S, 28S and 18S fractions. Labelled precursor was available to the uterine cells during the entire 45-min labelling period as evidenced by the presence of (³H-methyl)methionine in the organ at the time of killing of the animals. These data demonstrate that during the first 4 h of oestrogen action in the uterus of the ovariectomised adult rat the amount of new methylated 28S and 18S rRNA formed from the methylated 45S precursor per unit time is increased nearly fourfold.

We have routinely observed a methyl-labelled fraction slightly larger than 45S in uterine RNA samples isolated from the control animals which was not present following oestrogen stimulation (see Fig. 1*a*). Interestingly, Galibert *et al.*[9] have reported that there are three distinct components in the 45S pre-rRNA fraction of L-cells separable by electrophoresis through 1.7% polyacrylamide gels. Whether this heterogeneity represents a population of slightly different initial precursor molecules or early processing intermediates remains to be elucidated.

Table 2 Effect of oestrogen on the incorporation of (³H-methyl)-methionine into ribosomal RNAs by the rat uterus

Hormone treatment time (h)	Ribosomal RNA fraction 45S (%)	32S (%)	28S (%)	18S (%)
0	21	28	32	19
1	19	18	39	24
2	12	11	47	30
3	10	9	51	30
4	5	7	55	33

The percentages in this table are calculated from the radioactivity profiles shown in Fig. 1. The label in the 45S fraction was computed by summing the d.p.m. in gel slices 5–15; the 32S fraction by summing gel slices 16–22; the 28S fraction, gel slices 23–32; and the 18S fraction, gel slices 33–41.

Post-transcriptional mechanisms for regulating rRNA synthesis have recently been proposed in phytohaemagglutinin-stimulated lymphocytes[10,11], during compensatory renal hypertrophy[12], in a mutant of BHK cells[13,14] and in liver[15]. It is not yet clear, however, whether the accelerated rate of processing of pre-rRNA to 28S and 18S rRNAs in the oestrogen-stimulated uterus is due to more efficient methylation and cleavage, a more efficient processing pathway, or is determined by increased rates of rRNA synthesis[16].

This work was supported by a grant from the US NSF. We thank Mr Bruce Kessel and Mrs P. De Shon for assistance and Dr T.-S. Ro-Choi, Baylor College of Medicine, for the gift of nucleolar 45S pre-rRNA.

Thioredoxin and glutathione regulate photosynthesis in chloroplasts

Two recently found chloroplast proteins act in the ferredoxin-linked regulation of enzymes of photosynthetic carbon dioxide assimilation[1,2]. We report here the identification of one of these proteins, earlier termed assimilation regulatory protein b (ARP$_b$), as thioredoxin—a protein functional in the synthesis of DNA and previously not known in chloroplasts [3–5]. The other protein, assimilation regulatory protein a (ARP$_a$), is a new enzyme that catalyses the reduction of thioredoxin by reduced ferredoxin. We have renamed this protein 'ferredoxin–thioredoxin reductase.' In addition to identifying these proteins found earlier, we present evidence for a regulatory function of glutathione in chloroplasts. These findings permit for the first time the formulation of a light-dependent mechanism for protein-mediated enzyme regulation. In this mechanism, key regulatory enzymes are activated (reduced) photochemically via the ferredoxin–thioredoxin system and are deactivated (oxidised) in the dark via oxidised glutathione. The evidence indicates that photoreduced ferredoxin, in the presence of ferredoxin–thioredoxin reductase, controls the level of reduced thioredoxin required for enzyme activation. Glutathione reductase and glutathione peroxidase seem to control the level of oxidised glutathione available for enzyme deactivation.

Fructose 1,6-bisphosphatase of chloroplasts was assayed by measuring the release of inorganic phosphate (P$_i$) from the carbon-1 of fructose 1,6-bisphosphate[1,6]. Thioredoxin from *Escherichia coli* could fully replace native ARP$_b$ in the light-induced activation of chloroplast fructose 1,6-*bis*-phosphatase (Table 1). In this system, enzyme activation required ferredoxin, reduced photochemically with chloroplast fragments, and ARP$_a$ in addition to either ARP$_b$ or *E. coli* thioredoxin. ARP$_b$ and *E. coli* thioredoxin were also found to be equally effective when their capacity for phosphatase activation was tested in the presence of the non-physiological sulphydryl reagent dithiothreitol and in the absence of reduced ferredoxin and ARP$_a$ (refs 1, 6; Table 2).

The dithiothreitol assay was used previously to demonstrate that ARP$_b$ exists in the major types of living cells[2]. ARP$_b$ was found not only in photosynthetic plant and bacterial cells but also in their non-photosynthetic counterparts and in animal cells. In view of the ability of *E. coli* thioredoxin to replace ARP$_b$ in activation of the chloroplast fructose bisphosphatase, it seems likely that the active component found earlier in the different types of cells was thioredoxin. The known wide distribution of thioredoxin is in accord with that conclusion[7].

Table 1 Interchangeability of chloroplast ARP$_b$ and *E. coli* thioredoxin in the activation of chloroplast fructose 1,6-*bis*-phosphatase by photoreduced ferredoxin

Treatment	nmol P$_i$ released per min Chloroplast ARP$_b$	 *E. coli* thioredoxin
Light, complete	12	10
Light, minus ARP$_b$ or thioredoxin	2	2
Light, minus ferredoxin	4	2
Light, minus ARP$_a$	1	1
Light, minus fructose 1,6-bisphosphatase	0	1
Dark, complete	2	1

The reaction was carried out at 20 °C in Warburg vessels containing (in the side arm) 6 μmol of sodium fructose 1,6-*bis*-phosphate and (in the main compartment) 17 μg of fructose 1,6-*bis*-phosphatase dimer[26], spinach chloroplast fragments (P$_1$S$_1$) equivalent to 0.1 mg chlorophyll[10], 0.12 mg *Spirulina maxima* ferredoxin[27], 70 μg ARP$_a$ (in an aliquot containing 3 μmol 2-mercaptoethanol), and the following (μmol): Tris-HCl buffer (*p*H 7.9), 100; neutralised reduced glutathione, 5; sodium ascorbate, 10; 2,6-dichlorophenolindophenol, 0.1; MgSO$_4$, 1.0. ARP$_b$, 25 μg, or *E. coli* thioredoxin, 20 μg, were added as indicated. Final volume, 1.5 ml. After equilibration with nitrogen for 6 min, vessels were incubated for 5 min in the light (20,000 lx) or in the dark. The reaction was started by adding fructose 1,6-*bis*-phosphate from the side arm and was continued for 30 min under illumination or in the dark. The reaction was stopped by adding 0.5 ml of 10% trichloroacetic acid. After centrifuging off the precipitate, the P$_i$ released was estimated by a modified Fiske–SubbaRow procedure[10]. ARP$_a$ and ARP$_b$ were purified as before[1,6]. ARP$_a$ was then further purified by DEAE–cellulose and hydroxyapatitecol umn chromatography (details to be published elsewhere).

Table 2 Equivalence of chloroplast ARP$_b$ and *E. coli* thioredoxin in the activation of chloroplast fructose 1,6-*bis*-phosphatase by dithiothreitol

Treatment	nmol P$_i$ released per min
Chloroplast ARP$_b$, 12 μg	50
E. coli thioredoxin, 10 μg	47
Minus ARP$_b$ or thioredoxin	7

The reaction was carried out in air at 25 °C in test tubes containing, in 0.5 ml, fructose 1,6-*bis*-phosphatase, 9 μg; ARP$_b$ or thioredoxin as indicated, and the following (μmol): Tris–HCl buffer (*p*H 7.9), 50; MgCl$_2$, 0.5; dithiothreitol, 2.5; sodium fructose1,6-*bis*-phosphate, 3. The reaction was started by adding fructose 1,6-*bis*-phosphate and was continued for 30 min. The reaction was stopped by adding 2 ml of a mixture of the Fiske–SubbaRow reagents used to analyse P$_i$ (see Table 1).

The observation that *E. coli* thioredoxin is active in assays specific for ARP$_b$ suggests that ARP$_b$ might substitute for thioredoxin in the synthesis of DNA. This was confirmed by the finding that chloroplast ARP$_b$ showed thioredoxin activity in the *E. coli* ribonucleotide reductase assay system. Chloroplast ARP$_b$ replaced native thioredoxin to a low but significant extent in the enzyme-mediated reduction of ribonucleotides to their deoxy derivative. The low activity of chloroplast ARP$_b$ in this assay is attributed to its weak affinity for the enzymes of DNA synthesis in *E. coli*.

Our results show unforeseen similarities between two proteins that were discovered in very different lines of research—thioredoxin was found in studies on the synthesis of DNA in *E. coli* and ARP$_b$ was found in studies on the light-dependent regulation of enzymes in chloroplasts. It now seems that these two proteins are functionally similar. We therefore consider a revision of our original nomenclature timely and designate ARP$_b$ 'chloroplast thioredoxin'. By analogy, the protein earlier called ARP$_a$ is, on the basis of its ability to catalyse a thioredoxin-dependent oxidation of reduced ferredoxin (Table 3), designated 'ferredoxin–thioredoxin reductase'. We found no indication that chloroplasts contain an *E. coli*-type NADP-thioredoxin reductase[8] that links NADPH to the activation of fructose 1,6-*bis*-phosphatase.

The ferredoxin–thioredoxin system constitutes a new mechanism which, in chloroplasts, links light to the regulation of certain enzymes of carbon dioxide assimilation. An important aspect of this or any other system of enzyme regulation is the

Table 3 Identification of chloroplast ARP$_a$ as ferredoxin–thioredoxin reductase

Component added to oxidise photoreduced ferredoxin	nmol ferredoxin oxidised per min
None	0.0
ARP$_a$	0.6
Chloroplast thioredoxin	0.9
ARP$_a$+chloroplast thioredoxin	12.0

The reaction mixture contained, in 1.2 ml, *Spirulina maxima* ferredoxin, 0.18 mg; chloroplast fragments[10] (P$_1$S$_2$) equivalent to 5 μg chlorophyll; and the following (μmol): Tris-HCl buffer (*p*H 7.9), 100; MgSO$_4$, 1; sodium ascorbate, 10; and 2,6-dichlorophenolindol phenol (DPIP), 0.1. ARP$_a$, 230 μg (in an aliquot containing 6 μmol 2-mercaptoethanol) was added as indicated. Samples were gassed with argon for 5 min and transferred anaerobically to a glass cuvette of 2-mm light path. After fully reducing the ferredoxin photochemically by illumination with red light (Corning 2-58 filter), the light was turned off, and the rate of the oxidation of ferredoxin was followed in the dark. The extent of oxidation of ferredoxin was measured by increase in absorbance at 420 nm with a modified Beckman Model DU monochromator[29].

Table 4 Deactivation of chloroplast fructose 1,6-bisphosphatase by oxidised glutathione

Reductant used for activation	% of control activity after adding glutathione
Reduced ferredoxin*	53
Dithiothreitol†	5

*The reaction mixture was as in Table 1 except that 25 μmol oxidised glutathione were added to the second side arm and 104 μg ferredoxin–thioredoxin reductase (ARP_a) (plus 3 μmol 2-mercaptoethanol) were used. Vessels were equilibrated with nitrogen for 6 min and incubated 10 min in the light (20,000 lx). The reaction was started by adding fructose 1,6-*bis*-phosphate from the first side arm. After 10 min under illumination, the lights were extinguished, oxidised glutathione (or water) was added from the second side arm, and the reaction was continued for 20 min in the dark. The reaction was stopped and P_i was analysed as in Table 1. 15 nmol of P_i were released per min in the control treatment.

†Fructose 1,6-*bis*-phosphatase was activated (and deactivated) before assay. Fructose 1,6-bisphosphatase, 17 μg, was incubated in 0.1 ml of a mixture containing 0.1 M Tris-HCl buffer (*p*H 7.9), 10 mM dithiothreitol, and 25 μg chloroplast thioredoxin (ARP_b). After 10 min, 2.5 μmol of oxidised glutathione (or water) was added. After a further 20 min, the enzyme was then injected into 0.9 ml of the assay mixture containing 1.3 units of glucose 6-phosphate dehydrogenase, 4.2 units of glucose-6-phosphate isomerase, and the following (μmol): Tris-HCl buffer (*p*H 7.9), 40; $MgSO_4$, 1; fructose 1,6-*bis*-phosphate, 6; and NADP, 1.5. Fructose 1,6-*bis*-phosphatase activity was followed by measuring the reduction of NADP (increase in absorbance at 340 nm) with a Cary model 14 spectrophotometer. Temperature, 22 °C. 29 nmol of P_i were released per min in the control treatment.

way in which the component enzymes are converted from an active to a less active (deactivated) state. Until now, no deactivation mechanism was known for the ferredoxin–thioredoxin system. As seen in Table 4, glutathione—a sulphydryl–disulphide component of most if not all living cells[9]—functioned in that capacity. The oxidised form of glutathione deactivated the fructose *bis*-phosphatase that had been activated previously by thioredoxin reduced either photochemically with the ferredoxin system or non-enzymically with dithiothreitol. Under the same conditions, reduced glutathione had no effect.

The effectiveness of oxidised glutathione in deactivation suggests that *in vivo* a defined ratio of oxidised to reduced glutathione gauges the activity of enzymes, such as fructose bisphosphatase, in response to changing conditions in the chloroplast. This ratio, in turn, may be determined by two enzymes present in the soluble fraction of chloroplasts[10], glutathione reductase [11] (equation 1) and glutathione peroxidase[12] (equation 2).

$$NADPH_2 + \text{glutathione}_{\text{oxidised}} \xrightarrow[\text{reductase}]{\text{glutathione}} 2\ \text{glutathione}_{\text{reduced}} + NADP \qquad (1)$$

$$2\ \text{glutathione}_{\text{reduced}} + H_2O_2 \xrightarrow[\text{peroxidase}]{\text{glutathione}} \text{glutathione}_{\text{oxidised}} + 2\ H_2O \qquad (2)$$

The specific activity in μmol substrate converted per mg chlorophyll per h was 9 for glutathione reductase[13] and 12 for glutathione peroxidase[14]. Because of its relatively high activity, it seems possible that glutathione peroxidase could, in addition to its regulatory role described here, function together with glutathione reductase in removal of hydrogen peroxide produced in chloroplasts. Accordingly, glutathione peroxidase would replace catalase, which seems to exist mainly outside rather than inside chloroplasts[15,16]. Our finding of 1 mM glutathione[17] in chloroplasts is consistent with such a function for glutathione peroxidase.

Although the physiological agent for enzyme deactivation seems to be oxidised glutathione, other oxidants were also effective in this reaction. Sodium tetrathionate ($Na_2S_4O_6$) and the oxidised form of ascorbic acid (dehydroascorbic acid) showed deactivation effects similar to those reported in Table 4 for oxidised glutathione. In view of the high concentration of ascorbic acid in chloroplasts[18,19], these results indicate that dehydroascorbic acid, produced from ascorbic acid through oxidation, could possibly be involved in the control of enzyme activity.

Considering the wide distribution of ferredoxin and thioredoxin, a comment on the possible application of the ferredoxin–thioredoxin system to other organisms seems appropriate. It is possible that a mechanism of the type described could be used for the regulation of cellular processes in other organisms. Furthermore, because many cells are enzymically fitted to reduce thioredoxin independently of ferredoxin, by way of NADP, the presence of ferredoxin is not prerequisite to the operation of such a system. For example, a mechanism of the NADP-thioredoxin type could account for the thioredoxin-mediated reduction of proteins (for which the reported reduction of insulin provides a model[20]) or for modification of proteins through the formation of a stable thioredoxin–protein complex (as found for a specific DNA polymerase in phage-infected *E. coli* cells[21]).

The present results provide evidence for a new mechanism whereby specific enzymes are activated by reduction (via thioredoxin) and deactivated by oxidation (via oxidised glutathione). In chloroplasts this 'oxidation–reduction' mechanism acts in conjunction with the ion-mediated and effector-mediated mechanisms discussed previously[1,22] which link enzyme regulation to the absorption and utilisation of light. In the light, electrons from chlorophyll are transferred to ferredoxin and then, via a specific reductase enzyme, to thioredoxin (Fig. 1). Reduced thioredoxin, in turn, reduces and thereby activates certain regulatory enzymes of chloroplasts (fructose 1,6-*bis*-phosphatase, sedoheptulose 1,7-*bis*-phosphatase[23], and perhaps NADP-glyceraldehyde 3-phosphate dehydrogenase and phosphoribulokinase[1,24]). Our evidence indicates that, at least in the case of NADP-glyceraldehyde 3-phosphate dehydrogenase, reduction (activation) is accompanied by the formation of a stable thioredoxin–enzyme complex.

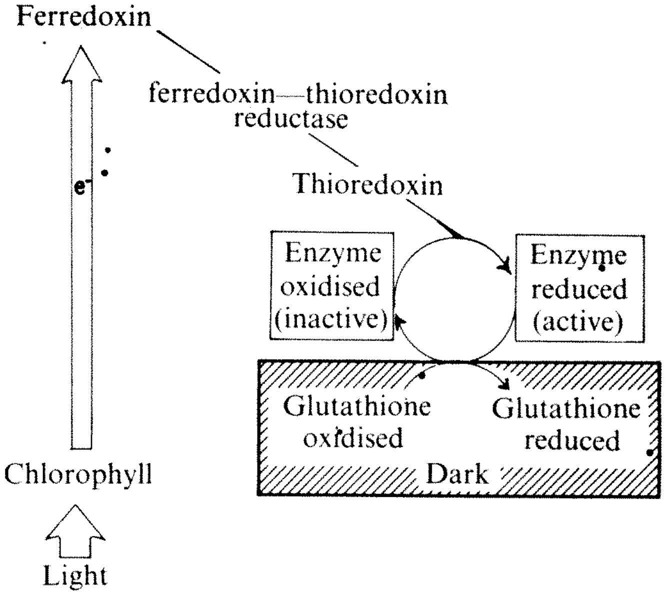

Fig. 1 A mechanism for the light-dependent regulation of enzymes in chloroplasts. The component[30–32] before the indicated soluble ferredoxin that accepts electrons from photoactivated chlorophyll is not shown.

In the dark, the activated (reduced) enzymes are deactivated (oxidised) by an oxidant such as oxidised glutathione. Figure 2 shows that, in the presence of hydrogen peroxide, glutathione peroxidase could act in the dark to convert reduced glutathione to the oxidised form that is functional in deactivation. It is likely that limited enzyme deactivation would occur also in the light in response to transient changes in the chloroplasts.

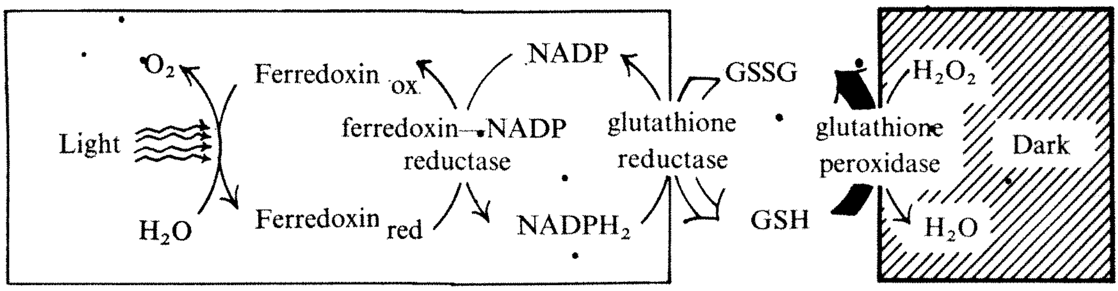

Fig. 2 A mechanism for controlling the ratio of oxidised (GSSG) to reduced (GSH) glutathione in chloroplasts.

The high concentration of reduced NADP prevailing in those conditions[25], however, would tend to impede such deactivation by converting the oxidised glutathione to its reduced form with the chloroplast enzyme glutathione reductase.

We thank Dr A. Holmgren, Karolinska Institute, Stockholm, for performing the thioredoxin assays and for a gift of *E. coli* thioredoxin. This work was supported by a grant from the US NIH to B.B.B.

Was photoresolution of amino acids the origin of optical activity in life?

SINCE Pasteur showed that the amino acid asparagine in plants was purely one optical isomer, constant interest has centred around the question of optical activity in life. The quantities of D-amino acids in the biosphere are practically negligible and none has ever been found in any enzyme or other protein, whereas the abundance of L-amino acids is well known. Many of the molecules important to living processes can be synthesised[1] in conditions which may have prevailed on a primitive planet and it is easier to suggest a prebiotic synthesis of a racemate than to explain an enantiomeric selection. Whereas many workers claim the clue might be found in various stereoselective mechanisms, likely to have operated already at the stage of the 'chemical evolution[2-5]', no example of the selection of a biologically crucial compound by means of circularly polarised light has been previously reported. Apart from an effect due to an enantiomorphous relationship between matter and antimatter[6-8], this is the only mechanism with selection capacity in a large system (the Earth)[9]. We report here that tartaric acid, α-alanine and glutamic acid partially resolve under circularly polarised irradiation. The L-amino acid dominance in the biosphere can by analogy, be explained by a selection caused by circularly polarised interstellar ultraviolet radiation.

Pairs of identical racemic aqueous solutions were simultaneously subjected to left and right circularly polarised light (quartz collimators/Glan prisms/Fresnel rhombs) from a Xe (450 W quartz, Osram) lamp, λ > 200 nm (aqueous infrared filter) and compared afterwards with respect to circular dichroism difference at the wavelengths of photolysis (Jasco J-41 dichrometer). Results are given in Table 1 and Fig. 1.

Fig. 1 Typical circular dichroism spectra (× 10^6) recorded on *a*, racemic tartric acid and *b*, glutamic acid after irradiation with right and left circularly polarised light. *c*, Recorded ΔCD deflections (× 10^6) at 210 nm in glutamic acid at different irradiation times (different symbols for different experiments).

*Defined as $100\times(\mathrm{CD_{obs}}/\mathrm{CD_{pure\ enantiomer}}) \approx 50\ \Delta\mathrm{CD}/(\Delta\varepsilon/\varepsilon)$.

†Theoretically possible figures in parentheses, obtained as $100\times(\mathrm{CD_{theor}}/\Delta\varepsilon\ Cl) \approx 40\ (\Delta\varepsilon/\varepsilon)^2A/Cl = 40\ \Delta\varepsilon/\varepsilon$.

Due to uncertain lamp intensity in the active range (200–230 nm) relevant quantum yields could not be estimated.

It is realistic to assume that the activation is achieved either by photodecomposition or by photoinversion leading to excess of the enantiomer that has positive circular dichroism at the photolytical wavelength, when right circularly polarised light is used and vice versa. Some amino acids may undergo photo-deamination to yield cinnamic acids, where the unsaturated character can cause obscuring absorption preventing complete photolytic yield. When optically active tartaric acid and aliphatic amino acids were subjected to non-polarised ultra-violet light ($\lambda > 200$ nm) absorptive products were generally not observed and the rate of loss of optical activity indicated a simultaneous photoracemisation. In the case of pure photo-decomposition the maximum absolute activity is expected when 63% of the material is decomposed, by a circular dichroism deflection[10]

$$|\mathrm{CD}| = 0.37\times(\Delta\varepsilon/\varepsilon)^2A_0 \qquad (1)$$

($\Delta\varepsilon = \varepsilon_l-\varepsilon_r$ and ε are molar, M^{-1} cm^{-1} circular dichroism and absorption coefficients, A_0 the initial absorbance. As was shown elegantly by Kagan[11] 100% purity can, however, be obtained at the end of the reaction. For photoracemisation a steady state

$$|\mathrm{CD}| = 0.5(\Delta\varepsilon/\varepsilon)^2A_0 \qquad (2)$$

should be reached. In both cases it is presumed that only the excited molecule undergoes reaction (and that it does so due to the dichroic transition), that is, that no radical attacks or sensitising effects occur. By the quadratic appearance of the dissymmetry factor $\Delta\varepsilon/\varepsilon$ the possibilities of experimental detection are restricted to molecules with bands having $|\Delta\varepsilon/\varepsilon| > 3\times10^{-3}$ due to the resolution of present day instruments, which is $\pm3\times10^{-6}$ absorbance units at unit absorbance. That the observed optical activity is due to optical selection among the starting materials and not to any optically active secondary product is indicated by the complete extinction of optical activity when the pure isomers are irradiated. The final proof was obtained by the observation of a constant line-shape of the CD-spectrum during the decay period.

Finally, it should be pointed out that a spectral requirement $\lambda > 200\pm30$ nm on the incident radiation is in excellent agreement with the current opinion of the composite ultraviolet absorption of the primitive atmosphere (due mainly to water vapour and carbon dioxide)[12]. The L-amino acids (except the cyclic imino-acid proline) are thus selected by this type of light (when right circularly polarised), while for instance nucleic acids should require $\lambda > 260$ nm for an effective yield (according to the circular dichroism spectrum with wings of both signs). We are also studying amino acid complexes with evolutionarily interesting metals and where magnetic dipole allowed d–d transitions (for example Cr(III)) can be expected to strongly enhance the photoresolution efficiency.

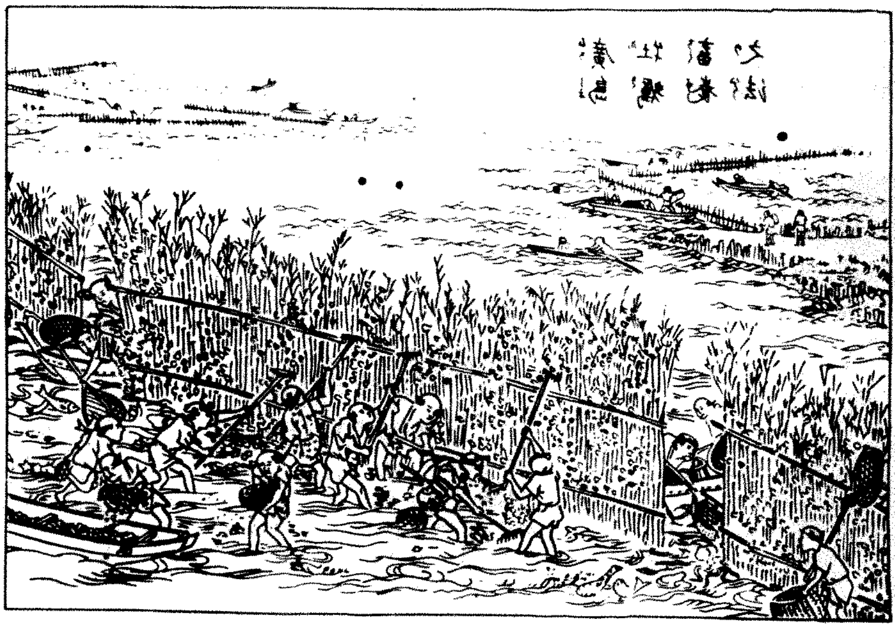
Aquaculture methods

C. M. Yonge

Farming Marine Organisms Low in the Food Chain. Farming Cupped Oysters of the Genus Crassostrea. *Farming the Flat Oyster of the Genus* Ostrea. *Farming Marine Fishes and Shrimps.* (Developments in Aquaculture and Fisheries Science, Vols 1–4.) By P. Korringa. (Elsevier: Amsterdam, Oxford and New York, 1976.) $30.95; Dfl.80 each volume.



Ancient method of oyster culture in Hiroshima Prefecture

AT this time of increasing competition for already over-exploited stocks of fish, any increase in marine productivity by aquaculture demands attention. No one is better qualified to write about this than Professor P. Korringa, Director, Netherlands Institute for Fishery Investigations. Responsible for restoration of the Dutch oyster beds following shell disease in the 1930s, he must since have visited every significant area of marine cultivation. This reviewer has memories of visits in his company to areas of oyster and mussel cultivation in France, Spain and Italy.

His descriptions of culture methods are based on actual procedures within selected aquacultural enterprises. For each he supplies a biological, geographical, oceanographic and even legal background—thus sheltered, pollution-free waters and security of tenure are all involved. Farming procedures include control of predators, parasites and disease. Economic problems including marketing are finally assessed.

Description of culture methods begins with that of the red seaweed 'Nori' (*Porphyra*) in Japan and concludes with that of rainbow trout and salmon in Norway. Cultivation of bivalve molluscs is inevitably the major theme; mussels (*Mytilus* spp.) clams and, above all, species of the flat oyster, *Ostrea*, are covered together with those of the ecologically more tolerant cupped oyster, *Crassostera*, which are everywhere replacing them.

Mussels, strangely neglected in North America and Japan, are reared on stakes in the long established 'bouchot' system in France, by mass transplantation in the Netherlands, and with impressive productivity in the sheltered "rias" in north-west Spain, where settlement and growth are on ropes suspended from moored pontoons or catamarans.

The great French oyster industry was initially based on studies of the surviving remnants of Roman culture methods in the Mediterranean. Large scale cultivation, between tide marks—first of *Ostea edulis*, then of the Portuguese *Crassostrea angulata* and now of the ubiquitous Japanese, *C. gigas*—was established; and its methods have now been widely copied throughout the world. The highly successful suspended culture method was initiated in Japan same fifty years ago, at first to offset restrictions caused by limited intertidal space.

All these methods involve collection of naturally produced spat in areas of relatively still water and subsequent growth in water rich in phytoplankton. Only in hatcheries (about which Dr Korringa has surprisingly little to say), where oysters are induced to spawn and the larvae and spat fed on reared algal species, can full culture be established.

With fish, only the cultivation of herbivores—here described for mullets (*Mugil*) in Israel and in 'valli' round the mouth of the Po in the Adriatic, and for milk fish (*Chanos*) long cultivated in Indonesia—represents economic production of animal protein. Japanese cultivation of the carnivorous yellow-tail (*Seriola quinqueradiata*) and red sea bream (*Chrysophrys major*)—with that of the no less carnivorous penaeid prawns (*Penaeus japonicus*)—involves conversion, with much accompanying labour, of lower into higher or more acceptable forms of animal protein. The result is an expensive luxury product.

Conditions are somewhat different with eel culture in Japan—supplying such a demand that elvers are imported from so far afield as Europe—and salmonid rearing in Norway and Scotland. These have the advantage of supplying an insatiable demand at a lower cost than that involved in collection of these fish in Nature.

These admirably produced and illustrated books are a pleasure to review. They will be of the greatest value to aquaculturists; nothing is described that has not been personally inspected and judged in the light of Dr Korringa's uniquely wide experience. □

Sir Maurice Yonge, formerly Professor of Zoology at Bristol and then Glasgow, is now Honorary Fellow in Zoology at the University of Edinburgh, UK.

Molecular genetics handbook

Handbook of Genetics. Vol. 5: Molecular Genetics. Edited by R. C. King. Pp.xi+667. (Plenum: New York and London, 1976.) $51.

THE fifth volume of the *Handbook of Genetics* in many ways belies its title. The book is in four sections devoted to the molecular organisation of chromosomes (six chapters), gene transcripts (five chapters), chloroplasts and mitochondria (five chapters), and a single chapter in a section called mutant enzymes. Only the chapters in the section on chloroplasts and mitochondria seem truly to combine both a molecular and genetical approach and deserve the title molecular genetics.

Particularly disappointing is the *pot pourri* section on molecular organisation of chromsomes, which manages to present a somewhat incoherent treatment of the subject in spite of excellent reviews of chromosomal protein structure and function, and of organisation and size of replicons. Individual chapters on repeated DNA in eukaryotes, cytological localisation of repeated DNAs, chromosomal proteins, organisation of genetic material in the macronucleus of hypotrichous ciliates, histones of sperm, and organisation and size of replicons, do not easily relate to each other and the section as a whole presents no overall picture of chromosome organisation. The chapter on repeated DNA in eukaryotes, by limiting itself to molecular renaturation studies, manages to ignore much interesting and relevant data provided by sequencing, restriction site mapping and electron microscopy of repeated DNAs.

The chapter on chromosomal proteins, although admirable in many ways, contains no reference to the unit of chromatin (nucleosome) and models which have been proposed for its structure. Such an omission can hardly be of the authors own making since it seems evident from the reference list that this chapter was complete by the end of 1973 (the only 1974 paper quoted is by the authors themselves) and the same seems to hold for the majority of chapters in this section; one exception being the chapter on macronuclear DNA of hypotrichs, which has references to 1976. Judging by the latest references in chapters of other sections they were completed towards the end of 1974 or beginning of 1975, although the chapter on mutant enzymes has no references after 1972. It is a pity that the relatively long lag between writing and publishing the chapters in section one has reduced its effectiveness as a contemporary review of a rapidly changing area of investigation.

The other sections are more successful. Section two, gene transcripts, has chapters on nuclear RNA, RNA transcription and ribosomal protein assembly in *Drosophila melanogaster,* cytoplasmic mRNA, tRNAs, and eukaryotic ribosomes; whereas section three, chloroplasts and mitochondria, has chapters on chloroplast DNA (physical and genetic studies), chloroplast ribosomes, nucleocytoplasmic interaction in *Acetabularia,* mitochondrial DNA, and mitochondrial ribosomes. The chapters on cytological localisation of repeated DNAs, histones of sperm, transfer RNAs, and mutant enzymes are little more than exhaustive catalogues of the structure, location or primary sequence of particular macromolecules.

In spite of some omissions which might have been included in a book with this title—for instance, considerable space is devoted to histones but no mention is made of histone genes, and similarly there is no mention of tRNA genes although all the known tRNA sequences are tabulated—there is a great deal of worthwhile and well presented material. As a reference book in certain areas, it should prove valuable.

The book has an author and subject index. But the subject index has innumerable deficiencies, and I pick one example to illustrate this point. The only reference to "globin" contains an interesting cross-reference "see Immunoglobin". There is, however, no entry under "Immunoglobin"; but under "Immunoglobulin" there is a reference to "chain of rabbit reticulocyte"! **Peter Ford**

Peter Ford is Lecturer in the Department of Molecular Biology, University of Edinburgh, UK.

Chemical relaxation

Relaxation Kinetics. By C. F. Bernasconi. Pp. xi+288. (Academic: New York and London, 1976.) $29.50; £20.95.

THERE can be no getting away from it —a large proportion of chemical reactions are fast. Generations of students may have obtained their grounding in chemical kinetics with reactions whose half-lives lie conveniently in the time range of minutes or hours, but the fact is that such reactions are the exception rather than the rule. One has only to recall the particular premium placed on the time factor in many biologically and industrially important reactions to appreciate the significance of our being able to measure the kinetics of rapid reactions.

It is not possible to apply classical kinetic techniques to many of these reactions but over the past fifteen years or so a variety of methods have been developed which have made most of them susceptible to study. All of these methods involve electronic equipment and the prospect of having to build one's own apparatus, together with the fact that a rather different approach is generally required in the analysis of the data, has tended to scare away all but the most physically-minded chemists. Times are, however, changing and it is thanks to the increasing availability of suitable commercial equipment and monographs such as Dr Bernasconi's that more and more chemists are reporting rate constants and activation parameters where in the past they would have used some such phrase as "too fast to measure".

The first two-thirds of Dr Bernasconi's book deals with the general theory of chemical relaxation and is largely given over to the problem of relating the relaxation time (or times) and the rate constants for different mechanistic schemes. Also included are a couple of chapters (out of ten) on the topic of relaxation amplitudes. The remainder of the book is concerned with the various experimental methods.

The author says that he has attempted to write a comprehensive treatment of the subject in the language of the organic or physical–organic chemist and in this I think he has on the whole been successful. Certainly, the mathematics should not overtax any mechanistically-minded research chemist (contrary to the impression he might gain on casually leafing through it) and there are many useful hints and practical comments hidden (the correct word, unfortunately) throughout the book.

Where I would be a little less than fulsome in praising the book is for its comprehensiveness. Although his choice will certainly not be universally applauded, it seems to me that Dr Bernasconi has quite properly and freely exercised his author's discretion on the topics for inclusion. Presumably, this is the reason behind his implication (with which I would not agree) that this is not a book for the physical-inorganic chemist. **D. N. Hague**

D. N. Hague is Senior Lecturer in Chemistry, University of Kent at Canterbury, UK.

Advances in Behavioral Pharmacology VOLUME 1

Edited by TRAVIS THOMPSON and PETER B. DEWS

This new continuing publication will cover major research areas in behavioral pharmacology (psychopharmacology), and provide a synthetic and analytic review of significant factors involving the effects of drugs on the behavior of both humans and experimental animals. The articles will largely be limited to the behavioral action of drugs, and will not generally include neurochemical, emotional, mental, or psychic processes or phenomena. However, from time to time papers dealing with basic mechanisms of action will be included. The articles will provide selective, critical, and in-depth analyses of research areas, rather than broad but superficial literature reviews.
